SECTION I Astrobiology: Definition, Scope, and Education

Chapter 1.1 Astrobiology: Definition, Scope, and a Brief Overview	3
<i>Vera M. Kolb</i>	
Chapter 1.2 Astrobiology Goals: NASA Strategy and European Roadmap	15
<i>David J. Des Marais</i>	
Chapter 1.3 Online, Classroom and Wilderness Teaching Environments: Reaching Astrobiology Learners of All Ages Around the World	27
<i>Bruce W. Fouke, Kyle W. Fouke, Tom Murphy, Colleen N. Cook, Bruce F. Michelson, Joseph L. Cross, Lizzanne DeStefano, Glenn A. Fried, Killivalavan Solai, Jacalyn Wittmer Malinowsky, Susan B. Kelly, Claudia C. Lutz, Erin Louer, Courtney C. Fenlon, Nicholas P. Vasi, Adrienne M. Gulley, and Mayandi Sivaguru</i>	
Chapter 1.4 Astrobiology as a Medium of Science Education	45
<i>Sun Kwok</i>	
Chapter 1.5 Astrobiology-as-Origins-Story: Education and Inspiration across Cultures	49
<i>Daniella Scalice</i>	

SECTION II Definition and Nature of Life

Chapter 2.1 Defining Life: Multiple Perspectives	57
<i>Vera M. Kolb</i>	
Chapter 2.2 A Generalized and Universalized Definition of Life Applicable to Extraterrestrial Environments	65
<i>Benton C. Clark</i>	
Chapter 2.3 Synthetic Cells and Minimal Life.....	75
<i>Daniel G. Gibson, Clyde A. Hutchison III, Hamilton O. Smith, and J. Craig Venter</i>	
Chapter 2.4 Communication as the Main Characteristic of Life	91
<i>Guenther Witzany</i>	

SECTION III Origin of Life: History, Philosophical Aspects, and Major Developments

- Chapter 3.1** Philosophical Aspects of the Origin-of-Life Problem: Neither by Chance Nor by Design 109
Iris Fry

- Chapter 3.2** Charles Darwin and the Plurality of Worlds: Are We Alone? 125
Michael Ruse

- Chapter 3.3** An Early History from Buffon to Oparin 137
Stéphane Tirard

SECTION IV Chemical Origins of Life: Chemicals in the Universe and Their Delivery on the Early Earth; Geology and Atmosphere on the Early Earth

- Chapter 4.1** Interstellar Molecules and Their Prebiotic Potential 147
Lucy M. Ziurys

- Chapter 4.2** Formation and Delivery of Complex Organic Molecules to the Solar System and Early Earth 165
Sun Kwok

- Chapter 4.3** Organic Molecules in Meteorites and Their Astrobiological Significance 177
Zita Martins

- Chapter 4.4** Ancient Life and Plate Tectonics 195
Clark M. Johnson and Martin J. Van Kranendonk

- Chapter 4.5** Atmosphere on Early Earth and Its Evolution as It Impacted Life 207
James F. Kasting

SECTION V Chemical Origin of Life: Prebiotic Chemistry

- Chapter 5.1** Prebiotic Chemistry That Led to Life 219
Juli Peretó

- Chapter 5.2** Prebiotic Chemical Pathways to RNA and the Importance of Its Compartmentation 235
Peter Strazewski

- Chapter 5.3** The Hydrothermal Impact Crater Lakes: The Crucibles of Life's Origin 265
Sankar Chatterjee

Chapter 5.4	Prebiotic Chemistry in Hydrothermal Vent Systems.....	297
	<i>María Colín-García, Saúl Villafranca-Barajas, Antoni Camprubí, Fernando Ortega-Gutiérrez, Vanessa Colás, and Alicia Negrón-Mendoza</i>	
Chapter 5.5	Prebiotic Reactions in Water, “On Water,” in Superheated Water, Solventless, and in the Solid State	311
	<i>Vera M. Kolb</i>	
Chapter 5.6	The Origin and Amplification of Chirality Leading to Biological Homochirality	341
	<i>Kenso Soai, Arimasa Matsumoto, and Tsuneomi Kawasaki</i>	
Chapter 5.7	Phosphorus in Prebiotic Chemistry—An Update and a Note on Plausibility	355
	<i>Alan W. Schwartz</i>	
Chapter 5.8	Phosphorylation on the Early Earth: The Role of Phosphorus in Biochemistry and Its Bioavailability	361
	<i>Carolyn Lang, Jennifer Lago, and Matthew A. Pasek</i>	
Chapter 5.9	Silicon and Life.....	371
	<i>Joseph B. Lambert</i>	

SECTION VI RNA and RNA World: Complexity of Life’s Origins

Chapter 6.1	Transitions: RNA and Ribozymes in the Development of Life	379
	<i>Eric J. Hayden, Niles Lehman, and Peter J. Unrau</i>	
Chapter 6.2	Three Ways to Make an RNA Sequence: Steps from Chemistry to the RNA World	395
	<i>Paul G. Higgs</i>	
Chapter 6.3	Coevolution of RNA and Peptides	409
	<i>Peter Strazewski</i>	
Chapter 6.4	Role of Cations in RNA Folding and Function.....	421
	<i>Jessica C. Bowman, Anton S. Petrov, and Loren Dean Williams</i>	
Chapter 6.5	The Origin of Life as an Evolutionary Process: Representative Case Studies	437
	<i>Iris Fry</i>	
Chapter 6.6	The Complexity of Life’s Origins: A Physicochemical View.....	463
	<i>Jan J. Spitzer</i>	

SECTION VII *Origin of Life: Early Compartmentalization—Coacervates and Protocells*

- Chapter 7.1** Oparin's Coacervates 483
Vera M. Kolb

- Chapter 7.2** Protocell Emergence and Evolution 491
Punam Dalai and Nita Sahai

SECTION VIII *Origin of Life and Its Diversification. Universal Tree of Life. Early Primitive Life on Earth. Fossils of Ancient Microorganisms. Biomarkers and Detection of Life*

- Chapter 8.1** The Progenote, Last Universal Common Ancestor, and the Root of the Cellular Tree of Life 521
Johann Peter Gogarten

- Chapter 8.2** Horizontal Gene Transfer in Microbial Evolution 527
Johann Peter Gogarten and R. Thane Papke

- Chapter 8.3** Viruses in the Origin of Life and Its Subsequent Diversification 535
Luis P. Villarreal and Frank Ryan

- Chapter 8.4** Carl R. Woese and the Journey toward a Universal Tree of Life 555
Bruce W. Fouke, Killivalavan Solai, Shelby L. Jones, Elizabeth M. Smith, Kyle W. Fouke, Kaitlyn E. Fouke, Claudia C. Lutz, Mayandi Sivaguru, and Glenn A. Fried

- Chapter 8.5** Fossils of Ancient Microorganisms 567
Kenichiro Sugitani

- Chapter 8.6** Biomarkers and Their Raman Spectral Signatures: An Analytical Challenge in Astrobiology 597
Howell G.M. Edwards

- Chapter 8.7** Fossilization of Bacteria and Implications for the Search for Early Life on Earth and Astrobiology Missions to Mars 609
Frances Westall and Keyron Hickman-Lewis

SECTION IX *Life under Extreme Conditions—Microbes in Space*

- Chapter 9.1** Extremophiles and Their Natural Niches on Earth 635
Aharon Oren

- Chapter 9.2** Microbes in Space 661
Kasthuri Venkateswaran

Chapter 9.3	Virus Evolution and Ecology: Role of Viruses in Adaptation of Life to Extreme Environments	677
	<i>Marilyn J. Roossinck</i>	

SECTION X Habitability: Characteristics of Habitable Planets

Chapter 10.1	The Evolution of Habitability: Characteristics of Habitable Planets.....	685
	<i>Charles H. Lineweaver, Aditya Chopra, and Sarah R. N. McIntyre</i>	

SECTION XI Intelligent Life in Space: History, Philosophy, and SETI (Search for Extraterrestrial Intelligence)

Chapter 11.1	Mind in Universe: On the Origin, Evolution, and Distribution of Intelligent Life in Space.....	701
	<i>David Dunér</i>	
Chapter 11.2	Where Are They? Implications of the Drake Equation and the Fermi Paradox	717
	<i>Nikos Prantzos</i>	
Chapter 11.3	SETI: Its Goals and Accomplishments	727
	<i>Eric J. Korpela</i>	
Chapter 11.4	Humanistic Implications of Discovering Life Beyond Earth.....	741
	<i>Steven J. Dick</i>	

SECTION XII Exoplanets, Exploration of Solar System, the Search for Extraterrestrial Life in Our Solar System, and Planetary Protection

Chapter 12.1	Exoplanets: Methods for Their Detection and Their Habitability Potential	759
	<i>Ken Rice</i>	
Chapter 12.2	Solar System Exploration: Small Bodies and Their Chemical and Physical Conditions.....	775
	<i>Hikaru Yabuta</i>	
Chapter 12.3	Solar System Exploration: Icy Moons and Their Habitability	787
	<i>Steven D. Vance</i>	
Chapter 12.4	Searching for Extraterrestrial Life in Our Solar System.....	801
	<i>Benton C. Clark</i>	
Chapter 12.5	Planetary Protection	819
	<i>Catharine A. Conley</i>	
Index.....		835

Preface

Handbook of Astrobiology is designed for astrobiology practitioners to enable them to review the major developments in the field and to learn about the newest discoveries. Since astrobiology is an interdisciplinary field, which draws on various other disciplines such as astronomy, physics, chemistry, biology, geology, planetary science, and philosophy, it is difficult for practitioners to be adequately informed about the new findings in the field, especially if these are not directly related to one's specific area of investigation. Further, rapid developments in astrobiology result in an ever-increasing number of publications, which makes it difficult to stay current in the field. However, a broad background and up-to-date knowledge of the field are important resources for astrobiologists, so that they can place their own findings in a broader context and integrate them with other findings in the field.

This handbook is designed to help astrobiologists reach the above goals. It is the first handbook of astrobiology and will hopefully fill a void in such literature in this broad field.

This handbook comprises 54 chapters divided into 12 sections. The chapters are written by experts in their respective fields. The chapters review the important topics in astrobiology and provide the newest developments.

As the editor, I had the privilege of shaping the content of the handbook by recruiting colleagues whose work I long respected and admired. Further, I have left my imprint on the handbook by following principles taught to me from 1992–1994 at the NASA Specialized Center of Research and Training (NSCORT) in exobiology, in San Diego, by Leslie Orgel and Stanley Miller. I was able to update and develop these principles by regularly attending and eagerly participating in various astrobiology conferences. Based on these experiences, I have built the sections of the handbook such that the content of the chapters intertwines and creates an exciting web of astrobiological knowledge that spans from the past to the present and reaches into the future.

Below I describe briefly the contents of the 54 chapters and 12 sections of the handbook to further illustrate the scope available to the reader.

In **Section 1**, which contains five chapters, the definition and scope of astrobiology are covered, including NASA strategy and the European roadmap, as well as various initiatives in astrobiology education.

Section 2 focuses on the definition and nature of life. Its four chapters cover multiple perspectives of definitions of life; a generalized and universalized definition of life applicable to extraterrestrial environments; synthetic life; and communication as a characteristic of life.

Section 3 covers the origin of life, its history, philosophical aspects, and major developments. It is comprised of three chapters, which analyze the evolutionary hypothesis for emergence of life as opposed to chance or design; a treatise on

Charles Darwin and the plurality of worlds; and the history of the ideas on the origin of life, from Buffon to Oparin.

In **Section 4**, chemical origins of life are discussed, including topics such as chemicals in the universe and their delivery on the early Earth, as well as the geology and atmosphere on the early Earth. This section consists of five chapters, which cover interstellar molecules and their prebiotic potential; formation and delivery of organic materials within the solar system and on early Earth; organic molecules in meteorites and their astrobiological significance; ancient life and crust and mantle evolution; and the atmosphere on the early Earth and its evolution and impact on life.

Section 5 comprises nine chapters which are devoted to the chemical origin of life and prebiotic chemistry. These chapters cover a wide range of interrelated topics, such as prebiotic chemistry that led to life; prebiotic chemical pathways to RNA and the importance of its compartmentalization; the hydrothermal impact crater lakes and origin of life; prebiotic chemistry in hydrothermal vent systems; prebiotic reactions in water, “on water,” in supercritical water, as well as “solventless,” and in the solid state; the origin of and amplification of chirality, and leading to biological homochirality; phosphorus in prebiotic chemistry; phosphorylation on the early Earth; and silicon and life.

Section 6 addresses RNA, the RNA world, and the complexity of life’s origins. It consists of six chapters, which cover the role of RNA and ribozymes in the development of life; three ways of making an RNA sequence and the steps from chemistry to the RNA world; coevolution of RNA and peptides; role of ions in RNA folding and function; the origin of life as an evolutionary process; and a physicochemical view of the complexity of life’s origins.

In **Section 7**, the origin of life in conjunction with an early compartmentalization and formation of coacervates and protocells is discussed. The two chapters in this section cover Oparin’s coacervates and protocell evolution.

Section 8 consists of seven chapters which cover origin of life and its diversification; the universal tree of life; early primitive life on Earth; fossils of ancient microorganisms; and biomarkers and the detection of life. Specific chapters include topics such as the progenote; LUCA; the root of the cellular tree of life; horizontal gene transfer in microbial evolution; viruses in the origin of life and its subsequent diversification; the work of Carl Woese; biomarkers and their Raman spectral signatures; fossilization of bacteria and the implication for the search for early life forms; and biosignatures in astrobiology missions to Mars.

Section 9 addresses life under extreme conditions, including those in space. Its three chapters cover extremophiles and their natural niches on Earth, microbes in space, and the role of viruses in adaptation of life to extreme environments.

Section 10 deals with habitability and characterization of habitable planets. These topics and the evolution of habitability are discussed in a single chapter in this section.

Section 11 includes four chapters on putative intelligent life in the universe; the history and philosophy of this subject; and SETI (Search for Extraterrestrial Intelligence). Specific topics include philosophical approaches to the origin, evolution, and distribution of intelligent life in space; implications of the Drake equation and the Fermi paradox on the search for intelligent life elsewhere; SETI and its goals and accomplishments; and humanistic implications of discovering life beyond Earth.

The final section of the handbook, **Section 12**, has five chapters which focus on exoplanets, exploration of the solar system, the search for extraterrestrial life, and planetary protection. Specifically, topics include methods for detection of exoplanets and their habitability potential; small bodies in the solar system and their chemical and physical conditions; icy moons and their habitability; searching for extraterrestrial life on Mars and in our solar system in general; and the history, goals and objectives of the planetary protection program.

Colour versions of figures can be downloaded from the CRC Press website <https://www.crcpress.com/9781138065123>. The password to access the figures is: 9781138065123

This brief overview of the topics covered in the handbook illustrates the comprehensive approach to astrobiology which I desired and hopefully have achieved.

Thanks are expressed to the authors of the chapters, whose contributions made this handbook possible, and to the editorial and production staff of the publisher, notably Rebecca Davies and Georgia Harrison, who facilitated the process of producing the handbook in the record time, thus ensuring that its content stays current.

I dedicate this handbook to the memory of my father, Dr. Martin A. Kolb, and my mother, Dobrila Kolb, who encouraged my early love for science and supported me in my path towards becoming a scientist. This dedication extends to my loved ones, Vladimir, Mirjana, and Natasha Kolb.

Finally, special acknowledgment is due to my teachers of astrobiology, who generously shared their knowledge with me, satisfied my thirst for knowledge, inspired my dreaming about this exciting field, and carried me, so to speak, on their wings. There were many, too many to list here, but the very special ones are Leslie Orgel, Stanley Miller, Gustaf Arrhenius, and, most recently, Benton Clark.

Vera M. Kolb
Kenosha, Wisconsin
June 15, 2018

Editor

Vera M. Kolb earned a BS in chemical engineering and an MS in organic chemistry from Belgrade University, Beograd, Serbia, followed by a PhD in organic chemistry at Southern Illinois University at Carbondale, Illinois. She was a chemistry professor at the University of Wisconsin–Parkside, Kenosha, Wisconsin, from 1985 to 2016, and is now a professor Emeritus. During her first sabbatical leave (1992–1994), she received training in astrobiology (then termed exobiology) at the NASA Specialized Center of Research and Training (NSCORT) in San Diego, where she has worked with Leslie Orgel at the Salk Institute, and Stanley Miller, at the University of California, San Diego, California. She has worked in the field of astrobiology ever since. In 1992 she received the University of Wisconsin–Parkside Award for Excellence in Research and

Creative Activity. During her second sabbatical (2002–2003) she studied sugar organo-silicates and their astrobiological importance with Joseph Lambert, at Northwestern University, Evanston, Illinois. Dr. Kolb was inducted in the Southeastern Wisconsin Educators' Hall of Fame in 2002. She is a recipient of numerous research and higher education grants and awards from the Wisconsin Space Grant Consortium/NASA, among others. At this time, she has published over 150 articles, including patents and books, in organic chemistry, medicinal chemistry, and astrobiology. She has edited a book, *Astrobiology, An Evolutionary Approach*, for CRC Press, which was published in 2014. Her second book, *Green Organic Chemistry and its Interdisciplinary Applications*, was published in 2016, also by CRC Press. Since both astrobiology and green chemistry study organic reactions in water, as in the primordial soup for astrobiology and as a benign solvent in green chemistry, the relationship between these two fields speaks of their true interdisciplinary character.

1.1.1 INTRODUCTION

In this chapter, the definition, scope, and a brief overview of astrobiology are given. Classification of astrobiology as a field of study, its specific goals, its multidisciplinary and interdisciplinary nature, and selected key developments are described. Astrobiology includes numerous research themes, which are expanding as the field evolves. Thus, it is not possible to cover all the developments in a single chapter, even briefly. Instead, an overview of selected astrobiology developments is presented, which is only a sampler of what is offered in this handbook.

1.1.2 ASTROBIOLOGY: DEFINITION, SCOPE, AND A BRIEF HISTORY

Astrobiology is defined as the study of the origin, evolution, distribution, and future of life in the universe (NASA's definition; Des Marais et al. 2008). Astrobiology seeks to answer fundamental questions about the beginning and evolution of life on Earth, possible existence of extraterrestrial life, and

the future of life on Earth and beyond. Astrobiology scope is delineated in the NASA's astrobiology roadmap (Des Marais et al. 2008). Specific goals include understanding the emergence of life on Earth, determining how the early life on Earth interacted and evolved with its changing environment, understanding the evolutionary mechanisms and environmental limits of life, exploring habitable environments in our solar system and searching for life, understanding the nature and distribution of habitable environments in the universe, and recognizing signatures of life on the early Earth and on other worlds. The NASA's astrobiology map is being updated as the astrobiology field advances. A similar roadmap has been developed for astrobiology research in Europe (Horneck et al. 2015, 2016). The topic of these roadmaps is further discussed and updated in [Section 1](#) of this handbook.

Astrobiology is a young science that acquired its name only in 1995 (named by Wes Huntress from NASA; Catling 2013). Astrobiology evolved from its predecessor, exobiology, which is the study of the origin of life and of possible life outside Earth (Dick and Strick 2004; Dick 2007). The term exobiology was coined in 1960 (by Joshua Lederberg).

The difference between the two fields is that astrobiology is broader and notably includes the evolution of life on Earth. The exobiology era coincided with the space missions, notably the Viking mission on Mars in 1976, which followed a series of reconnaissance missions in the 1960s and early 1970s. The Viking mission searched for the microbial life on Mars (DiGregorio 1997; Jones 2004), but it did not confirm its existence. The early experiments that used radio astronomy to search for extraterrestrial intelligence by the Search for Extraterrestrial Intelligence (SETI) program (Tarter 2007) did not result in positive findings. In 1996, the analysis of the Martian meteorite ALH84001, which was found in Antarctica, indicated possible presence of the fossils of bacterial life (Goldsmith 1997; Jones 2004), but the results were not convincing enough. Disappointments regarding a lack of positive results in the search for extraterrestrial life (Dick and Strick 2004; Dick 2007, 2012) continue to this date. The only life we know of is the life on Earth. Search for extraterrestrial life and extraterrestrial intelligence is further discussed in [Sections 10](#) through [12](#) of this handbook.

While astrobiology is a new science, it comes from a very old and long history of ideas, which go all the way back to the antiquity. The history of one of the core ideas of astrobiology, a possibility of extraterrestrial life, is described in the books: “Plurality of worlds: The origins of the extraterrestrial life debate from Democritus to Kant” (Dick 1984), “The extraterrestrial life debate, 1750–1900” (Crowe 1999), “Medieval cosmology: Theories of infinity, place, time, void, and the plurality of worlds” (Duhem 1987), and other sources. A comprehensive coverage of the ideas about extraterrestrial intelligent life is covered in the books: “Extraterrestrials: Science and alien intelligence” (Regis 1987), “Extraterrestrials: Where are they?” (Zuckerman and Hart 1995), “Beyond contact: A guide to SETI and communicating with alien civilizations” (McConnell 2001), and “Civilizations beyond Earth: Extraterrestrial life and society” (Vakoch and Harrison 2013), among other sources.

The future of life on Earth and its potential uniqueness are discussed in the books “The life and death of planet Earth: How the new science of astrobiology charts the ultimate fate of our world” (Ward and Brownlee 2002), and “Rare Earth: Why complex life is uncommon in the universe” (Ward and Brownlee 2004). Search for exoplanets, some of which may be habitable, is a subject of recent studies (Kasting 2010; Summers and Trefil 2017). This subject is further covered in [Section 12](#) of this handbook.

The major hypothesis about the origin of life on Earth, which later became accepted as a key foundation of both exobiology and astrobiology, was proposed independently by A.I. Oparin in 1924 and J. B. S. Haldane in 1929 (Oparin 1965, 1968, 1994; Deamer and Fleischaker 1994; Haldane 1994). This hypothesis states that the origin of life on Earth can be understood based only on the laws of chemistry and physics. Life arose in Earth’s distant past by chemical reactions and physical processes under the specific conditions on the early Earth and over a long period of time. Numerous rapid developments based on the Oparin–Haldane proposal followed

(Miller and Orgel 1974; Mason 1991; Brack 2000; Zubay 2000; Chela-Flores 2001, 2011; Fenchel 2002; Lurquin 2003; Gilmour and Sephton 2004; Luisi 2006; Sullivan and Baross 2007; Sullivan and Carney 2007; Kolb 2014a; Longstaff 2015). New developments on chemical origins of life and prebiotic chemistry are covered in [Section 5](#) of this handbook.

1.1.3 CLASSIFICATION OF ASTROBIOLOGY AS A FIELD OF STUDY

Astrobiology is commonly referred to as a field of study rather than a discipline. Dick (2012) examined the question if astrobiology is a separate discipline and if it should be considered as such. This question is still open to discussion. Astrobiology as a discipline would include origins of life (interstellar molecules, complex organics, development of laboratory experiments, life in extreme environments, genomics/phylogenetic relationships), planetary systems (theoretical studies, atmospheric biosignatures, extrasolar planets, circumstellar disks), planetary science (rock biosignatures, biogeochemistry, geochemistry exploration of Mars, Europa, moons, etc.), and SETI (Dick 2012). A common approach is that astrobiology is not a discipline itself but draws upon other disciplines, subdisciplines, and specialized areas of research. Physics, chemistry, biology, geology, and astronomy were the initial disciplinary pillars of astrobiology. Rapid developments in astrobiology and astrobiology-relevant disciplines led to an expanded list, which included cosmology, atmospheric science, oceanography, evolutionary science, paleontology, planetary science, biochemistry, molecular biology, microbiology, and ecology. Astrobiology also seeks insights from history of science and philosophy (Fry 2000). The latter approach is also covered in [Section 3](#) of this handbook.

An all-encompassing goal for astrobiology is to understand cosmic evolution. NASA embraced the idea of cosmic evolution, comprising the following evolutionary sequence: Big Bang, galaxies, stars, biogenic elements, planets, chemical evolution, origin of life, pre-Cambrian biology, complex life, intelligent life, cultural evolution, civilization, science and technology, and the study of life in the universe (Dick 2007). This formidable goal adds many more disciplines and subdisciplines of various fields of study for astrobiology to rely upon. It becomes clearer why it would be difficult to classify astrobiology as a single discipline.

NASA classified astrobiology as a field of study that is multidisciplinary in its content and interdisciplinary in its execution. Astrobiology requires a close coordination of not only various disciplines but also programs, including space missions (Race 2007).

The distinction between multidisciplinary and interdisciplinary studies is described in the book “Interdisciplinary research, process and theory” by Repko (2012). Both types of studies are used to investigate complex problems and issues, which are beyond the ability of any single discipline. These studies are thus well suited for astrobiology. Repko addresses the “multi,” “inter,” and “disciplinary” parts of these terms. A brief account is given here. In a multidisciplinary approach,

a problem is studied from the perspective of several disciplines at one time. This approach tends to be dominated by the method and theory preferred by the main discipline of the investigator. This prevents effective integration of the insights from all the disciplines that were consulted. In contrast, the interdisciplinary approach successfully integrates disciplinary insights to construct a more comprehensive understanding of the problem. While employing a research process that subsumes the methods of relevant disciplines, interdisciplinary research does not privilege any disciplinary method or theory. Thus, the interdisciplinary approach is more powerful but not always easy to achieve (Repko 2012).

Although the modern astrobiology field is commonly perceived as mostly based on the developments in the natural sciences and technology, contribution to astrobiology from other disciplines needs to be considered equally. This is demonstrated in a review paper by Dick (2012) titled “Critical issues in the history, philosophy, and sociology of astrobiology”.

In its study of some complex problems, such as the future of life and the humanistic implications of discovery of extraterrestrial life (Dick and Lupisella 2009; Dick 2015), astrobiology may use a transdisciplinary approach. This approach is useful in studies of complex and mega problems, which are at once between the disciplines, across different disciplines, and beyond all disciplines (Repko 2012).

Interdisciplinary and transdisciplinary nature of astrobiology is especially needed for the study of cosmic evolution. Progress in understanding of the individual steps of this evolution has been made based mostly on the multidisciplinary approach. However, a full integration of the insights from the individual disciplines that are involved in these evolutionary steps has not yet been achieved. This is notably the case for the cosmic evolutionary step of the origin of life on Earth.

Astrobiology may also be considered an evolutionary science. The multi-/interdisciplinary nature of astrobiology evolves to include more disciplines and subdisciplines and to achieve a better integration of the disciplinary insights. Astrobiology research tools, which are typically initially borrowed from its contributing disciplines, become more advanced and specialized for astrobiology use, which allows for new research programs to emerge. Technological advances enable space missions that search for extraterrestrial life and habitable places within our solar system. Based on these and many more new developments, critical issues, goals, and objectives of astrobiology evolve accordingly. An evolutionary approach to astrobiology is presented in a recent book (Kolb 2014a).

In the next section, selected key developments in astrobiology are overviewed.

1.1.4 A BRIEF OVERVIEW OF SELECTED KEY DEVELOPMENTS IN ASTROBIOLOGY

As shown in the previous section, astrobiology research themes are numerous and constantly expanding. There are “astro” and “bio” themes, and the organization of their coverage presents

a challenge. A choice taken here is to focus on the themes that are most closely related to the central focus of astrobiology as a study of the origin and evolution of life and on a possibility of life elsewhere.

1.1.4.1 UNDERSTANDING THE CONCEPT OF LIFE

Among key problems that astrobiology is yet to solve is to define life (Popa 2014). Many such definitions have been proposed, but none is universally accepted (Popa 2014). While each definition addresses some features of life, none appears inclusive of all the features. Even the most inclusive definitions may only describe what life does but may not state what life is (Catling 2013). We may not know enough about the theory of life to define it properly (Cleland and Chyba 2007). Our ability to define life is also dependent on our understanding of the origin of life. Currently, the NASA’s operational definition of life that is used most often is: “Life is a self-sustained chemical system capable of undergoing Darwinian evolution” (Popa 2014). This definition, however, is not very useful in search for extraterrestrial life, since it would require observation of evolution (Catling 2013). What is desired is a definition of life that will also be applicable to life in general and thus to the putative extraterrestrial life. A universal definition of life in which living beings are considered autonomous systems with open-ended evolutionary capacities has been proposed (Ruiz-Mirazo et al. 2004). A generalized and universalized definition of life has been proposed for the identification of extraterrestrial and artificial life forms (Clark 2004). An examination of the proposal that prebiotic evolution that leads to life is Darwinian continues, with no definitive conclusion (Perry and Kolb 2004). One area of progress is a better understanding of viruses, which are in the twilight zone of life (Villarreal 2004). The question if viruses are alive is also discussed from the philosophical point of view of dialetheism, which allows for viruses to be considered both alive and not alive (Kolb 2010a). The problem of defining life is further discussed in [Section 2](#) of this handbook.

1.1.4.2 CHEMICALS IN THE UNIVERSE AND THEIR DELIVERY TO THE EARLY EARTH

The formation of chemicals in the universe and their delivery to the early Earth (Shaw 2006; Longstaff 2015; Kwok 2016, 2017) were necessary for life to evolve. Many interstellar molecules are prebiotically relevant. Complex organic molecules were formed in space and delivered to the solar system and early Earth. The delivery occurred mostly by the comets (e.g., Chyba et al. 1990) and meteorites. The origin of terrestrial water, which is critical to life, is from comets but also from other sources (O’Brien et al. 2018). Meteorites of the carbonaceous chondrite type (McSween 1999) delivered complex chemical compounds, many of which were important for the emerging life. They include amino acids and nucleobases (Sephton 2004; Schmitt-Kopplin et al. 2010, 2014; Burton et al. 2012). This is further discussed in [Section 4](#) of the handbook.

1.1.4.3 PREBIOTIC CHEMISTRY AND THE RIBONUCLEIC ACID WORLD

In 1953, Stanley Miller published the results of a seminal experiment that showed that the amino acids, which are the building blocks of proteins, can be synthesized in the laboratory under the reaction conditions that simulate those on the early Earth (Miller 1953; Mesler and Cleaves 2016). Miller built a glass apparatus consisting of a series of connected flasks and tubing to simulate the primitive Earth's environment. One flask was filled with water, representing the early ocean. Water could be heated to simulate evaporation. Another flask simulated the early atmosphere. It contained gases methane, hydrogen, ammonia, and water vapor, which reflected the belief at that time that the early Earth's atmospheric conditions were reducing. The source of energy in the experiments was electrical spark generated by Tesla coil. Various amino acids were formed, including glycine and alanine. Miller's experiment showed that organic compounds that are important for life can indeed be formed under prebiotic conditions.

Many more prebiotic experiments by different investigators followed. Much progress has been made by the early 1970s, as shown in the book "The origins of life on earth" (Miller and Orgel 1974). Prebiotic syntheses of amino acids, urea, fatty acids, porphyrins, vitamins, purines, pyrimidines, sugars, and nucleosides have been attempted, and some gave excellent yields.

Further progress in prebiotic syntheses has been achieved in the next three decades (Brack 2000; Bilgen 2004; Orgel 2004; Herdewijn and Kisakürek 2008; Peretó 2012). Some of these syntheses facilitated new proposals on the origins of life. Selected examples are presented here. Miller performed syntheses of amino acids under mildly reducing or non-reducing conditions, which reflected an updated view on the atmospheric conditions on the early Earth. The results were less favorable than those in the reducing atmosphere, but, in combination with other prebiotic factors, these results were judged adequate (Miller 2000). Wächtershäuser proposed that the original source of prebiotic organic material under deep-sea vents conditions may have been a reduction of carbon dioxide with hydrogen sulfide over ferrous sulfide as the reducing agent. He believed that life originated in an iron–sulfur world (Wächtershäuser 2000, 2008; Orgel 2004). Based on the clues from the present-day biology, De Duve (2000) proposed an early thioester world, in which thioesters had a role in primitive (proto) metabolism. Progress in non-enzymatic autocatalysis and self-replication, notably by von Kiedrowski and coauthors, has been made (Burmeister 2000).

The proposal of ribonucleic acid (RNA) world emerged as a leading hypothesis for the origins of life (Joyce and Orgel 1993; Orgel 2004). This hypothesis postulates that the RNA is the original self-replicator that has a capability to carry the genetic information and act as a catalyst. Within this hypothesis, various aspects of RNA were studied. Examples include non-enzymatic polymerization of RNA monomers to RNA, with montmorillonite clay as a catalyst (Ferris 2000), and the enzymatic ribozyme (RNA that acts as an enzyme) catalysis

that might have facilitated polynucleotide replication (James and Ellington 2000; Orgel 2004).

Key discoveries in prebiotic chemistry and the origin of the RNA world up to the early 2000s were reviewed by Orgel (2004). This review includes work on template-directed synthesis of nucleotides by Orgel and his coworkers. Eschenmoser's work is also highlighted. With his coworkers, he synthesized and studied close chemical alternatives to RNA and DNA in a systematic manner to gain an insight into the selection of the naturally occurring forms. They synthesized RNA and DNA analogs in which the sugar component, ribose for RNA and deoxyribose for deoxyribonucleic acid (DNA), were substituted with a different sugar type or a different sugar form (in both RNA and DNA, the sugar form is a five-membered ring). For example, they synthesized homo-DNA, in which the five-membered ring was expanded to a six-membered ring, an analog of glucose. They also prepared pyranosyl-RNA, based on a six-membered sugar form rather than the five-membered form found in RNA. In addition, they varied a sugar type and prepared threose nucleic acid (TNA), which is based on the sugar threose rather than ribose. Eschenmoser put together all the experimental results to determine "chemical etiology" of nucleic acids (Eschenmoser 1999). The latter explains how changes in chemical structures influence hydrogen bonding, folding, and other properties of nucleic acids. For example, while homo-DNA can make a stable double helix via hydrogen bonds, the type of its helix is incompatible with the RNA helix. This prevents formation of a double helix between a strand of homo-DNA and a strand of RNA, which makes homo-DNA unsuitable for the transcription process. This etiology of nucleic acids provided an insight into the selection of the present-day type and form of nucleic acids (Eschenmoser 1999). Benner expanded the genetic alphabet from standard AGCT/U (adenine, guanine, cytosine, thymine/uracil) with synthetic unnatural nucleobases. He also synthesized sulfone-linked RNAs (Benner 2004). The sulfone-based RNA backbone is not charged, as opposed to the natural phosphate backbone. Like Eschenmoser, Benner used the experimental results to gain insight into the structure and function of nucleic acids by considering their hydrogen bonding and folding properties and the reasons why some natural structures are superior to the analogous unnatural ones. As one example, sulfone-linked RNAs are unsuitable, since they fold and aggregate in water. This shows the importance of charged backbones in nucleic acids, since charges prevent undesired folding and aggregation in water. Charged backbones are thus selected in nature.

Prebiotic synthesis of biological compounds (Cleaves 2013, 2014) as well as the work on biochemical pathways as evidence for prebiotic synthesis (McDonald 2014) have advanced. The progress in prebiotic synthesis continued with a new, innovative prebiotic synthesis of nucleotides (Powner et al. 2011; Islam and Powner 2017; Sutherland 2017), which has previously been only marginally successful. Significant new work on the RNA world and its connection to the origins of life has been recently reported (e.g., Robertson and Joyce 2012; Higgs and Lehman 2015; Pressman et al. 2015; Mathis et al.

2017). The advances in prebiotic chemical pathways to RNA and the properties of RNA that enable its self-replication and enzymatic activity are further covered in [Sections 5](#) and [6](#) of this handbook.

1.1.4.4 PREBIOTIC REACTIONS IN HYDROTHERMAL VENTS

Prebiotic reactions under the conditions of hydrothermal vents gained importance, since such vents on Earth are rich with life. These vents provide both chemicals and energy sources, making them feasible as a niche for the emergence of life. Thus, other bodies in the solar system that possess hydrothermal vents could also be habitable. Chemistry under the conditions of the hydrothermal vents has a substantial prebiotic potential (Holm and Andersson 2000; Orgel 2004; Padgett 2012; Sojo et al. 2016). As one example, components of the citric acid cycle, which are important for development of protometabolism, have been synthesized under these conditions (Orgel 2004). Prebiotic chemistry in hydrothermal vents is further discussed and updated in [Section 5](#) of this handbook.

1.1.4.5 PREBIOTIC REACTIONS IN WATER AND IN THE SOLID STATE

Progress has been made in prebiotic organic reactions in water as a reaction medium, a model for the prebiotic soup. While most organic compounds are not water-soluble, prebiotic reactions are supposed to happen in water, which is the ubiquitous solvent on Earth and is also the medium for life. Recent findings show how prebiotic reactions of water-insoluble organic compounds can occur in water, by a special mechanism called “on-water” reactions. According to this mechanism, insoluble organic materials are driven toward each other in water by the hydrophobic interactions. The proximity between the molecules then facilitates the reaction. Furthermore, selectivity and specificity of the reactions are often improved (Kolb 2014b). This type of reaction is an exception from the usual formation of intractable mixtures in the prebiotic experiments (Benner et al. 2012; Benner 2014).

Many classical organic reactions, which are a bread and butter of prebiotic chemistry, are possible in superheated water and thus under hydrothermal conditions. They have been studied in context of green chemistry (environmentally friendly) (e.g., Kolb 2016). This is covered in more detail in [Section 5](#) of this handbook.

Prebiotic chemistry in water–ice matrix occurs readily (Menor-Salván and Marín-Yaseli 2012). Organic materials and salts concentrate in the liquid phase of the crystalline ice matrix and form eutectic solutions. The concentration effect generally increases the reaction rates. Thus, prebiotic chemistry in the ice world is feasible.

Prebiotic reactions can also occur quite successfully in the solid state. Surprisingly, the reactions are often very fast and specific. This has a direct application to the chemistry on asteroids and meteorites (Kolb 2010b, 2012). These reactions are also covered in [Section 5](#) of this handbook.

1.1.4.6 PHOSPHORUS IN PREBIOTIC CHEMISTRY

Life on Earth requires phosphorus in DNA/RNA and in the chemical energy sources. Thus, the study of the role of phosphorus in prebiotic chemistry is important. A convincing scenario for the incorporation of phosphorus from geologically plausible sources into chemical systems on the early Earth was not initially conceived, leading to the so-called “phosphorus problem.” Progress has been made on this front, as a result of several approaches (Fernández-García et al. 2017; Pasek et al. 2017), as well as the discovery of a meteoritic source of reactive phosphorus, which may have been delivered to the early Earth (Maciá 2005; Pasek and Lauretta 2005; Schwartz 2006; Pasek 2014). This subject is further discussed in [Section 5](#) of this handbook.

1.1.4.7 PREBIOTIC EVOLUTION OF HOMOCHIRALITY

The origin of biological homochirality is one of the central problems in understanding chemistry of life. Chiral molecules (or other objects) are not superimposable with their mirror images (such as the left hand and the right hand). Each of the pair of such molecules is termed an enantiomer. Homochirality occurs when all the constituent units are molecules of the same chiral form (enantiomer).

Many key biochemical compounds are chiral. Chiral properties provide an extra dimension in the specificity of molecular recognition, such as between the enzymes and their substrates. Homochirality is common in biology. Thus, nature uses almost exclusively L-amino acids and D-sugars, thus only one out of the two possible forms. A question is posed about the origin of homochirality, if it occurred prebiotically or during the biotic evolution. Prebiotic evolution of homochirality is envisaged to occur in three steps: mirror-symmetry breaking, chiral amplification, and chiral transmission. The mirror-symmetry breaking occurs under the influence of circularly polarized light or other physical causes. It results in a minute enantiomeric imbalance. A slight enantiomeric excess observed in the meteoritic amino acids indicates an asymmetric influence on organic chemical syntheses under abiotic conditions (Cronin and Pizzarello 1997; Pizzarello 2008). The second step, chiral amplification, leads to enantiomeric enrichment. The third step, chiral transmission, enables the transfer of chirality between molecules. Studies on the origin of a single chirality of amino acids and sugars indicate that a partial enantioenrichment in prebiotic world may have been sufficient to trigger chemical and physical processes to enable further amplification of the enantiomeric excess (Hein and Blackmond 2012). Enantioselective automultiplication of chiral molecules can occur via asymmetric catalysis, in which a chiral compound acts as a chiral catalyst for its own production (Soai et al. 2000). Reviews of the prebiotic origins of homochirality are available (Coveney et al. 2012; Ruiz-Mirazo et al. 2014). Origin and chemical evolution of biological homochirality are further discussed in [Section 5](#) of this handbook.

1.1.4.8 APPROACHES TO RECONSTRUCTING THE ORIGIN OF LIFE

The emergence of life is a historical process, which scientists try to reconstruct. Different approaches exist to this problem. The “metabolism first” approach envisions that the process starts with the development of a primitive metabolism. Others believe that compartmentalization is the essential first step (Deamer 2000, 2007). The “genetics first” proponents believe that the formation of self-replicating polymers, such as RNA, is critical. Peretó discusses problems and controversies of these approaches (Peretó 2005). Most believe that the origin of life is linked to the RNA world, in which RNA has both genetic and enzymatic properties and is capable of self-replication.

The research approaches that are employed for reconstruction of the origin of life are bottom-to-top and top-to-bottom approaches. In the former, prebiotic chemistry is studied experimentally under simulated prebiotic conditions, starting from the simple compounds and moving toward molecular complexity that is characteristic of life (Lahav 1999). This research pathway benefited greatly from new developments in prebiotic synthetic methods and an increased knowledge of the environmental conditions on the early Earth under which these syntheses occurred. Lahav considered different ways of bottom-up reconstruction of early stages of chemical evolution. The reconstruction could be without or with specific biogeochemical constraints. The latter included minerals that acted as catalysts or were involved in energy production and transfer, among other roles (Lahav 1999). The bottom-to-top approach needs to be looked at in conjunction with the conditions on the Early Earth (Burton et al. 2012; Scharf et al. 2015; Domagala-Goldman et al. 2016). Also, the chemistry on meteorites, which are the prebiotic laboratory, needs to be considered.

In the top-to-bottom approach, a reconstruction of the origin of life is attempted, going from its most primitive life forms to the putative RNA world (Lahav 1999; Sephton 2004) and the pre-RNA world (Hazen 2005). Development of new research tools, notably those in molecular biology, facilitated this approach. These tools are responsible for rapid recent advances in the understanding of RNA and the RNA world (Ruiz-Mirazo et al. 2014). Progress has been made in modeling the RNA world by the RNA viral quasispecies (Padgett 2012; Eigen 2013). The newest research on this topic is covered in [Sections 5](#) and [6](#) of this handbook. It includes various aspects of prebiotic pathways to RNA, coevolution of RNA and peptides, and the role of RNA and ribozymes in the development of life, among others. This is the most significant and most rapidly developing area of research into the origins of life, which thus justifies its extensive coverage in this handbook.

1.1.4.9 ABIOTIC-TO-BIOTIC TRANSITION

Both bottom-to-top and top-to-bottom approaches to the origins of life lead to a putative transition zone between life and non-life. The nature of this zone is not elucidated, but it is assumed to contain a complex mixture of organic compounds. The mechanism by which life emerged from the transition

zone is not known. Progress has been made in the understanding of the nature of life as an organized complexity. Life represents order, which imposes thermodynamic requirements between the life entity (typically a compartmentalized system) and its environment. However, both thermodynamic and kinetic factors constitute driving force for the emergence of life (Pross 2003, 2012). Emergence of order out of chaos has been invoked as a way for an organized system to emerge from chaotic mixtures of components (Kauffman 1993, 1995, 2000). Properties attributed to chemical systems that are transitioning to life are complex chemical behaviors, such as self-organization and self-assembly; formation of autocatalytic networks and protometabolic cycles; and establishment of self-replicating systems (Padgett 2012; Peretó 2012; Ruiz-Mirazo et al. 2014). Possible scenarios of protobiological events prior to the emergence of the last universal common ancestor (LUCA) have been proposed (Mann 2013). The idea of an alternative living world that existed prior to the LUCA of the organisms, as we know them, is introduced. Peretó discusses proposed stages in the origin of life, which comprise prebiotic, protobiological, and biological stages. Each stage consists of the additional sub-stages, such as the pre-RNA world (Peretó 2005). Joyce (2012) also discusses pathways to life and considers the pre-RNA life, which was based on different types of RNA. Krishnamurthy (2017) took a chemical approach to the transition from prebiotic chemistry to protobiology and analyzed how a diverse pool of prebiotic building blocks could lead to a self-assembling system that is capable of chemical evolution. His analysis encompassed different classes of biomolecules that built the thioester world, protein world, metabolism world, lipid world, and RNA world.

Theoretical and computational approaches have been used to examine if there is an algorithm for abiotic-to-biotic transition (Walker 2014). The nature of biological information, informational limits of evolution, Shannon information content of biopolymers, molecular quasispecies, and replicator equations were addressed. While no definitive conclusion was reached, it appears that the answer to how life emerged from non-life will probably come from some combination of chemistry and information-based formalism. Since life is an organized complexity, studies of complexity and in relation to life are relevant to the understanding of the nature of transition zone to life and to the emergence of life (Waldrop 1992; Holland 1995; Mitchell 2009; Lineweaver et al. 2013). The topics of transition from prebiotic toward biotic world and life are updated and further discussed in [Section 6](#) of this handbook.

1.1.4.10 EARLY COMPARTMENTALIZATION AND DEVELOPMENT OF PROTOCELLS

Since his original proposal in 1924, Oparin made experimental progress in study of coacervates. Coacervates are feasible as prebiotic compartmentalized systems and can serve as prebiotic chemical reactors. In addition, they are capable of undergoing a primitive “reproduction” by splitting into smaller units (Oparin 1968).

It is believed that an early compartmentalization and development of protocells were necessary for the development of life. Compartmentalization could be achieved by forming prebiotic coacervates, micelles, vesicles, and primitive membranes (Deamer 2000; Luisi 2006; Frankel et al. 2014; Kolb 2015). Such compartmentalization enabled encapsulation of macromolecules. These topics are further covered and updated in [Section 7](#) of this handbook.

1.1.4.11 ASTROBIOLOGY AND EVOLUTION OF LIFE

One of the astrobiology goals is to understand the evolution of life, its mechanisms, and evolutionary transitions, starting from the early primitive life on Earth (Fenchel 2002; Agutter and Wheatley 2007). Examples of specific goals are the determination of the evolutionary mechanisms (molecular, genetic, and biochemical) that control and limit evolution, metabolic diversity, and acclimatization of life (Des Marais et al. 2008). Aspects of evolution, such as the role of viruses in the origin and evolution of life (Ryan 2002; Villarreal 2005, 2014; Jalasvuori and Bamford 2014), development of the tree of life (Hug et al. 2016), and horizontal gene transfer (Fenchel 2002; Soucy et al. 2015), are all used to ascertain the origin of life, by the top-to-bottom approach. The topic of astrobiology and evolution is updated and discussed in [Section 8](#) of this handbook.

1.1.4.12 BIOSIGNATURES AND DETECTION OF LIFE

Biosignatures are used to detect life, past or present, on Earth or elsewhere. The list of the life features that are used as biosignatures is long (Westall and Cockell 2016). It includes metabolic gases; spectral signatures of biology, such as the red edge of vegetation in earthlight, reflected from the Moon; biomolecules and/or their degradation products; homochiral organic molecules; isotopic fractionation of bioelements, such as C, S, N, and others; biominerals formed by microbial metabolism, such as carbonate and phosphate; morphological features produced by microorganisms and their activities; bacterial fossils; and many more. Discovery of Earth's early bacterial fossils helped pin down the beginning of the biological evolution (Schopf 1999, 2006; Brasier et al. 2015). The issue of the putative biosignatures on Mars is examined, which will be useful for the future mission to Mars (Westall et al. 2015). These topics are updated and discussed in [Sections 8](#) and [12](#) of this handbook.

1.1.4.13 LIFE UNDER EXTREME CONDITIONS

One of the rapidly developing areas in astrobiology is the study of life under extreme conditions, including that in space. Extremophiles are microbes that live under extreme conditions on Earth, which are generally hostile to most other life. Extreme conditions include extreme heat or cold, high concentration of salts, and high pressure. Many extremophiles are polyextremophiles. They are adapted to multiple forms of stress (Seckbach et al. 2013). These microbes are good models for the survival under extraterrestrial extreme conditions. Progress in space

missions allowed for the study of such microbes in space. They were found to be able to survive in space under a specific limited exposure (Horneck and Moeller 2014). Adaptation of life to extreme environment includes viruses. These topics are updated and discussed in [Section 9](#) of this handbook.

1.1.4.14 HABITABILITY WITHIN THE SOLAR SYSTEM AND BEYOND

Another rapidly developing area of astrobiology is a study of the habitability within the solar system (and beyond). Much of the modern focus of the “astro” part from astrobiology is on the habitability and its limits and on the characteristics of habitable planets (Kasting 2010). The habitability study is facilitated by the advances in planetary sciences and the results of many space missions, notably those on Mars. Planetary science studies planets and processes that formed them. Studies of the Earth, moons, and planets in our solar system provide information about their environments (Beatty et al. 1999; Bennett et al. 2003); these can then be checked against those on Earth, which are hospitable to life. Knowledge about the environments on the Earth's Moon, Mercury, Venus, Mars, Europa, Ganymede, Callisto, Titan, Triton, Pluto, Charon, comets, asteroids, and meteorites is increasing rapidly. As its counterpart, the knowledge about the life on Earth under the extreme condition is also increasing. A combination of these two can guide studies of habitability. For example, Europa is now considered habitable (Jones 2004). The topic of habitability is discussed in [Section 10](#) of this handbook.

Another modern “astro” focus of astrobiology is on the search for planets outside our solar system (exoplanets) (Summers and Trefil 2017). Such search has resulted in a discovery of over 3500 planets so far, and the number is rapidly increasing. Some of these planets may be habitable and may hopefully harbor life. Exoplanets are covered in [Section 12](#) of this handbook.

1.1.4.15 SOME RAPIDLY ADVANCING ASTROBIOLOGY AREAS

Rapid advances and a huge output of new data in some areas of astrobiology make regular updates mandatory. Examples of such areas are studies of habitable planets and other bodies in the solar systems, search for microbial life within the solar system, analog studies (studying places on Earth with environmental conditions that are extreme for life, which can then serve as laboratories to simulate extraterrestrial environments), developments of instruments for astrobiology research and exploration, missions to Mars and other missions, search for exoplanets, and the planetary protection program. Some of these examples are briefly addressed below.

The planetary protection program develops protocols for the prevention of contamination of Earth with the putative extraterrestrial microbes that may be carried back on the space vehicles or samples that are returned to Earth and

for the prevention of contamination of space bodies with microbes from Earth delivered by spaceships, landers, and astronauts (Rummel 2007; Meltzer 2010).

Instruments for the assessment of habitability and search for life on Mars (Conrad 2007) and for the observation and spectroscopic analysis of planets and satellites in the solar system and exoplanets are rapidly developing. Some instruments are designed for a specific mission. For example, Mars Exploration Rover (MER) mission employed panoramic imagers (for visual characterization of environment), microscopic imager (for providing detailed images of rock textures), miniature thermal emission spectrometer (for the identification of minerals), and other instruments to study the surface of Mars (Conrad 2007).

The coverage and updates on these topics are provided in [Section 12](#) of this handbook.

1.1.5 SUMMARY

This chapter provides an overview of astrobiology, which includes its definition, scope, a brief history, and classification as a field of study. In addition, it briefly presents selected topics in astrobiology. Within the narrative of this chapter, contents of various sections of this handbook are announced. Selected key references are cited.

DEDICATION

I dedicate this chapter to the memory of two great scientists, Leslie E. Orgel and Stanley L. Miller, with whom I have worked from 1992 through 1994.

1.2.1 INTRODUCTION

As stated in [Chapter 1.1](#), astrobiology seeks to understand the origins, evolution, distribution, and future of life in the universe. Because this compelling charter statement is also quite ambitious, a framework is needed to identify key concepts and advocate priorities. An astrobiology roadmap or strategy provides this framework.

[Figure 1.2.1](#) illustrates one example of an area of investigation that is centrally important to astrobiology and also requires a combination of expertise in multiple disciplines.

This figure illustrates that four complementary approaches are being pursued in order to understand the origins of life on Earth and beyond. One can envision a timeline that led up to, included, and followed an origin of life event. Two approaches investigate forward in time and address the processes and

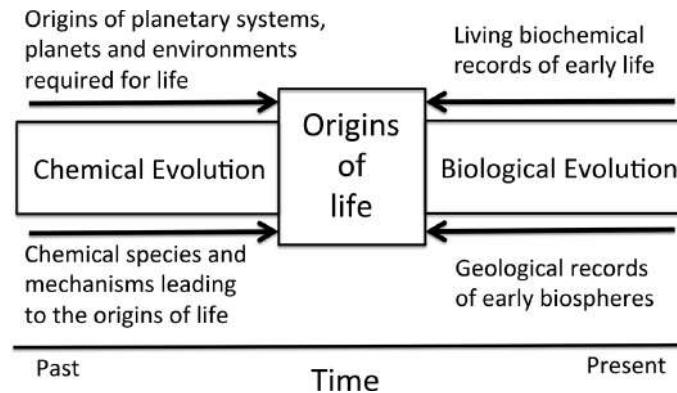

FIGURE 1.2.1 Four disciplinary approaches to understanding the origins of life.

materials that set the stage for life. The fields of astronomy, astrophysics, and planetary science investigate the cosmic origins and distribution of key elements and compounds, the formation of planetary systems, and the maintenance of planetary environments conducive to life. The fields of chemistry, geochemistry, and molecular biology address the environmental conditions and processes leading to an origin of life. Two additional approaches investigate back in time from the present to discern the history of life. Geologists investigate ancient rock records to characterize habitable environments and to identify any “signatures of life” or “biosignatures.” Molecular biologists investigate the biochemistry of extant biota in order to trace evolutionary events back in time to infer the earliest attributes of living systems. Astrobiologists strive to identify effective strategies for each of these approaches.

The broad scope of astrobiology also necessitates advances in both technology and access (i.e., missions) to environments beyond Earth. Accordingly, space agencies have supported research in astrobiology that, in turn, informs technology development and missions. A roadmap should highlight research, technologies, and missions that are not just relevant to astrobiology but are also either currently possible or achievable in a realistic near-term time frame. Accordingly, the goals and objectives of the NASA Astrobiology Strategy and the European Roadmap are necessarily also influenced by the opportunities and constraints imposed by the government agencies and programs from which astrobiology research and exploration derive support.

1.2.2 RESEARCH TOPICS AND THEMES

NASA’s 2015 Astrobiology Strategy (abbreviated as “NAS” herein; Hays et al., 2015), the European Space Agency (ESA’s) 2016 Astrobiology Roadmap (or “EAR”; Horneck et al., 2016), and NASA’s 2008 Astrobiology Roadmap (or “NAR”; Des Marais et al., 2008) articulated Themes (NAS), Research Topics (EAR), and Goals (NAR), respectively. Each of these documents delineated a sequence of investigations that addresses the progression of developments leading to the origins of life and its subsequent evolution. The six sections below summarize this sequence, starting with the cosmic origins of prebiotic compounds and planetary systems, then progressing through

the development of habitable planetary environments and biospheres, and ultimately to more complex life. Each section cites the particular Theme, Research Topic, and Goal that address the topic of that section. For example, [Section 1.2.3](#) draws its content from NAS Theme 1, EAR Research Topic 2, and NAR Goal 3.

The intent of this chapter is to provide a concise yet moderately detailed guide to the NAS and EAR. These documents are substantial both in length and in detail—in published form, the NAS and EAR are on 215 and 43 pages, respectively. These documents introduce each of their themes or research topics, summarize recent progress on each, articulate the research objectives, and finally outline approaches toward achieving those objectives. This chapter summarizes principally the research objectives recommended by the NAS and EAR. The NAR is not summarized in detail, as it is an earlier document and its content is substantively captured by the NAS and EAR.

1.2.3 NONBIOLOGICAL ORIGINS OF ORGANIC COMPOUNDS IN SPACE AND IN PLANETARY ENVIRONMENTS (NAS THEME 1, EAR RESEARCH TOPIC 2, AND NAR GOAL 3)

In order to understand how life can begin, it is essential to know what organic compounds might have been available and how they interacted within planetary environments. Any chemical syntheses occurring in the solid crust, hydrosphere, and atmosphere are likely to be key sources of relevant compounds. Interesting organic compounds also occur in interstellar clouds, which are birthplaces of planetary systems. Laboratory simulations of interstellar ices have demonstrated that key prebiotic molecules can be synthesized under conditions occurring in interstellar clouds, and such materials can contribute to nascent planetary systems. Many compounds relevant to biological processes occur in meteorites, interplanetary dust particles, and comets. Substantial inventories of organic matter probably were delivered to Earth during late accretion, providing feedstock for chemical evolution and early life. So, it is important to establish sources of prebiotic organic compounds and to understand their histories in

terms of the processes that occur on a newly formed planet. Investigations should include pan-spectral astronomical observations, sample return missions, laboratory studies of extraterrestrial materials, and realistic laboratory simulations of inaccessible cosmic environments.

1.2.3.1 NAS THEME 1: IDENTIFYING ABIOTIC SOURCES OF ORGANIC COMPOUNDS

Sources, activities, and fates of organic compounds on the prebiotic Earth. This topic addressed the relationships between monomers utilized by living organisms and prebiotically relevant molecules in a range of environments. Relevant aspects include identifying plausible sources of compounds consisting of the elements C, H, N, O, P, and S, as well as determining the properties, formation pathways, and parent environments of molecules that were utilized by the first life forms.

Role of the environment in the production of organic molecules. This topic addressed various conceivable nonbiological sources of organic matter in planetary environments. This includes the primary mechanisms for organic synthesis within planetary environments, the delivery of organics from space, the relative importance of these two sources, and the roles played by different energy sources in determining the nature of the organic matter produced.

Role of the environment on the stability and accumulation of organic molecules. The survival and modification of small organic molecules in various environments are also important. Key aspects of this include the role of processes in environments that host organic synthesis and the survivability of organics from various sources during delivery through a range of atmospheric compositions. It is also important to understand how enantiomeric excesses arose at the monomer level and what processes were important for determining biological chirality.

Constraints that the rock record places on the environments and abiotic reactions of the early Earth. Earth's earliest environments probably played crucial roles in shaping the course of prebiotic evolution. Therefore, the nature of Earth's early atmosphere, oceans, and crust should be determined. The bombardment history of Earth is probably an important aspect of this. Accordingly, the search for additional rocks of the Archean and older ages should continue in order to characterize early environments.

1.2.3.2 EAR RESEARCH TOPIC 2: ORIGINS OF ORGANIC COMPOUNDS IN SPACE

Understand the diversity and the complexity of abiotic organics. The EAR emphasizes the need to study the mechanisms for the formation of organics and their evolution under space conditions. It advocates

research to understand the role of catalysts associated with the formation of abiotic organic matter in a variety of environments.

Understand better the molecular evolution of abiotic organics present in solar system objects. Research should address the combined role of physical agents such as thermal variations, high-energy particles, photons, and solar wind irradiation. This effort should include organics on the early Earth.

Understand the role of spontaneous inorganic (organic) self-organization processes in molecular evolution. Investigations should identify and characterize self-organized inorganic and organic systems and determine their potential roles in the prebiotic synthesis of biomolecules.

1.2.4 ORIGIN AND EVOLUTION OF PLANETARY SYSTEMS AND HABITABLE ENVIRONMENTS (NAS THEME 6, EAR RESEARCH TOPICS 1 AND 4, AND NAR GOALS 1 AND 2)

A planet or planetary satellite is habitable if it sustains life that originates there or if it sustains life that is carried to it. The goal is to understand the most fundamental environmental requirements for an environment to be habitable. As currently envisioned, an environment must provide chemical building blocks (nutrients), extended regions of liquid water, energy sources to sustain metabolism, and conditions that favor the assembly and maintenance of complex organic molecules. A major long-range goal is to characterize habitable environments beyond the solar system, independent of the presence of life, or to recognize habitability by detecting the presence of life. Terrestrial planets and large satellites might form in a state where they are likely to become habitable. Alternatively, habitable environments might emerge only after a sequence of less probable events. How frequently do habitable environments arise on solid planets, including large satellites? What are the specific indicators of habitability and habitation, and how might such indicators differ between planets having different attributes (e.g., mass, distance from the star, history, and relative abundances of volatile compounds)?

1.2.4.1 NAS THEME 6: CONSTRUCTING HABITABLE WORLDS

Fundamental ingredients and processes of a planet that can define a habitable environment. These attributes include the following: 1) size of the planet; 2) inventory, distribution, and role of critical elements and minerals within the planet's interior: radiogenic nuclides, water, and the elements C, H, N, O, P, and S; 3) core formation (e.g., separation of Fe/H, Mg/Si, C/O, magnetic field, and siderophile element distributions); 4) geophysical evolution of the interior

(e.g., heat budget, rate and manner of mantle-surface exchange, redistribution of bio-relevant compounds, and energy sources); 5) energy from radiogenic, accretionary, tidal, differentiation, and chemical processes; 6) crustal processes and their evolution (e.g., volcanism, plate tectonics, erosion, sedimentation, geochemical reactions and cycles, and atmospheric effects); and 7) plausible energy sources for prebiotic processes.

Exogenic factors in the formation of a habitable planet.

These include the following: 1) initial inventory and distribution of volatiles and the mass and oxidation state of the protoplanetary disk; 2) disk processes (e.g., accretion, migration, and stellar activity); 3) properties of the host star; 4) time when the stellar environment permits the formation and preservation of stable environments (ocean, atmosphere, and shielding from solar radiation); 5) abundances of elements and molecules in the protoplanetary disk (e.g., Mg/Si ratio, C/O ratio, Fe/H ratio, and radiogenic isotopes); 6) dynamical environment of planets that are conducive to habitability (system architecture, obliquity, tidal and resonant effects, spin-orbit coupling, satellite systems, impactors, primary and late accretion, bombardment(s), and volatile delivery); 7) processing of water and organic molecules from interstellar clouds through disks to planet formation; 8) chemical evolution of protoplanetary disk interiors, including planet formation (traced by applying spectroscopic methods and identifying molecules); and 9) accretion of terrestrial planets (investigated by applying exoplanet census data to constrain accretion models).

Insights from Earth about general properties of habitability (and what aspects might be missing). Earth's rock record provides some clues about the conditions and processes present when life emerged (e.g., conditions and composition of oceans, atmosphere, and near-subsurface; redox state; abundance and diversity of life across various niches; and tectonic processes). The availability of bio-relevant compounds is influenced by processes associated with the (bio) geochemical cycles of elements that are key for life. These include processes that affected the composition of the atmosphere over time and the roles played by an intrinsic magnetic field in maintaining habitable conditions.

Processes on other types of planets that could create habitable niches. Relevant factors include the following: 1) how processes mimic those on Earth; 2) effects of very large or very sparse atmospheres; 3) the nature of hydrospheres on icy, water-rich, or water-poor planets; 4) processes of heat flow and mantle-crust exchange of materials; 5) effects of alternative styles of rock-atmosphere-ocean cycles; 6) potential reservoirs and processing of prebiotic, bio-relevant, or biological materials; 7) formation

of volatile-rich/potentially habitable moons orbiting giant planets; and 8) how to measure habitability indicators and quantify the relative uncertainties in the observations.

Changes in habitability through time. These include the following parameters: 1) volatile inventory in the aftermath of planet formation and formation-like impact events; 2) evolution and variation of the host star; 3) how long a favorable environment must persist to foster the emergence of life; 4) climate stability, internal heat budget, geochemical inventories and cycles, and tectonic regimes; 5) effects of climate stability, heat flows, chemical inventory, and tectonic regimes on the persistence of habitable environments; 6) effects of orbital dynamics over time (e.g., spin-orbit coupling, stabilization from satellites, changing semi-major axis, and eccentricity); and 7) movement of the host star through the galaxy.

1.2.4.2 EAR RESEARCH TOPIC 1: ORIGIN AND EVOLUTION OF PLANETARY SYSTEMS

The EAR identified objectives that are very similar to those advocated by the NAS.

Assess the elemental and chemical picture of protoplanetary stellar discs. 1) Understand the metallicity of stars; 2) improve chemical models of protoplanetary disc formation and evolution; 3) improve our understanding of the evolution of circumstellar discs, in relation to their host stars; 4) determine the chemical history of key molecules (such as water and oxygen) in the evolution from molecular clouds to star-planet(s) system; and 5) link chemical processes to disc hydrodynamics and structure.

Understand our solar system better: planet formation, dynamical evolution, and water/orgamics delivery to Earth and to the other planets/satellites. 1) Understand the transition from planetesimals to planets and satellites (end to end); 2) understand the dynamical evolution of the “young” solar system; 3) improve models of conditions for the survival and/or generation of essential molecules during impacts; 4) identify dynamical processes that can redistribute essential material throughout a system; 5) better understand the effects of post-formation bombardment episodes on Earth and other planetary bodies generally assumed to have been important for the development of life; 6) define the timeline of the formation of the solar system and water/organic delivery on Earth; and 7) interpret the temporal link between solar system evolution and the rise of life on Earth.

Understand better the diversity of exoplanetary systems and the development of habitable environments. 1) Understand the dynamical mechanisms that lead to the observed diversity of exoplanetary architecture,

and assess how they affect habitability; 2) identify biomarkers and promising methods of detection; and 3) determine how the study of exoplanets can help to fill the gaps in our understanding of the formation of our own solar system.

1.2.4.3 EAR RESEARCH TOPIC 4: LIFE AND HABITABILITY

The following aspects of this topic address the attributes and exploration of habitable environments: 1) Expand our knowledge of the diversity, adaptability, and boundary conditions of life on Earth. The quest to identify the ultimate boundaries of habitable environments starts with determining the ultimate environmental limits of life as we know it. This knowledge serves as a starting point for defining the fundamental attributes of habitable environments and how to identify them beyond Earth; and 2) assess the habitability of extraterrestrial environments. Mars, icy moons of Jupiter and Saturn, and exoplanets are key exploration targets.

1.2.5 ORIGINS OF LIFE (NAS THEME 2, EAR RESEARCH TOPIC 3, AND NAR GOAL 3)

The origin(s) of life on Earth likely represents one path among many, along which life might emerge. This view forms the foundation for pursuing observations and missions to search for extant or extinct life elsewhere in the universe. Astrobiologists must strive to understand the universal principles that underlie not only the origins of life on Earth but also its possible origins elsewhere. A starting point for identifying these principles is to determine the raw materials of life that can arise from chemical evolution in space and on planets ([Section 1.2.3](#)). Then, the mechanisms should be identified by which organic compounds are assembled into more complex molecular structures and how the functions of these structures are coordinated in order to form complex evolving systems that are such a key aspect of life. These systems must be able to perform and coordinate the capture of energy and nutrients from the environment, catalyze the chemical reactions that maintain and grow these systems, and synthesize copies of key biomolecules. Evidence both from biomolecular and fossil records and from diverse extant microorganisms should be explored for clues that can identify the fundamental properties of the living state.

1.2.5.1 NAS THEME 2: SYNTHESIS AND FUNCTION OF MACROMOLECULES IN THE ORIGIN OF LIFE

The following questions address paths that can lead to our DNA/RNA/protein-dominated world.

What is the chemistry of macromolecular formation reactions? The nature and sources of any chemical coupling agents, along with the sources of energy and pathways of energy utilization for enabling these agents, should be identified. It is important to understand how their stability and activity can be

maintained in aqueous environments, despite their probable chemical instability in water. The mechanisms whereby high effective concentrations of monomers can facilitate macromolecular formation should be identified. The potential role of noncovalent molecular assemblages in the formation of covalently bonded macromolecules merits attention.

How do information transmission and chemical evolution occur? Plausible chemical mechanisms for information transmission and mutation should be identified. This includes identifying molecules that can be replicated with errors, where the errors themselves are replicable. Perhaps, nontemplated production of informational macromolecules is possible. The physical parameters of pre-ribonucleic acids (RNAs) and preproteins that influence kinetics and the accuracy of replication should be investigated.

What are the chemical alternatives? How and why do they occur? If plausible alternative backbones and side chains exist for functional and informational macromolecules, their properties should be identified. Perhaps, homochirality arose either during monomer synthesis or during polymerization/assembly. The degree of homochirality that is necessary or optimal should be identified.

What is the role of the environment? Conceivably, the mechanisms of polymerization in modern biology (primarily condensation polymerization and aldol reactions) offer clues about the environment in which the polymers evolved. For example, perhaps, oligomerization was driven by cyclic conditions (e.g., water activity, temperature, tidal, and convection). Perhaps, nonaqueous solvents and environments (formamide, hydrocarbons, deep eutectic solvents, micelles, etc.) played key roles in condensation polymerization. Understanding how nonstandard solvents and environments (formamide, hydrocarbons, deep eutectic solvents, micelles, etc.) affect the activity of functional macromolecules might offer key insights.

Macromolecular function: how did physicochemical effects develop over time? The following key aspects merit particular attention: 1) roles that the solubility, solvation, and hydrophobicity of polymers play in the origin of function, 2) types of rudimentary functions that might promote polymer persistence, assembly, and growth, 3) folding properties of macromolecules that are sufficient for function to arise, 4) molecular properties (such as specific binding and catalysis) that are optimal for function, 5) other chemical linkages that exhibit the simultaneous thermodynamic instability and kinetic stability that characterize phosphate diesters.

What are the advanced steps of macromolecular function? The functions that are most likely to emerge early should be identified. Also relevant is the range of chemical functions, besides the ones that contemporary biology proteins and/or RNA could

accomplish. Regarding “alternative biochemistries,” the biological and protobiological functions of non-natural polymers should be explored.

What led to macromolecular complexity? Key aspects include the following: 1) how polypeptides and polynucleotides began to cooperate; 2) how the genetic code arose; and 3) the forces that selected for regulatory processes in the prebiotic world.

1.2.5.2 EAR RESEARCH TOPIC 3: ROCK-WATER-CARBON INTERACTIONS, ORGANIC SYNTHESIS ON EARTH, AND STEPS TO LIFE

The EAR emphasized understanding key aspects of the cosmic, geological, and geochemical processes that shaped prebiotic planetary environments. The following factors should be better characterized: 1) dynamic redox interactions of rock, water, and carbon in their geological context on planets and moons; 2) transition metals as electron sources and catalysts in geo-organic chemistry; 3) carbon reduction in modern serpentinizing hydrothermal vents; 4) hydrothermal modification of carbon delivered to Earth from space; and 5) role of molecular self-organization, higher-order organization, and cellular organization in the origin of life.

1.2.6 THE LIVING RECORD OF EVOLUTIONARY MECHANISMS AND THE ENVIRONMENTAL LIMITS OF LIFE (NAS THEME 3, EAR RESEARCH TOPIC 4, AND NAR GOAL 5)

Life, as we know it today, is an outcome of interactions between genetic opportunities, metabolic capabilities, and environmental changes. The metabolism and evolution of microorganisms have substantially influenced Earth’s habitable environments for most of their existence. Geological, climatologic, and microbial processes have interacted across geological timescales to change the physical-chemical environments on Earth that influenced the path of biological evolution. For example, fundamental environmental changes at the global scale were triggered by the production of molecular oxygen by cyanobacterial photosynthesis and by the colonization of Earth’s surface by metazoan life. These changes, in turn, created novel evolutionary opportunities for life, leading ultimately to the rise of extant plants and animals. The “co-evolution” of organisms and their environment has been an intrinsic feature of our biosphere.

1.2.6.1 NAS THEME 3: EARLY LIFE AND INCREASING COMPLEXITY

Theoretical considerations regarding the origin and dynamics of evolutionary processes in living systems. Theoretical work has highlighted the following perspectives that merit attention: 1) “Environmental

conditions and genetic context of a genotype can heavily influence its phenotype but their interactions are unclear and unpredictable but absolutely crucial for understanding evolution and the emergence of innovations”; 2) biology can innovate in myriad ways, but we do not yet understand how to manipulate or analyze this crucial capability; 3) interacting networks (e.g., molecular, genetic, epistasis, metabolism, and ecosystems) are central to life, but we know relatively little about their interactions; 4) theoreticians have extensively addressed evolutionary landscapes, but comparatively, little experimental work has been done because of technical difficulties; 5) how mechanisms of selection in evolution change as well as interact across increasing levels of biological complexity (e.g., biomolecules, individuals, communities, and ecosystems); 6) physical, chemical, and developmental constraints on selection in the evolution of developmental complexity (e.g., in multicellular life forms); 7) the extent to which “life [is] a generic outcome of the laws of physics, an inevitable planetary phenomenon if certain conditions of disequilibrium are met.”

Fundamental innovations in earliest life. This part of NAS Theme 3 addressed aspects of life’s origins that were also identified by Theme 2. For example, it is important to determine how the essential traits of life arise from the geochemical environment, which factors are considered essential for the most basic living systems, and what were the history and order of biological innovations associated with the emergence of life. The following paragraphs summarize topics that were not addressed by Theme 2.

Genomic, metabolic, and ecological attributes of life at the root of the evolutionary tree. This part explores several implications that arise from the observation that present-day organisms share several fundamental commonalities. This implies that life, as we know it, evolved from a “Last Universal Common Ancestor,” abbreviated as “LUCA.” These commonalities include cellularity and many of the genes, proteins, and biological functions shared by all modern lineages. Most likely, LUCA consisted of many different organisms or populations that readily exchanged their cellular attributes. Understanding such populations might help us understand fundamental aspects of life elsewhere in the universe. The following topics address the evolutionary history and ecological context of LUCA: 1) the amount of time and evolution that occurred between the origin of life and LUCA; 2) the possibility that genomic, proteomic, or metabolic attributes of LUCA might help to elucidate earlier stages of evolution; 3) whether LUCA represents a single individual, species, or population of species; 4) the roles played by horizontal gene

transfer in the development of LUCA; and 5) the selection factors that led from LUCA to develop discrete lineages and their evolution.

The LUCA concept also helps to highlight the following objectives: 1) identify the gene families that had evolved by the time of LUCA and the order in which these earliest functions emerged; 2) determine the metabolic networks associated with LUCA and how they might help to constrain the early geochemical environment; 3) determine the nature of early cellular membranes; 4) identify the genetic material of LUCA; and 5) determine the timing of LUCA with respect to the geological and geochemical records.

Dynamics of the subsequent evolution of life. Biological innovations have been mediated by changes in both their biological and physical environments; thus, it is useful to address both intrinsic and extrinsic drivers of evolutionary dynamics. Key intrinsic drivers that merit attention include the following: 1) the evolution of complexity (e.g., advent of chemotrophy, autotrophy, intracellular structure, regulation of internal conditions, and multicellularity); 2) energy acquisition in living systems; and 3) in particular, the origin and early evolution of phototrophy, especially oxygenic photosynthesis, which profoundly affected subsequent evolution and the global environment. Key extrinsic drivers influencing evolutionary dynamics include the following: 1) environmental gradients (temperature, moisture, redox potential, light spectra and intensity, nutrients, etc.) and how those gradients have developed through time; and 2) effects of environmental perturbations on extinctions, biodiversity, and innovations. Of course, many evolutionary events (e.g., the Cambrian “explosion”) probably reflect the combined effects of both intrinsic and extrinsic factors.

Common attributes of living systems on Earth. Key research questions include the following: 1) understanding the extent to which common attributes of life on Earth arise from common ancestry (homology) or indicate limited solutions to common problems (convergence); and 2) identifying those attributes common to all life on Earth that are likely to arise elsewhere in our solar system and beyond.

1.2.6.2 EAR RESEARCH TOPIC 4: LIFE AND HABITABILITY

This topic addressed the following key factors that were also identified by NAS Theme 3 (summarized earlier): 1) expand our knowledge of the diversity and adaptability of life on Earth; 2) explore the diversity of life on Earth; 3) explore biological interactions and systems ecology; and 4) expand our understanding of the general principles of life and habitability.

1.2.7 GEOLOGICAL RECORD OF THE EVOLUTION OF OUR BIOSPHERE (NAS THEME 4, EAR RESEARCH TOPIC 4, AND NAR GOAL 4)

Environmental changes have influenced biological evolution, which, in turn, has profoundly altered local and global environments over time. Life interacts with its environment on all spatial scales. Insights into the early evolution of life in a global context can emerge both by documenting the effects of microbial metabolism in the form of proxy geochemical records in ancient rocks and by interpreting the preserved biosignatures of microorganisms. Major transitions in the physical state of Earth that have influenced its biosphere included changes in volcanism, plate tectonics and continents, impacts, and climatic transitions and extremes such as global-scale glaciations. Major extinctions, which were triggered by geological and biological processes and by cosmic processes in some cases, also profoundly affected the evolution of the biosphere. An improved understanding of these interactions will enhance our efforts to detect and characterize any habitable environments and life beyond Earth.

1.2.7.1 NAS THEME 4: CO-EVOLUTION OF LIFE AND THE PHYSICAL ENVIRONMENT

Earth history can indicate how climates, atmospheric compositions, interiors, and biospheres can co-evolve.

Interactions between these components can be explored by addressing the following aspects: 1) how interactions between life and its environment affect Earth’s ability to retain habitability; 2) how processes in Earth’s interior and their surface manifestations have shaped habitable environments and how life has affected these physical processes; 3) how climate and atmospheric processes have shaped habitability and how life has affected these physical relationships; and 4) how studies of Earth’s deep history as well as numerical modeling can inform our understanding of future environmental changes.

Characterizing interactions between life and its local environment could inform our understanding of biological and geochemical co-evolutionary dynamics. This topic should be investigated as follows: 1) document how geochemical variations in space and time have affected biological diversity; 2) understand how ecosystems have been structured through time; 3) determine how changing patterns of life through time have impacted the environment; and 4) devise strategies for measuring the co-impacts of life and the environment.

Determining how our current ignorance about microbial life on Earth hinders our understanding of the limits of life. Objectives are as follows: 1) reduce biases associated with current methodologies and database limitations; 2) identify, to a greater extent,

the physiological characteristics of uncultured organisms; 3) link newly discovered genomes to the functional roles the microbes play in a community and/or environment; and 4) elucidate catabolic strategies that might be employed by organisms in largely unexplored environments.

1.2.7.2 EAR RESEARCH TOPIC 4: LIFE AND HABITABILITY

This research topic endorses the objectives identified by NAS Theme 4.

Expand our knowledge of the diversity, adaptability, and boundary conditions of life on Earth. Document more thoroughly the diversity of life on Earth in order “to improve our knowledge of the origin, diversity, and limits of life and the habitability of different environments on Earth and elsewhere.” Explore biological interactions and systems ecology. *Expand our understanding of the general principles of life and habitability.* Characterizing interactions within ecosystems in both extreme and nonextreme environments is essential for understanding the evolution and survival of life as a planetary phenomenon.

1.2.8 SIGNATURES OF HABITABLE ENVIRONMENTS AND LIFE IN THE SOLAR SYSTEM AND BEYOND (NAS THEME 5, EAR RESEARCH TOPIC 5, AND NAR GOAL 7)

The premise that habitable environments and biosignatures will be recognizable within their planetary contexts is a fundamental principle of astrobiology. Localities that exhibit evidence of past or present habitable environments are promising targets to search for biosignatures. A *biosignature* is an object, substance, and/or pattern whose origin specifically requires a biological agent. The usefulness of a biosignature is determined not only by the probability that life created it but also by the improbability that nonbiological processes produced it. For example, a biosignature can be a complex organic molecule and/or structure whose formation is unachievable in the absence of life. A *potential biosignature* is a feature that is consistent with biological processes and that compels investigators to examine it and its local environment more thoroughly in order to determine more conclusively the presence or absence of life. The EAR uses the term *bioindicator* when referring to a potential biosignature.

1.2.8.1 NAS THEME 5: IDENTIFYING, EXPLORING, AND CHARACTERIZING ENVIRONMENTS FOR HABITABILITY AND BIOSIGNATURES

Characterize habitability at different spatial scales. A variety of observable features of planets and planetary systems can help to assess habitability. Examples

of such features include the following: 1) the type and metallicity of the parent star(s); 2) the architecture of a planetary system; 3) planet size, mass, and composition; 4) the composition and structure of the atmosphere; 5) the nature, extent, and duration of water activity at regional and local scales and in the near-subsurface; and 6) evidence of temporal changes in surface and near-surface environments, including understanding how they form and evolve. A key objective is to develop instrumentation to characterize such features. Such efforts will be guided by a better understanding of the range of parameters that influence habitability. An enhanced ability to quantify the relative merits of planetary systems, individual planets, and potential landing sites will enhance our search for evidence of life elsewhere.

Enhance the utility of biosignatures to search for life in the solar system and beyond. Biosignatures include the following features that, ideally, are formed exclusively by biological processes: 1) Organic compounds having diagnostic molecular structures (e.g., porphyrins, steranes, and hopanoids); 2) other chemicals and their abundance patterns (e.g., consequences of metabolism, disequilibria, and biological redox reactions); 3) molecular stable isotopic abundance patterns (e.g., enzymatic isotopic discrimination during redox processes); 4) minerals (e.g., those whose stability is created by biological processes); 5) microscopic structures and textures (e.g., cells and biofilms); 6) macroscopic physical structures and textures (e.g., stromatolites); 7) atmospheric gases (e.g., molecular oxygen in certain global environments); 8) surface spectral reflectance features (e.g., arising from forest canopies); 9) temporal variability (e.g., chemical or spectral changes caused by active metabolism); and 10) technosignatures (e.g., radio signals created by technology). The following objectives seek to enhance the utility of biosignatures: 1) Characterize better the processes influencing biosignature formation, preservation, and destruction; 2) determine how the properties of habitable environments can affect the attributes of biosignatures and their detectability (i.e., identify any contextual information needed to enhance the confidence in the interpretation of biosignatures); 3) better define the fundamental characteristics of life (even as we do not know it) that may translate into biosignatures; 4) identify any potential abiotic mimics of biosignatures; and 5) identify new types of biosignatures and how they can be detected.

Identify habitable environments and search for life within the solar system. Some habitable environments on Earth offer opportunities to study extraterrestrial habitable environments by analogy. Extreme environments on Earth can reveal how environmental stresses influence the persistence and activity of life and can help us understand the potential for preserving biosignatures in such environments.

Mars and Earth might have hosted relatively similar environments, particularly in the distant past; therefore, Mars has become a prime exploration target for astrobiology. Efforts should continue to determine where, when, and for how long habitable conditions were maintained on the surface of early Mars and whether habitable environments exist on Mars today. This requires an improved understanding of the major processes that degrade or preserve evidence of habitable environments and biosignatures. These efforts enhance efforts to seek signs of life.

The icy worlds in our solar system present some of the clearest evidence beyond Earth for liquid water on a global scale. Future space missions should characterize the processes related to subsurface oceans. This includes determining the key energy sources that affect these water reservoirs and how they evolved over time. Observations should seek to document the roles that interior and/or atmospheric chemical processes play in the formation of prebiotic compounds on the icy worlds.

Recent discoveries of diverse planetary systems indicate that the search for habitable planets and any evidence life in deep space holds enormous potential. Astrobiologists can augment efforts by astronomers to observe and characterize potentially habitable exoplanets. They can help to identify the diversity of detectable biosignatures that might be expected for habitable exoplanets. This effort includes, for example, recognizing atmospheric biosignatures and distinguishing them from potential false positives.

1.2.8.2 EAR RESEARCH TOPIC 5: BIOSIGNATURES AS FACILITATING LIFE DETECTION

Distinguish life from nonlife. As with NAS 5, earlier, this objective seeks to identify and evaluate the various categories of biosignatures for their capacity to distinguish life from nonlife. Our knowledge of the environmental conditions conducive to the origin and persistence of life is required to characterize the context (“background noise”) against which we might detect the presence of any biosignatures. Measurements should be developed to achieve these objectives more effectively by remote observations and by landed spacecraft.

Follow the energy: Identify energy sources, redox couples, and photoreactions. This objective focuses on energy, both as a necessary resource in a habitable environment and as an approach to life detection. It addresses how life interacts with photochemical reactions and redox reactions and how biological activity might be identified as a component in such interactions. For example, biosignatures in

atmospheres might arise as redox pairs in a variety of environmental conditions on other planets.

Follow the data: Evaluate the potential for life in different planetary environments (from microscale to planets). This objective focuses on super-Earths—planets ranging in size up to 10 Earth masses—and asks how attributes such as plate tectonics, climate, photochemistry, and mineralogy might affect the development of life and the detection of any biosignatures in their atmospheres. The objective identifies super-Earths orbiting cooler stars (M dwarfs and K dwarfs) as key targets of exploration.

Follow biosignatures with time: Reach a better understanding of the evolution and preservation of bio-signature assemblages with time. The various categories of biosignatures differ regarding the potential for their preservation under a range of environmental and geological conditions. Important examples include the following: 1) Remote detection of atmospheric biosignatures depends upon their survival against photochemical destruction, etc.; 2) preservation of biosignatures in the rock record depends upon their preservation against destruction by oxidation, radiation, temperature, and pressure; and 3) attributes of planetary environments probably influence the nature of life that might develop there and the categories of biosignatures that life creates.

1.2.9 ASTROBIOLOGY AT NASA

Funding agencies and their associated scientific communities have shaped the scope, operating principles, and current priorities of astrobiology research and exploration. [Sections 1.2.9](#) and [1.2.10](#) address this topic for the astrobiology communities in the U.S. and Europe, respectively.

NASA is the lead agency for supporting astrobiology-related research and flight missions in the U.S. The agency works closely with other organizations in the U.S. Government; it also collaborates with other nations that support planetary exploration and astronomy.

The NAS advocates the roles played by astrobiology in spaceflight missions; it also articulates several operating principles of astrobiology.

1.2.9.1 SPACEFLIGHT MISSIONS

Mars. During its history, the climate of Mars has been more similar to that of Earth than has the climate of any other planet in our solar system. This similarity and the proximity of Mars make it a principal focus for astrobiology. Characterizing any habitable environments and life on Mars has become a key goal of NASA’s Mars Exploration Program (MEPAG, 2015). For example, the two Mars Exploration Rovers, the Curiosity rover, and the MAVEN orbiter have gathered evidence to

determine past and present environmental conditions. NASA's "Mars 2020" rover will extend these efforts and also carefully select samples that will ultimately be returned to Earth to search for evidence of past life. NASA-sponsored astrobiology research supports these missions by quantifying the qualities of environments that enhance their habitability, by elucidating the variety and attributes of biosignatures that make them definitive signs of life and by understanding the environments and processes that favor preservation of biosignatures.

Icy worlds in our solar system. Discoveries by recent missions of subsurface liquid water on Jupiter's moons and icy plumes and organic matter on the Saturn's moons indicate that these bodies might harbor habitable environments. Astrobiology has become a key driver for future missions to these bodies. As with Mars, astrobiology research can help to characterize any evidence for habitable environments and biosignatures while taking into account the factors that could affect their preservation. Astrobiologists are participating in the planned mission to Europa and are formulating mission concepts for missions to the moons of Saturn.

Exoplanets. Exoplanets orbit stars other than our own. The discovery that exoplanets are common and diverse indicates that Earth-like habitable worlds might be observed directly. This would enable a far more comprehensive search for distant life. But characterizing the climates of newly discovered promising planets remains far more challenging than their discovery. Astrobiologists must collaborate with astronomers to develop instrumentation and numerical models to characterize the geological processes and atmospheres of these distant worlds.

1.2.9.2 ASTROBIOLOGY PRINCIPLES

In addition to articulating key Themes and Goals, the NAS and NAR explicitly stated the following key attributes of astrobiology that distinguish it from more traditional scientific disciplines. The EAR articulates a vision that is fully consistent with these attributes.

Interdisciplinary research and exploration. "Astrobiology is multidisciplinary in its content and interdisciplinary in its execution. Its success depends critically upon the close coordination of diverse scientific disciplines and programs, including space missions."

Stewardship. "Astrobiology encourages planetary stewardship through an emphasis on protection against forward and back biological contamination and recognition of ethical issues associated with exploration."

Societal engagement. "Astrobiology recognizes a broad societal interest in its endeavors, especially in areas such as achieving a deeper understanding of life, searching for extraterrestrial biospheres, assessing

the societal implications of discovering other examples of life, and envisioning the future of life on Earth and in space."

Inspire future generations. "The intrinsic public interest in astrobiology offers a crucial opportunity to educate and inspire the next generation of scientists, technologists, and informed citizens; thus, a strong emphasis upon education and public outreach is essential."

1.2.9.3 HUMANITIES AND SOCIAL SCIENCES

The above principles illustrate how astrobiology extends beyond the natural sciences. The humanities and social sciences can also make meaningful contributions to the field. The NAS provides the following examples of such contributions: 1) Epistemology might help to identify comparative standards of evidence in astrobiology-related fields and to address the challenge of envisioning a meaningful definition of life. 2) The social sciences can help to understand the basis of the public's interest in, and support for, astrobiology. 3) The legal profession can help to address the costs and benefits of planetary protection protocols as well as the legal implications of major discoveries in astrobiology. 4) Professional educators are exploring strategies whereby astrobiology can enhance skills in creative and critical thinking, cross-disciplinary awareness, and science, technology, engineering, and mathematics (STEM), from K-12 through postgraduate educational levels.

1.2.10 ASTROBIOLOGY IN EUROPE

The EAR advocates principles and mission objectives similar to those summarized earlier for the NAS. But, of course, there are qualitative differences between Europe and ESA versus the U.S. and NASA. It is essential that research and exploration efforts are coordinated not only across scientific disciplines but also across international boundaries.

1.2.10.1 BIOTECHNOLOGY

Astrobiological investigations of extremophiles and the origins and evolution of life on Earth are relevant to research in medicine, biotechnology, and industry. Methodologies developed in these other fields can, in turn, be applied to astrobiology.

1.2.10.2 A PAN-EUROPEAN PLATFORM FOR ASTROBIOLOGY RESEARCH

Space science in Europe has traditionally been strong and has maintained parity with space-faring countries outside of Europe. However, particular areas need improvement. The following objectives of a proposed "pan-European astrobiology platform" are quoted directly from the EAR:

- "Encourage and capitalize on multidisciplinary research and projects that include diverse space sciences and/or Earth science disciplines;

- Allow a rational, possibly prioritized, access to relevant research infrastructures and equipment, possibly through development of specific networks;
- Allow the implementation of (and mobilize around) a prioritized research plan, taking into consideration the strengths and expertise available in different countries and allowing them to be further improved and shared;
- Provide a platform for the management, access, and archiving of relevant scientific data;
- Facilitate the design and development of new techniques and technologies;
- Provide stable funding and support allowing scientific objectives to be addressed in the medium to long term;
- Catalyze and facilitate undergraduate and graduate education and help with the development of PhD programs and postdoctoral opportunities;
- Facilitate exchange of scientific and technical staff;
- Represent a European anchor for international relations; and
- Represent a focal point for coherent public outreach and engagement.”

The pan-European astrobiology platform also should embody the following attributes:

- “Be science-driven with a strong representation of the community in its governance.
- Evolve organically, starting with pilot initiatives such as a network of institutes and laboratories, a framework for PhD students/postdoc exchange, a framework for the use of infrastructures and access to field sites dedicated to collaborative projects, and eventually grow towards a more institutionalized structure, using the experience gained through pilots.
- Be flexible and able to adapt to the European and international landscape as well as evolving priorities and breakthrough discoveries.
- Be decentralized as much as possible to reap the benefits of European diversity without involving a heavy administrative burden and overhead costs.

- Be, as much as possible, in a position to provide end-to-end funding with a common (set of) scheme(s) to avoid the complication of various funding procedures and principles.”

1.2.11 ASTROBIOLOGY ROADMAPS AND STRATEGIES ARE LIVING DOCUMENTS

What is a ‘living document?’ Evolution is an essential attribute of life; it must also be an essential aspect of astrobiology roadmaps and strategic plans. U.S. President Eisenhower quoted the following words of military wisdom: “Plans are worthless, but planning is everything. The very definition of ‘emergency’ is that it is unexpected, therefore it is not going to happen the way you are planning.” The same perspective applies to research and exploration—we cannot predict scientific discoveries and other relevant developments. Yet, insightful roadmaps and strategic plans can enhance the likelihood of discoveries that will, in turn, drive the ongoing evolution of our science and our strategies and roadmaps.

1.3.1 INTRODUCTION

The clearest way into the Universe is through a forest wilderness.

—John Muir, 1890 (Wolfe 1966)

The search for life throughout the cosmos originates from the most basic of human desires: to understand the universe within and around us. That quest lies at the heart of the imagination

and spirit of the NASA Astrobiology Institute (NAI). A highly interdisciplinary organization dedicated to interstellar science, the NAI seeks to answer three fundamental questions (Des Marais et al. 2008):

- How does life begin and evolve?
- Does life exist elsewhere in the universe?
- What is the future of life on Earth and beyond?

Founded in 1997, the NAI is designed to produce transformative research that: (1) infuses astrobiology science into ongoing and future NASA missions; (2) nurtures a coherent and interactive astrobiology research community; and (3) establishes dynamic, long-lasting Education and Public Outreach (EPO) programs that connect the public with the latest astrobiology scientific discoveries (Hays et al. 2015; National Research Council 2018; NASA Astrobiology Institute 2018).

A recent NAI program, *Towards a Universal Biology: Constraints from Early and Continuing Evolutionary Dynamics of Life on Earth*, was awarded in 2012 to a consortium led by the University of Illinois Urbana-Champaign that included Baylor University College of Medicine and the University of California, Davis (*Illinois-Baylor-Davis NAI*). The program was housed in, and orchestrated from, the Carl R. Woese Institute for Genomic Biology (IGB) on the University of Illinois Urbana-Champaign campus. The Carl R. Woese IGB opened the 186,000 sq. ft. open floor plan in Spring 2007, with the explicit intent of serving as a dynamic platform for cross-disciplinary genome-enabled research and education. The Illinois-Baylor-Davis NAI initiative has addressed multiple goals of the NASA Astrobiology Roadmap (Des Marais et al. 2008), including *Biochemical Adaptation to Extreme Environments* and *Biosignatures to be sought in Solar System Materials*. Major evolutionary transitions through geological time that occur in living matter, act to constrain the diversity of life, and govern the way in which energy and information are utilized by life have been studied. A unifying theme in these projects derives from NASA-sponsored research of the late Professor Carl R. Woese at the University of Illinois. As the first scientist to identify the Archaea, Woese established a three-domain Tree of Life, providing our first insights into the emergence of the Last Universal Common Ancestor (LUCA; Woese and Fox 1977; Woese et al. 1990). Of special importance to NASA missions, this Tree of Life is a fundamental framework for deciphering how life has evolved on Earth. The Tree of Life informs the search for extraterrestrial life forms, as well as their classification, as interplanetary explorations unfold.

The Illinois-Baylor-Davis NAI team has implemented an ambitious EPO effort for the rapid distribution of astrobiology research results. At the outset, the team identified and addressed learning challenges that impede understanding in scientific disciplines and targeted specific diverse demographic audiences by using multifaceted methods of content delivery to reach learners of all ages from around the world. These initiatives have been dedicated to the inclusion of new and challenging interdisciplinary scientific and cultural astrobiology content from active NAI research. Simply put, the goal has been to bring this work to learners around the world on their own terms. With that purpose in mind, dynamic delivery approaches were chosen for effectiveness in a wide variety of global learning environments. The resultant Illinois-Baylor-Davis NAI EPO program, which has already achieved considerable scope and scale, provides valuable insight for developing future astrobiology outreach initiatives that emphasize lifelong learning and global engagement.

This review highlights the accomplishments of the Illinois-Baylor-Davis NAI EPO, which has engaged more than 100,000 students of all ages from around the world via integrated online, classroom, and wilderness learning opportunities. These efforts have included the development and ongoing offering of: (1) a *Hybrid Textbook*, integrating the basics of astrobiology science with nature photography in Yellowstone National Park, with 6,000 hardcopies and more than 10,000 eBook versions distributed worldwide at no cost; (2) an *Open Educational Resources and Global Outreach*, providing a series of short two-minute videos called *SciFlix* and a free Massive Open Online Course (MOOC) on the Coursera platform that has enrolled 50,000 students internationally; (3) *Higher Education*: learning experiences for thousands of students on the University of Illinois campus, including an accredited 3-credit-hour course in the university's Campus Honors Program, with a capstone field experience in Yellowstone National Park; an accredited 3-credit-hour classroom and laboratory Campus Honors Program course that has already served more than 500 students of the University of Illinois; and special outreach to underrepresented communities on the University of Illinois campus; (4) a *Youth Outreach* program that has served an additional thousands of students annually, with the help of classroom and laboratory lectures, laboratories, workshops, and camps, which included a Research Outreach Carbonate Hot-Spring Simulation (ROCHSS) laboratory teaching apparatus, Scholar-Athlete "Sports in Space" Summer Camps, and a 4-H Academy Summer Camp; (5) *Teaching Teachers*: workshops and field trips for a Student-Teacher-Scientist Partnership (STSP) program; (6) *Teaching in the Wild*: a series of outdoor astrobiology lectures and nature hikes taught in Yellowstone National Park in collaboration with the National Park Service (NPS), as well as Emergence of Life displays for exhibit at the Field Museum of Natural History in Chicago, Illinois; (7) *Public Policy and International Engagement*: a 2012 course with 38 undergraduate students that studied arctic climate change in Stockholm, Sweden, and Svalbard, Norway; and (8) *Lifelong Learning*: a blended course through the Osher Lifelong Learning Institute (OLLI) on the University of Illinois campus that to date has engaged more than 300 learners 50 years of age or older, in addition to lifelong learner wilderness courses with the Yellowstone Forever Institute (YFI).

1.3.2 HYBRID TEXTBOOK

A hybrid textbook, *The Art of Yellowstone Science: Mammoth Hot Springs as a Window on the Universe*, has been written for use in both formal and informal educational settings by science and non-science secondary and higher education students, lifelong learners, and visitors of all ages to Yellowstone National Park. Available in both hardcopy and eBook formats, *The Art of Yellowstone Science* (Fouke and Murphy 2016; **Figure 1.3.1**), is unique in its focus on the geological and biological history of the region; moreover, as a textbook, it is outstanding for the quality and abundance of its nature photography and instructional illustrations. A supplementary

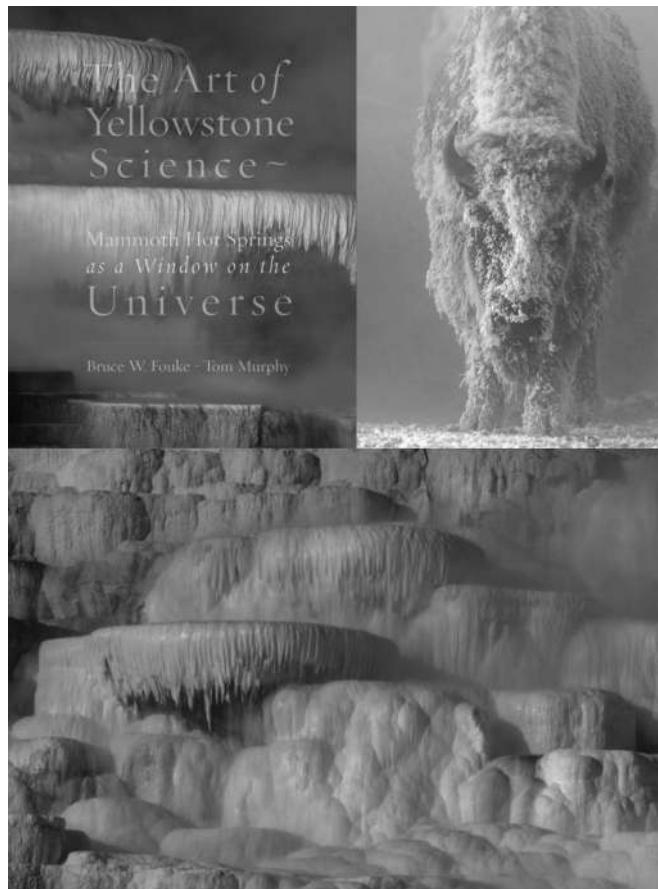

FIGURE 1.3.1 (Top left) Cover of the *The Art of Yellowstone Science* (From Fouke, B.W. and Murphy, T., *The Art of Yellowstone Science: Mammoth Hot Springs as a Window on the Universe*, Crystal Creek Press, 2016.) written to complement and support the Illinois-Baylor-Davis NAI EPO activities. (Top right) Field photograph by of a frosted bison when the air temperature was -37°C . (Bottom) Travertine terraces at Mammoth Hot Springs. Photographs by Tom Murphy.

interactive website, with additional teaching materials, lesson plans, and interactive exercises, is openly available on the University of Illinois servers (Fouke 2016). More than 6,000 hard copies and 10,000 eBooks copies have been distributed at no cost to middle schools and high schools around the world. Hard copies have been provided to science teachers and libraries of hundreds of collaborating secondary schools, colleges, and universities across the nation and internationally. A lecture series, underway at museums, public, libraries, civic organizations, and universities nationally and internationally, has reached thousands of attendees.

The Art of Yellowstone Science showcases how fundamental understandings of the Earth's biosphere are rapidly changing, propelled by analyses of DNA, RNA, proteins, and other life molecules in a variety of natural and manmade environments. Microorganisms, essential to the healthy functioning and evolution of all living things, are proving critical to solving global challenges in everything from environmental sustainability, human medicine, food security, and energy generation to the search for life elsewhere in the universe. These insights

are presented to showcase the elegant interconnectedness of life and the contextual history of an ever-changing Earth. This narrative requires an integration of many fields of study in the sciences and humanities, and *The Art of Yellowstone Science* demonstrates how both visual art and science originate from the same human desire to understand the world in which we live. Photographic art is melded with natural sciences to emphasize the importance of observation and the need for a willingness to embrace the unexpected. Because biological evolution is the ultimate expression of integrated life and Earth processes, Mammoth Hot Springs is studied as a window on the universe.

Co-authors Bruce Fouke and Tom Murphy first met at Mammoth Hot Springs in the winter of 2008, when NPS rangers requested a photographic record of the fieldwork being done there, for use in educational displays at the then-new Old Faithful Visitor Center. From this encounter began an extraordinary collaboration founded on a passion for the wilderness. *The Art of Yellowstone Science* contains 260 field and laboratory photographs that were shot over the course of 60 years. Fouke contributes his 30 years of integrated scientific research and teaching that focuses on hot springs, coral reefs, subsurface hydrocarbons, Roman aqueducts, human kidney stones, and astrobiology, bringing thousands of students into the field around the world. Murphy contributes three decades of nature photography and wilderness insights. In residence near Yellowstone since 1975, Murphy established Wilderness Photography Expeditions in 1986 and has built an internationally renowned photography seminar company, teaching natural history photography in Yellowstone and other locales around the globe.

The Art of Yellowstone Science is composed of seven chapters with the following content:

Chapter 1 Wilderness Laboratory: It explains why Mammoth is such an extraordinary site for artistic inspiration and scientific inquiry.

Chapter 2 Perspectives: It considers the basic approaches required to complete astrobiology science in complex natural environments.

Chapter 3 Dynamics: It delves into the details of water-microbe-mineral interactions at Mammoth Hot Springs in Yellowstone National Park.

Chapter 4 Emergence of Life: It explains the work of Carl Woese, his development of the three-domain Tree of Life, and its scientific implications.

Chapter 5 Deep Time: It reviews major epochs that have shaped life and Earth interactions.

Chapter 6 Human History: It reviews the westward expansion of the United States and events leading to the founding and scientific analyses of Yellowstone National Park.

Chapter 7 Worldwide Laboratory: It explains how results from research on the natural laboratory of Mammoth Hot Springs provide a window for understanding natural processes around the world and throughout the universe.

The Art of Yellowstone Science relates how Mammoth Hot Springs has long served as a natural laboratory for astrobiology research that investigates how microbes form fossilized “biomarkers” in ancient calcium carbonate (CaCO_3) limestone (*travertine*) rock deposits. Similar to conditions found on Earth hundreds of millions of years ago, the water temperature, chemistry, and flow at Mammoth still support heat-loving (thermophilic) microbes that evolved in the earliest periods of life on Earth. Requiring a combination of field and laboratory experimentation, this research has expanded into practical applications: coral reef preservation, oil and gas exploration, the functioning of the Roman aqueducts, and human kidney stone disease. The overarching goal is to understand the unifying physical, chemical, and biological themes of biomineralization in a natural system like Mammoth on every level, from the single microbial cell to the entire ecosystem, and how these components and dimensions interact. After decades of investigation, Mammoth is beginning to reveal how it came into existence, how its vitality and scope can best be conserved, and how its secrets contribute to the well-being of humanity. *The Art of Yellowstone Science* emphasizes that the time is now for curious, inquisitive, caring, and good-hearted people to come together from all fields and sectors of science, art, and society to preserve nature and wilderness. Ordinary citizens everywhere, enticed by direct experience with natural settings or moved by photographs and paintings of the world around us, must join the quest to better understand Earth. For our survival on this water-rich planet, we must know much more about how physical, chemical, and biological components of natural systems have evolved to work together and to incorporate that knowledge into our everyday life.

1.3.3 OPEN EDUCATIONAL RESOURCES AND GLOBAL OUTREACH

1.3.3.1 SciFlix

A critical need exists to reduce the time lag between scientific discovery in university, government, and industry research centers and to disseminate that knowledge to formal and informal learning environments around the world. Illinois-Baylor-Davis NAI EPO program activities have been designed to reduce this delay. One effective approach has been the creation of a series of *SciFlix*, free 2-minute videos developed in collaboration with the Illinois Center for Innovation in Teaching and Learning (CITL) group. The *SciFlix* series targets secondary and higher education teachers and their students, as well as lifelong learners, to deliver clear, concise summaries of key advances in astrobiology science. For ease of access, these videos have been made available on YouTube. Because each *SciFlix* video and its supporting curriculum materials made available online have been designed to augment state and federal K-12 curriculum requirements in the natural sciences, decisions about the use of *SciFlix* reside with teachers, who can include these short-duration videos into lesson plans as they see fit. These resources are also further supported with free 1-day workshops to encourage teacher adoption. The *SciFlix* series also integrates with other federally funded educational programs

such as the Global Learning and Observations to Benefit the Environment (GLOBE) program, Project WILD (conserving wildlife through education), the Worldwide Water Education (WET) program, and other initiatives commissioned by the National Academy of Science (NAS), the National Research Council (NRC), the National Science Teachers Association (NSTA), and a variety of non-governmental agencies.

1.3.3.2 EMERGENCE OF LIFE MASSIVE OPEN ONLINE COURSE

An *Emergence of Life* Massive Open Online Course (EoL MOOC) was developed, filmed, and produced over a 2-year period in collaboration with the staff of the Illinois CITL and has been offered on the Coursera platform since 2015 (Fouke 2015). Summarizing and updating the research of Carl R. Woese that established the three-domain Tree of Life, this no-tuition course delves into the implications of the Tree of Life for NASA astrobiology missions while exploring evolutionary history. Interviews with Woese, in which he explains how he approached and accomplished his scientific discoveries (Figure 1.3.2), are complemented with interviews of several of his renowned contemporaries and protégés in the fields of astrobiology, molecular microbiology, and evolutionary biology.

The target audience of the EoL MOOC are learners of all ages and incentives from around the world. More than 50,000 participants representing 160 countries have enrolled to date, of which approximately 25% finished the entire course.

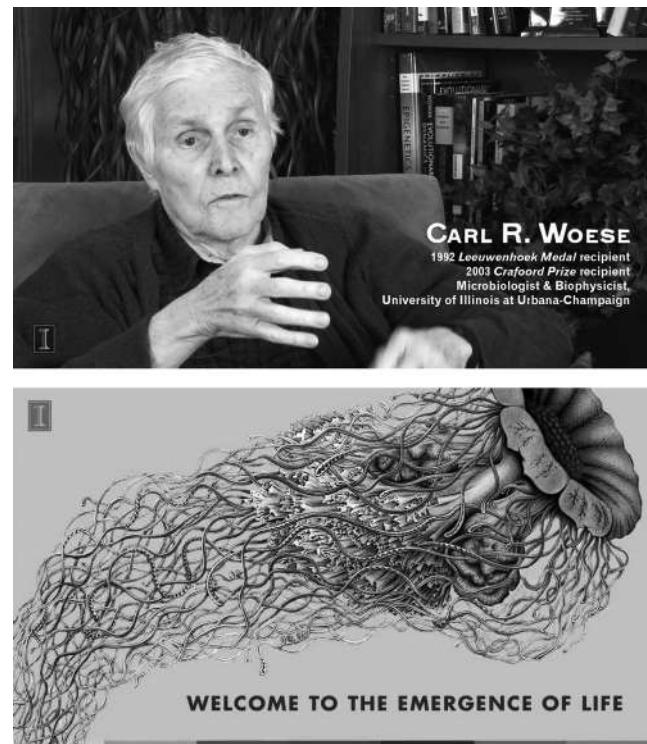

FIGURE 1.3.2 (Top) Interview with Professor Carl R. Woese in the *Emergence of Life* Massive Open Online Course. (Bottom) Website home page for the GEOL 111 *Emergence of Life* course. Filming and production by Colleen Cook and the CITL staff.

Participants include middle and high school students, college and graduate students, postgraduate students, professionals, lifelong learners, and teachers, who receive continuing professional development units (CPDUs) for completing the course. There are two examples of the project's global impact: in 2015, Fouke was completing research SCUBA on a coral reef off the coast of Na Trang, Vietnam. When he returned to shore at the end of a dive, he encountered a group of local high school students, two of whom had completed the EoL MOOC. Greeting Fouke by name, they asked him detailed questions about the Tree of Life as he emerged from the water. In another instance: via the EoL MOOC website, a single mother of five children, living in Dehradun, India, has engaged in regular weekly discussions about the Tree of Life with a retired petroleum geologist living in Tampa, Florida.

Though the EoL MOOC was initially offered with fixed start and end dates, after 1 year, it was transitioned into a constantly available "On Demand" format. Comprehensive teaching assessments were completed by the University of Illinois CITL staff. The 8-week EoL MOOC is composed of 80 video lectures, each approximately 4 to 7 minutes in duration, which cover the following topics:

- Week 1: *Geological Time, the Nature of Science and the Early Earth*
- Week 2: *The Tree of Life and Early Earth Environments*
- Week 3: *Fossilization and Precambrian Life-Earth Interaction*
- Week 4: *Paleozoic Life after the Advent of Skeletons*
- Week 5: *Paleozoic Plants, Reptiles and the Transition to Land*
- Week 6: *Mesozoic Reign of Dinosaurs and the Development of Flight*
- Week 7: *Cenozoic Mammals and Global Environmental Change*
- Week 8: *Astrobiology and the Search for Life in the Cosmos*

1.3.4 HIGHER EDUCATION

1.3.4.1 GEOL 111 EMERGENCE OF LIFE

An 8-week version of the EoL MOOC, Geology 111 *Emergence of Life* (GEOL 111 EoL), with significantly expanded content and requirements, was adopted in 2015 as a formal full-tuition 3-hour course in the University of Illinois Department of Geology (GEOL) through the College of Liberal Arts and Sciences. The target audience is formally enrolled science and non-science undergraduate students from disciplines across the University of Illinois campus. The course is offered in each spring semester and has an enrollment of 250 students. In 2016, GEOL 111 EoL became the first online course to be accredited as a General Education fulfillment. GEOL 111 EoL significantly expands beyond the composition and structure of the EoL MOOC and is intended to appeal to students from a wide variety of disciplines. This includes those taking GEOL 111 EoL for general education credit as well as those taking

it as majors in the natural sciences, who take the course to broaden their background in earth system science and evolution. The course also makes full use of multiple asynchronous and synchronous methods of communication with the instructor and graduate student teaching assistants. In addition, the contributions of women and minorities who have worked on the origin and evolution of life are included and emphasized (e.g., the critically important yet overlooked accomplishments in x-ray diffraction analyses of DNA by Rosalind Franklin in the laboratory of Crick and Watson). GEOL 111 EoL also includes extended video recordings of instructor presentations, guest lectures, and virtual field trips to the coral reefs of Curaçao in the Caribbean, the hot springs of Yellowstone National Park, the dinosaur fossils of the Field Museum in Chicago, and an animated trip to Mars. In addition to learning from the instructor and teaching assistants through regular discussion forums, students are expected to learn from each other through peer-reviewed essays and reflections.

1.3.4.2 ILLINOIS CAMPUS HONORS PROGRAM

A formally accredited astrobiology and geobiology course has been offered for each year of the Illinois-Baylor-Davis NAI EPO program. *Yellowstone Biocomplexity*, a 3-hour credit seminar for advanced undergraduate students of all majors in the Illinois Campus Honors Program, has filled to capacity every offering, achieving a total enrollment to date of almost 100. The centerpiece of the course is to study about feedback interactions among thermophilic (heat-loving) microbes, extreme water conditions, and rapid mineral precipitation in terrestrial and marine hot springs around the world. Studies of the modern-day ecosystems are evaluated as a means to better interpret the ancient fossil record of microbes on Earth while aiding the search for life on other planets. The semester-long Illinois campus-based portion of each semester includes an extensive essay-based midterm examination and an oral presentation-based final examination. The seminar culminates with fieldwork on these astrobiology dynamics and interactions at the hot springs at Mammoth. Students work in groups of four to develop an experiment to be conducted from the boardwalks at Mammoth, using infrared thermometers and cell phone cameras. Resulting data is used to test meaningful astrobiology-relevant hypotheses, which the students then orally present and defend 1 week after their return to campus. These students have completed their work even under challenging field conditions (low temperatures and heavy snow), requiring them at times to conduct their research on skis and snowshoes.

Mammoth Hot Springs is a unique federally protected natural laboratory for these types of courses, which are offered under strictly controlled NPS educational permits. Mammoth contains a high diversity of microbial communities and travertine deposits that are systematically distributed along the outflow drainage channels of each hot-spring system (Fouke 2011). Students focus on tracking ways in which the environment influences and controls microbial life and, in turn, ways in which microbial life rises to influence and alter the environment. Students

are also exposed to system-scale dynamics and learn how linked carbonate-microbe systems grow, retreat, and change across large spatial and temporal scales. Gaining first-hand experience with four basic parameters within the Mammoth geo-ecosystem, students have learned to quantify, contextually integrate, track, and predict key mineral-water-microbe interactions. These include (1) spring water temperature; (2) spring water pH; (3) hot-spring water flow rate and dynamics; and (4) all basic contextual observations of the substrates flooring the drain outflow systems (i.e., travertine and microbial mat color, shape, size, growth rates, and distance along the drainage system, away from the vent). Concepts behind these basic modeling approaches to parameters are applicable to other sciences and can be translated to a broad range of grade levels. Several students have continued their Mammoth project as directed research in future semesters, contributed as co-authors to publications, and eventually joined the Fouke laboratory to complete their graduate degrees.

1.3.5 YOUTH OUTREACH

The current focus in the United States on standardized testing in secondary schools has produced unintended consequences observable in undergraduate populations of 4-year universities across the country. Professors and researchers in the sciences are concerned about a decline of critical thinking skills and curiosity, both of which are essential to scientific inquiry. At the same time, public secondary schools face constricted budgets, preventing teachers from enriching their curricula beyond state and national requirements. To address these

issues directly, the Illinois-Baylor-Davis NAI EPO has developed a series of in-person classroom, laboratory, and field lectures, as well as summer workshops and camps, which have been presented to thousands of secondary education-level students. These teaching efforts, focused on the core astrobiology principles included in the EoL online courses and textbook, have been presented in secondary schools in the United States (Illinois, Wyoming, Idaho, Montana, California, and Washington, D.C.), Europe (Sweden, The Netherlands, and Italy), and Asia (Vietnam).

In this outreach, emphasis falls on five cornerstone illustrations from *The Art of Yellowstone Science* textbook (Fouke and Murphy 2016). These have proven effective in teaching cutting-edge astrobiology scientific principles and approaches that nurture curiosity and interest in students. The science content of these illustrations is also aligned with the Next Generation Science Standards (NGSS) (2018) in a variety of subject areas, including biology, chemistry, physics, and geology. These connections and free downloadable teaching materials are available online. The five illustrations receiving special emphasis include (1) *Tree of Life* (Figure 1.3.3), integrating geological time, specific geological events, the Tree of Life, and the origin of life in deep seafloor spreading centers; (2) *Tree of Life Comparisons* (Figure 1.3.4), illustrating the difference between the Woese three-domain Tree of Life and other constructs, now outmoded, that still appear in textbooks; (3) *Powers of 10* (Figure 1.3.5), an organizational principle relating examples from the Yellowstone ecosystem to immense hierarchical dimensions of space and time evaluated in astrobiology scientific studies; (4) *Scientific Inquiry* (Figure 1.3.6), graphically representing the

Scientific Method as an endless spiraling process of inquiry and discovery; and (5) *Deep Geological Time* (Figure 1.3.7), coalescing the deep geological time into a handful of select ages, time intervals, and historical events.

1.3.5.1 RESEARCH OUTREACH CARBONATE HOT-SPRING SIMULATION

An experimental laboratory apparatus, constructed at the University of Illinois IGB, permits real-time, in-person, and online teaching of hot-spring astrobiology principles to secondary and higher education students. Named the *Research Outreach Carbonate Hot-Spring Simulation* (ROCHSS), this experiment simulates Mammoth Hot Springs in Yellowstone National Park by continuously heating and transporting 1,200 L of mineral- and CO₂-charged water along a 1-m-long precipitation runway (Figure 1.3.8). This apparatus allows students to manipulate and track a basic suite of physical, chemical, and biological parameters (i.e., temperature, flow rate, microbial composition, and water chemistry), using remote-controlled probes and video cameras. Students are therefore able to test directly astrobiology-relevant hypotheses pertinent to understanding the formation of biosignatures in the rock record on Earth, with likely relevance to other planets. The ROCHSS is designed to (1) expose 6–12 students and educators to university-level interdisciplinary scientific research applicable to a variety of middle and high school subject areas; (2) allow 6–12 students and educators to directly interact with university faculty, staff, and students; and (3) develop a sustainable experimental platform that can be used for both teaching and research.

The ROCHSS water begins in a pressurized mixing tank (Figure 1.3.8). Here, carbon dioxide (CO₂), CaCO₃, sodium chloride (NaCl), and other minerals and salts are dissolved

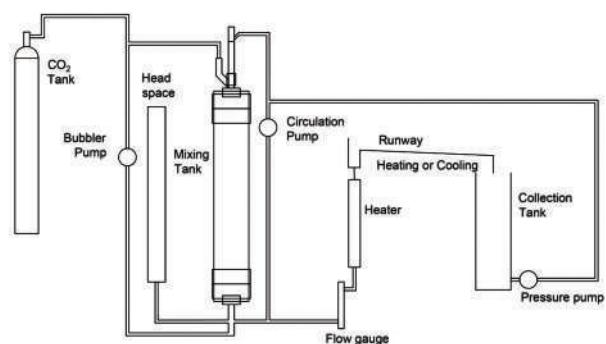

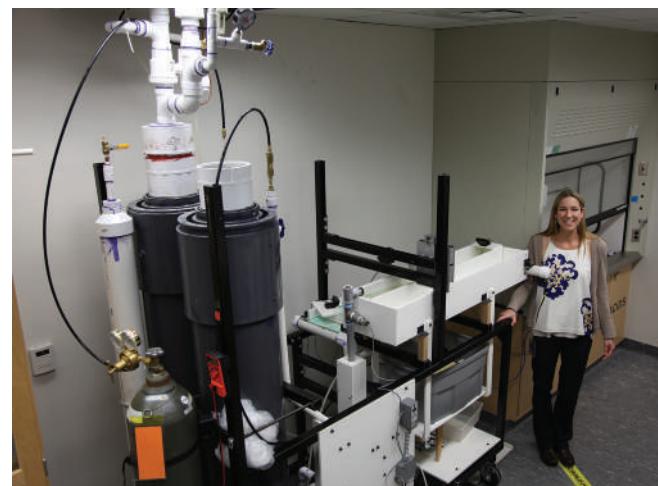

FIGURE 1.3.8 The ROCHSS laboratory teaching experiment. (Top) The ROCHSS instrument under construction at the University of Illinois Urbana-Champaign. (Bottom) Schematic of the ROCHSS experiment. Design and construction by Glenn Fried (shown working in top photograph).

to make a solution very similar to the water that erupts from the ground at Mammoth Hot Springs (Fouke 2011). At this point, the experiment either runs under default settings or is inoculated with living microbial cultures from our University of Illinois IGB laboratories. Next, the water travels through a heater, where the temperature can reach 70°C and pH can reach 6. It then flows along a runway (Figure 1.3.8), where CaCO₃ in the form of travertine is deposited and microbial mats grow simultaneously. As the hot water further cools and continues to degas CO₂, microbial mats upregulate proteins that serve to catalyze the travertine growth rate (Fouke 2011). Water flowing out from the downstream end of the travertine deposition runway is collected, pumped back into the mixing tank, and recycled with a circulating pump, while CO₂ is continuously bubbled through the recharge tanks (Figure 1.3.8).

The ROCHSS project was designed to support a broad range of teachers and students in learning basic hot-spring astrobiology principles, either in person at the IGB or online by accessing the experiment virtually. This virtual capability has dramatically expanded the reach of this University of Illinois campus project to national and international learning communities and can be easily coordinated into the EoL online courses. The online presence of the ROCHSS experiments requires that all sensors and cameras be controlled remotely with secure connections to a website that automatically organizes experimental data into an accessible database. This process includes streaming data from sensors that measure pH, temperature, ion concentration, CO₂, and flow. Cameras also feed streaming video and still images directly to the website, allowing for real-time monitoring and tracking of the experiment. At the conclusion of each trial, these data are “packaged” as downloadable files with associated time-lapse videos. Prior experimental data sets are also stored and accessible via the online portal for future reference and experimental comparisons. The versatility of this innovative platform will permit the ROCHSS to be utilized for a wide range of scientific topics, principles, and over a prolonged period of time.

Beyond accessing the experiment, educators and students can also access teaching materials, examples of experimental approaches, and laboratory exercises created using the five cornerstone illustrations from *The Art of Yellowstone Science*. These materials are linked to the astrobiology concepts presented in the EoL online course and are aligned to both state and federal NGSS (2018). Lessons cover up-to-date concepts on the Tree of Life, scientific inquiry, units of measurement, Yellowstone’s ecosystems and history, and a classroom outreach project. By connecting these foundational illustrations and the concepts they represent to the NGSS Physical Science, Life Science, Earth and Space Science, and Engineering Design Standards, the site supports diverse teachers in making connections to a variety of existing secondary education courses, including biology, chemistry, physics, and environmental science.

In addition to providing teaching materials, students have a chance to take an active role in the experimental design process using ROCHSS and to submit proposals

for future experiments. Because these proposals need to include the specific experimental parameters to be measured, a hypothesis to be tested, a statement about the expected outcomes, and the astrobiology relevance and significance of the overall experiment, they provide important introductory experience in thinking like a scientist. When a proposal receives approval, IGB staff set the requested experimental parameters and run the experiment, monitored in real time by the students. The ROCHSS tests can run from a few days to several weeks in duration, given the millimeters-per-day growth rates of the travertine observed at Mammoth (Fouke 2011). Throughout these experiments, emphasis is placed on the concept that microorganisms are essential to the healthy functioning and evolution of all living things and that microbes are critical to solving global challenges in environmental sustainability, human medicine, food security, energy generation, and space exploration.

The IGB ROCHSS team will also host three in-person and online professional development days each year for middle and high school teachers. The goals of these workshops are (1) to support teachers in creating additional lessons aligned with the NGSS; and (2) to connect middle school and high school teachers with scientists, professors, graduate students, and the IGB staff. During these workshops, educators will have the opportunity to ask pertinent astrobiology questions, develop realistic and meaningful hypotheses to use in their classrooms, collaborate with other educators, and earn CPDUs. This professional development, identified as important by middle school, high school, and university staff, is vital to the ROCHSS project, as it provides a rare venue for middle school and high school teachers to discuss vertical alignment of standards and content, connect with university faculty, and build a sense of community in the ROCHSS program. Eventually, a group of teachers and students will also be included in a field trip to experience Mammoth and Yellowstone (Houseal et al. 2010).

1.3.5.2 SCHOLAR-ATHLETE SPORTS IN SPACE SCIENCE CAMPS

The Illinois-Baylor-Davis NAI EPO will partner with the Illinois IGB and the Illinois Division of Intercollegiate Athletics (DIA) in Summer 2018 to offer three 4-day Scholar-Athlete “Sports in Space” Science Camps for secondary education-level students. A total of 180 campers will participate from the Illinois DIA Men’s and Women’s Tennis, Men’s and Women’s Gymnastics, and Men’s Golf camps. If this experiment is successful, future camps could include thousands of campers from other Illinois DIA Division I sports, possibly including basketball, football, baseball, volleyball, and soccer. During each workshop, students will be exposed to cutting-edge astrobiology science in the integrated fields of genomic biology, medicine, geobiology, astrobiology, nutrition, kinesiology, and information technology through hands-on learning experiences. These experiences will

challenge students to consider (1) the role of the human microbiome and its possible implications on health and athletic performance; and (2) key concepts of space, including sports in space. Throughout the duration of these camps, each scholar-athlete will be asked to apply these concepts to their own athletic performance. Their camp experiences will aim to (1) increase campers' awareness of Science, Technology, Engineering, and Mathematics (STEM) fields and research and increase their desire to pursue a STEM major in college; (2) have campers engage with interdisciplinary science underway at the University of Illinois and to build teamwork and laboratory inquiry skills in a variety of genomic-driven astrobiology scientific disciplines; and (3) provide campers with tools to evaluate their own health and performance long after the camp has concluded ([Figure 1.3.9](#)).

Building directly upon astrobiology insights contextualized by the Tree of Life, these scholar-athletes will learn about recent medical studies that estimate that as much as 90% of the total number of cells comprising the human body are single-celled microorganisms (*microbes*). These microbial communities (Bacteria, Archaea, and Eucarya) create a *human microbiome* that interacts with the mammalian host (Eucarya). They will also learn how the microbiome concept has fundamentally impacted all aspects of human medicine and will reshape how sports medicine is practiced in the future. From food and nutrient assimilation to muscle strength and fitness, the human microbiome is a fundamentally important concept for athletes to understand and incorporate into their training to maximize their health, strength, and athletic performance. The University of Illinois Department of Kinesiology is conducting research specifically on the influence of the human microbiome on sports performance (e.g., Allen et al. 2017). As a result, Kinesiology

faculty and graduate students will assist our IGB team in presenting at these camps. During the Scholar-Athlete "Sports in Space" Science Camps, students will plate and grow microbial communities collected from their bodies. They will also record and analyze basic body measurements, including temperature, weight, CO₂ exchange, hydration, food nutrition, and athletic achievement, to gauge and evaluate performance and efficiency of their bodies over the duration of each camp. In turn, these factors will be related to fundamental principles of Yellowstone astrobiology and experimentation, using the ROCHSS laboratory. For instance, CO₂, temperature, nutrients, and extent of dehydration are the factors that influence microbial communities in both Mammoth Hot Springs (extent of travertine deposition) and the human body (sports performance). These linkages will be carefully explained to further emphasize the global interconnectedness of life and Earth processes.

Each camp includes 2 contact teaching hours each day, for a total of 4 consecutive days, as follows:

Day 1 Nutrition: Scholar-athletes are introduced to nutrition awareness and are asked to evaluate their eating habits based on their intake of water, sugar, protein-to-carbohydrate ratio, and their consumption of processed versus natural foods.

Day 2 Fuel and Hydration: Scholar-athletes learn about the role of the human microbiome in nutrition and sports; run experiments on their own bodies, including testing their substrate utilization with a certified sports nutritionist; and learn how to optimize their nutritional and water intake.

Day 3 Microbiomes, ROCHSS and Genomic Sciences: Scholar-athletes will evaluate the human microbiome

FIGURE 1.3.9 Scholar-Athlete outreach on the University of Illinois Urbana-Champaign campus. Urbana High School scholar-athletes in a lecture (left) and using microscopes (right) at the Carl R. Woese Institute for Genomic Biology at the University of Illinois Urbana-Champaign.

within the context of the Tree of Life, run real-time experiments on the ROCHSS laboratory device that utilize the same parameters that they have measured on their bodies, and have in-depth discussions about the role of their microbiome on sports performance.

Day 4 Exercise and Sports in Space: Scholar-athletes will evaluate human activity, health, and performance at low or zero gravity and calculate basic parameters such changes in the gravitational force that influence the way in which their sport will need to be played under extraterrestrial environmental conditions; campers will then predict how their chosen sport would need to be modified to be played on a spacecraft or other planets.

1.3.5.3 UNIVERSITY OF ILLINOIS 4-H ACADEMY

Closely following the content and approach presented in the EoL MOOC, a 4-day residential course for 30 secondary school students was offered to expose secondary education students to astrobiology sciences and work with university researchers through the University of Illinois 4-H Academy. Entitled *Yellowstone: A Window on How the Universe Works* (Figure 1.3.10), this course offered and explored fundamental astrobiology concepts and approaches, including (1) the structure and implications of the Tree of Life; (2) how Scientific Inquiry is conducted; and (3) key events in the Deep Geological history of the universe. In the process, students took a “virtual” trip to Yellowstone through high-definition videos and interactive laboratories. Students also scrutinized the dynamics of a flowing fountain on the Illinois campus (Figure 1.3.10), integrating their powers of observation with strategic photographic skills. Students were also provided with an overview of biotechnologies being used in the life and natural sciences at the Illinois Roy J. Carver Biotechnology Center. In addition, students also visited Illinois IGB laboratories in which cutting-edge genomics, proteomics, bioinformatics, and other analyses are underway.

1.3.5.4 OUTREACH TO UNDERREPRESENTED COMMUNITIES

The University of Illinois Graduate College is committed to fostering an inclusive community, and Fouke serves on its coordinating Equity and Access Commission. The Illinois-Baylor-Davis NAI EPO program has been actively engaged with making astrobiology learning experiences a part of four major outreach programs within the Graduate College. The *Community of Scholars Program* is a campus-wide initiative that invites admitted students from these populations to visit and tour the campus, meet peers, and get to know faculty. The *Grad Mentoring @Illinois Program* is a mentoring network dedicated to increased recruitment, retention, and successful academic and career outcomes for underrepresented graduate students. The *Summer Pre-Doctoral Institute* (SPI) provides incoming graduate students from these constituencies with an 8-week orientation to graduate study before they arrive at Illinois for the fall semester. The *Summer Research*

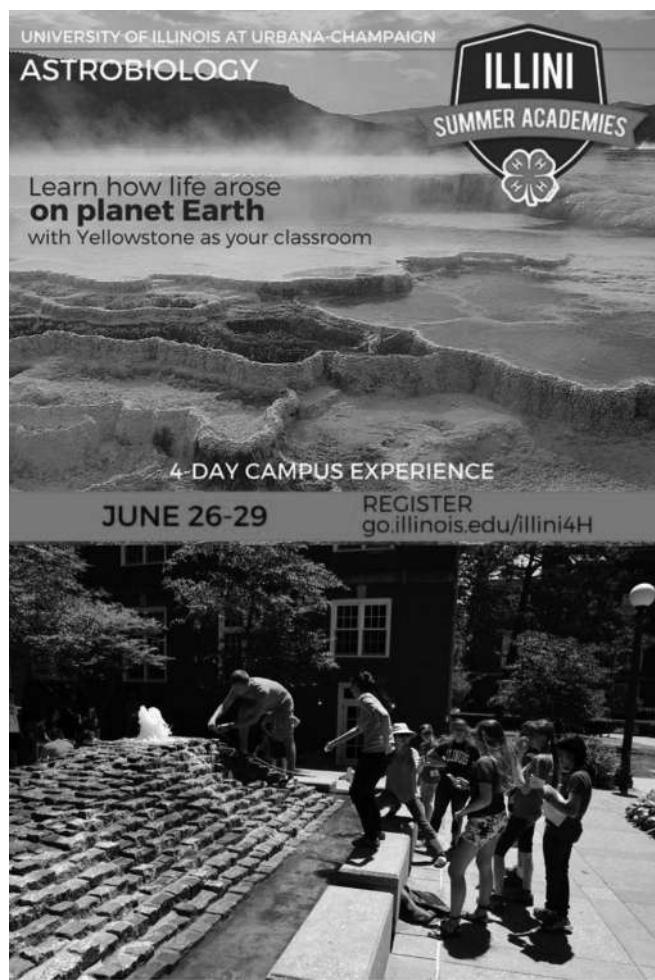

FIGURE 1.3.10 4-H Summer Academy residential camp presented on the University of Illinois campus in June 2016. (Top) Advertisement for the camp. (Bottom) Teaching assistant demonstrates techniques for measuring hot-spring water discharge in Yellowstone.

Opportunities Program (SROP) provides minority undergraduate students with an opportunity to explore careers in research, providing each student with an experience to strengthen his or her knowledge base, skills, and understanding of graduate work. The Graduate College has also worked with the Illinois-Baylor-Davis NAI EPO team to build connections with minority-enrollment institutions in Chicago, including Northeastern Illinois University and Chicago State University. The Illinois NAI E/PO program has also coordinated with the Graduate College office of the *Educational and Equity Programs* (EEP). The NAI faculty also worked with the *American Indian Studies* (AIS) Institute to work with Native American populations in the Midwest. Working relationships have also been forged with the Illinois *Center for African Studies* and the *Center for Latin America and Caribbean Studies* to provide astrobiology learning experiences to students from those ethnic and racial backgrounds.

The University of Illinois campus is also a national leader in support and outreach to persons with disabilities. Formal

coordination has been established between the Illinois-Baylor-Davis NAI EPO program and the Illinois *Division of Disability Resources and Educational Services* (DRES) to integrate these students. The mission of DRES is to ensure that qualified individuals with disabilities are afforded an equal opportunity to participate in and benefit from the programs, services, and activities of the university through the provision of effective auxiliary aids and services, the establishment of innovative educational services, and the pursuit of interdisciplinary disability research.

1.3.6 TEACHING TEACHERS

1.3.6.1 STUDENT-TEACHER-SCIENTIST PARTNERSHIP

An STSP program was established in collaboration with the Yellowstone NPS, in which a series of 1-day workshops were held to teach teachers for several years at the Illinois IGB and at Mammoth Hot Springs. Each of these workshops had an enrollment of 20 secondary education teachers, who received CPDUs for participating. Emphasis was placed on the astrobiology scientific themes presented in the EoL online courses and the textbook, with these resources utilized throughout the workshops. After returning to their home classrooms, teachers presented these concepts as modules of 1 or 2 weeks in working with their students. Periodically throughout the ensuing academic year, the Illinois-Baylor-Davis NAI team of researchers held live question-and-answer sessions with each classroom on Google Hangout. An online supplemental curriculum was developed specifically for this project and made available online from Illinois servers, which included (1) real-time engagement with active astrobiology research in Yellowstone; (2) discussion of hypothesis-driven research by using an iterative systems model that focuses on field research best practices; (3) focus on systems-level, astrobiology-relevant water-microbe-mineral interactions at Mammoth, including the geological “plumbing” under the system, carbonate cycling, and microbial ecosystems within the hot springs; (4) familiarity with astrobiology principles and protocols intended to protect Earth from extraterrestrial inoculation; and (5) sharing of findings with student colleagues and partners.

1.3.7 TEACHING IN THE WILD

Illinois-Baylor-Davis NAI EPO activities have embraced Yellowstone National Park as a dynamic natural classroom and laboratory within which to offer astrobiology learning experiences that are contextualized by the grandeur of wilderness. In such a unique context, students can be immersed in the complexity, scale, and relevance of natural processes. There is no substitute for astrobiology exploration and teaching in the wild, where scientific encounter with the primordial origins of our humanity encourages students to contemplate urgent challenges to the survival of species, including our own (Fouke 2014).

Thus far in the course of the Illinois-Baylor-Davis NAI EPO program, more than 50 lectures have been offered to visitors and ranger groups throughout Yellowstone National Park, in collaboration with the NPS and the Youth Conservation Corps (YCC). Locations for these talks have included Mammoth Hot Springs, Old Faithful, Fishing Bridge, the Norris Geyser Basin, and the Lamar Valley. In addition to the previously described astrobiology themes of the EoL online courses and textbook, these talks focus on teaching visitors to view Yellowstone hot springs as a natural laboratory in which to develop new scientific understandings of global processes ([Figure 1.3.11](#)).

Though Mammoth Hot Springs and coral reef ecosystems may seem like wildly different and unrelated environments, closer examination indicates that these awe-inspiring places exhibit a host of striking similarities and scientific parallels. The spring water emerging from Mammoth Hot Springs in northern Yellowstone is derived from rain and snowmelt runoff in the Gallatin Mountains, which flow down along faults into the rock subsurface. Heated by the Yellowstone supervolcano to approximately 100°C, the water chemically dissolves deeply buried 350-million-year-old Mississippian-age marine limestone and evaporates deposits called the Madison Formation. The water then flows back up to the surface to emerge from vents at a temperature of 73°C (Fouke 2011), in a cycle requiring hundreds to thousands of years. During this hydrologic journey, the Mammoth water evolves into a salty chemical fluid that is remarkably similar to seawater. Furthermore, much of the travertine that precipitates to form the classic millimeter- to centimeter- to meter-scale terraced steps of Mammoth is composed of a mineralogical form of CaCO₃ called aragonite. This is the same mineral that corals use to precipitate and grow their skeletons in warm shallow tropical seas. Furthermore, several of the microbes identified in the 73°C–25°C hot-spring drainage patterns at Mammoth are similar, and sometimes closely related, to microbes inhabiting coral tissues, coral mucus, and seawater (Fouke 2011).

Results of our field-based controlled experiments at Mammoth are therefore being used to predict how corals will respond to future global warming and associated increases in sea surface temperature. Heat-loving (thermophilic) microbes living at 62°C–71°C at Mammoth can respond to rapid shifts in water flow rate and temperature by changing the rate at which travertine rock is deposited on the floor of the spring outflow drainage channels. Biogeochemical analyses further suggest that the microbes do this by producing different types of membrane-bound proteins under changing water temperatures and flow conditions (Fouke 2011). These proteins, in turn, change the level and distribution of cell surface energy that controls the rate at which ions in the spring combine to form a solid travertine mineral precipitate. These dynamics established at Mammoth are now being used to establish new interpretations of how density banding in the aragonite skeleton of tropical corals (similar to tree rings) reflects coral response to the changing sea surface temperature (Fouke and Murphy 2016).

1.3.8 PUBLIC POLICY AND INTERNATIONAL ENGAGEMENT

An ongoing series of lectures and displays has been developed for general audiences; this series presents astrobiology science themes highlighted in the EoL online courses and *The Art of Yellowstone Science* textbook. More than 20,000 people have participated across the United States, including (1) at Yellowstone, in collaboration with the NPS and YFI; (2) at the Field Museum in Chicago, Illinois; (3) at the Mayo Clinic in Rochester, Minnesota; (4) at libraries in small towns and large cities; (5) at organization gatherings such as 4-H and the Rotary Club; (6) at various public and private colleges and universities; and (7) at the European Union and other embassies in Washington, D.C.

1.3.8.1 CHICAGO FIELD MUSEUM OF NATURAL HISTORY

Illinois-Baylor-Davis NAI EoL displays were constructed on the Illinois campus, transported to Chicago, and shown as part of a 3-day University of Illinois IGB *World of*

Genomics event presented in Stanley Hall, the largest venue at the Field Museum of Natural History. Situated between a complete *Tyrannosaurus rex* named Sue and the warring bull elephants, these NAI exhibits received more than 15,000 visitors, according to museum's estimates. In addition to NAI, partners for the event included Carl Zeiss Microscopes, the Yellowstone NPS, and the YFI (the Park's official education and fundraising non-profit partner). Featuring four Carl Zeiss petrographic microscopes and manned by 15 members of our NAI research group, the display included (1) the Emergence of Life on Earth and potentially on other planets; (2) microbial biomarkers in hot springs and potentially on other planets; and (3) the revolutionary NASA-supported work on molecular phylogeny, pioneered by Carl R. Woese. To further maximize the outreach impact of these exhibits, more than 500 students were bused to the field museum from schools in the Chicago Public School System, including Fenger Academy, Schurz High School, Gwendolyn Brooks College Prep, and Prosser Career Academy. More than 80% were students from under-represented populations ([Figure 1.3.12](#)).

FIGURE 1.3.12 (Top) *Emergence of Life* and *Universal Tree of Life* interactive displays in the Stanley Hall of the Field Museum in Chicago, Illinois. (Bottom) Lectures being given to 500 Chicago Public School students at the field museum.

1.3.8.2 ARCTIC CHANGE COURSE IN STOCKHOLM, SWEDEN, AND SVALBARD, NORWAY

NASA runs multiple ongoing satellite-based missions that monitor Earth and that directly integrate with NAI planetary research goals (NASA Missions 2018). Upon receiving the NAI funding in 2012, an opportunity immediately emerged to develop a new broadly interdisciplinary course targeting university undergraduates from around the world. The course, as part of the Illinois-Baylor-Davis NAI EPO, fully integrated astrobiology science with Earth-based NASA satellite missions. This was made possible via a formal exchange agreement between the University of Illinois Urbana-Champaign and the KTH Royal Institute of Technology in Stockholm, Sweden (formally called the Illinois-Sweden Program for Educational and Research Exchange *INSPIRE*). Entitled *Arctic Change*, this 8-week formally accredited university undergraduate course within the *INSPIRE* program had a

total enrollment of 17 students from the University of Illinois and 18 students from KTH. *Arctic Change* included 7 weeks of instruction in Stockholm and 1 week of instruction in Longyearbyen on the remote glaciated Svalbard (Spitsbergen) island archipelago, north of the Arctic Circle. *Arctic Change* offered a unique international integration of classroom, laboratory, and field experiences that linked Nordic humanities with environmental, life, and space sciences. The course contextualized these concepts with the Tree of Life and basic astrobiology sciences, while tracking these connections through deep geological time. This progressive breadth of cross-disciplinary education in a single field-based course is unparalleled in other universities around the world.

Arctic Change emphasized biocomplex relationships that arise from dynamic interactions between the physical, chemical, biological, and social components of the Svalbard ecosystem. Cornerstone parameters such sea surface temperature, air temperature, glacier thickness and retreat, polar bear

FIGURE 1.3.13 *Arctic Change* field course in Svalbard, Norway, that included students from the University of Illinois Urbana-Champaign and the KTH Royal University in Stockholm, Sweden.

and reindeer ecology, the emergence of infectious disease, changing human behavior, and cultural history were evaluated across multiple spatial (microns to thousands of kilometers) and temporal (nanoseconds to eons) scales. These were then directly compared to astrobiology-relevant life phenomena, such as NAI studies of the Antarctic Dry Valleys (e.g., Gilichinsky et al. 2007), that are fundamental to the search for life on other planets. Emergent phenomena and feedbacks through time were used as a framework to better understand the development and logistics of Nordic society, language, and culture in its own unique environmental setting.

The *Arctic Change* course emphasized the powerful influence of the ecology and evolution of microorganisms when discussing natural resources and land use by human inhabitants in the Arctic (e.g., food, fuel, water purification, and erosion control). This was evaluated with cutting-edge molecular sequencing and OMICS science tools, which are also central to the role of new biotechnical initiatives throughout the Nordic countries. Discussions and exercises were consistently linked back to the Tree of Life. To reinforce these principles, students were brought to tour the KTH-Karolinska SciLifeLab in Stockholm prior to departing for Svalbard. *Arctic Change* students were from internationally diverse cultural and academic backgrounds. Student participants were majoring in everything from oceanography, geology,

hydrology, microbiology, ecology, physics, chemistry, and the biosciences, as well as contemporary and historical Danish, Norwegian, Swedish, and Svalbard cultures, languages, and societies (Figure 1.3.13).

1.3.9 LIFELONG LEARNING

1.3.9.1 ILLINOIS OSHER LIFELONG LEARNING INSTITUTE AND YELLOWSTONE FOREVER INSTITUTE

In order to strengthen and more widely disseminate astrobiology science to lifelong learners, the Illinois-Baylor-Davis NAI EPO program presented a series of new hybrid courses on the *Emergence of Life* and *The Art of Yellowstone Science*. These were offered through the University of Illinois OLLI and the YFI to participants who were 50 years of age and older. Future emphasize needs to be continually placed on learners in order to provide inspiring educational opportunities for this rapidly growing cohort of accomplished and experienced people around the world. The Illinois-Baylor-Davis NAI EPO courses at the OLLI were offered in the spring semester for 8 weeks, with one class meeting each week. The linked objectives of astrobiology, Yellowstone science, and art naturally lend themselves perfectly to the OLLI classroom presentations and seminars. As a result, the maximum enrollment

FIGURE 1.3.14 Lifelong learners participating in Yellowstone Forever Institute course at Mammoth Hot Springs in Yellowstone National Park.

of 103 students per course was quickly reached, with long waiting lists each time the course was offered. Mirrored courses were also presented multiple times through the YFI at Mammoth Hot Springs (Figure 1.3.14).

1.3.10 SUMMARY

An NAI's program entitled *Towards a Universal Biology: Constraints from Early and Continuing Evolutionary Dynamics of Life on Earth* was awarded in 2012 to a consortium led by the University of Illinois Urbana-Champaign and included the Baylor University College of Medicine and the University of California, Davis. A key initiative in this work has been to further advance the work of Professor Carl R. Woese, whose pioneering research was the first to identify the Archaea, establish a three-domain Tree of Life, and provide our first glimpse of the evolutionary events that led to the emergence of the Last Universal Common Ancestor. The three-domain Tree of Life also provided the fundamental framework required to search for, identify, compare, and interpret extraterrestrial life forms that might be discovered in the foreseeable future. A progressive EPO effort that directly translated NAI team's ongoing astrobiology research

discoveries to online, classroom, and wilderness learning opportunities was completed. Mammoth Hot Springs in Yellowstone National Park was fully utilized as a dynamic classroom and natural laboratory for astrobiology research-inspired teaching opportunities, which have included development and presentation of (1) *Hybrid Textbook*; (2) *Open Education Resources and Global Outreach*; (3) *Higher Education*; (4) *Youth Outreach*; (5) *Teaching Teachers*; (6) *Teaching in the Wild*; (7) *Public Policy and International Engagement*; and (8) *Lifelong Learning*.

ACKNOWLEDGMENTS

Financial support was provided by the National Aeronautics and Space Administration (NASA) through the NAI's EPO initiative under Cooperative Agreement No. NNA13AA91A, issued by the Science Mission Directorate. Partial support was also provided by the National Science Foundation Biocomplexity in the Environment Coupled Biogeochemical Cycles Program (EAR 0221743), the National Science Foundation Geosciences Postdoctoral Research Fellowship Program (EAR 0000501), the Petroleum Research Fund of the American Chemical Society Starter Grant Program (34549-G2), and the University of Illinois Urbana-Champaign Critical Research Initiative. In addition, several organizations partnered to make these EPO activities a reality, including the Illinois College of Liberal Arts and Sciences (LAS), the Illinois Carl R. Woese IGB, the National Science Foundation (NSF), the NPS, the YFI, the Mayo Clinic, the Carl Zeiss Microscopy, and several middle and high schools across North America and Europe. Conclusions in this study are those of the authors, and they do not necessarily reflect those of these funding agencies and partners.

The NAI EPO field activities were completed under a series of YNP NPS education permits and research permit number 3060R. We are indebted to the many Yellowstone NPS Rangers who made this NAI EPO program possible, including Bob Fuhrmann, Ann Rodman, Christie Hendrix, Brian Suderman, Hank Heasler, Stacey Sigler, and Sarah Haas. We thank you for your pivotal role in supporting and allowing integrated research and teaching activities in Yellowstone and for fulfilling your absolutely vital roles of stewardship, protection, oversight, and partnership.

The ongoing guidance and support of Daniella Scalice at the NAI and of Hilarie Davis were crucially important in advancing all stages of this NAI EPO program. Sincere thanks also for the immense efforts and diligence of the entire Illinois CITL staff in creating the online courses, and special thanks to Jason Mock, Robert Dignan, and Liam Moran Gerard. Invaluable and significant contributions toward this work were also provided by all members of the Fouke laboratory research group at Illinois. We also acknowledge and appreciate the permission from parents and teachers to present the photographs of high school students who participated in our wilderness courses.

1.4.1 ASTROBIOLOGY AS AN INTERDISCIPLINARY APPROACH OF TEACHING SCIENCE

Astrobiology is the study of the origin, evolution, and distribution of life in the universe. Through the study of how life developed on Earth, we extrapolate this knowledge to extraterrestrial objects and speculate on how life could have developed under different conditions. Using remote observations with telescopes and direct physical experimentation with space probes, we are actively searching for evidence of life beyond Earth.

Living organisms on Earth are made of cells, and their constituents can be broken down into carbohydrates, lipids, proteins, and nucleic acids. These biomolecules are made of chemical elements, origins of which are found in stars. The present life forms on Earth are the result of billion years of biological evolution, which occurred through periods of geological transformation of Earth. The emergence of life altered the composition of the Earth's atmosphere and the biological evolution on Earth was interrupted by external events such as cometary and asteroid impacts, resulting in major extinctions. Earth, being one of the four terrestrial planets, was formed out of solid debris of the primordial solar nebula, which is a remnant of interstellar clouds and stellar ejecta. The birth-to-death life cycles of stars are part of the galactic evolution and cosmic evolution of the universe.

Astrobiology is an interdisciplinary subject that draws from research in astronomy, biology, biochemistry, chemistry, geology, microbiology, physics, and planetary science. It also touches upon the disciplines of history, philosophy, and sociology. Education in astrobiology therefore helps students develop the awareness that all sciences are related. Astrobiology studies the origin of life on Earth and the search

for extraterrestrial life (biology); both are governed by universal physical laws (chemistry) but could develop under different rules of biochemistry. The evolution of life on Earth occurred in a changing physical environment (geology), which has been influenced by external events in the solar system (planetary science). Earth has changed greatly over time as the result of interactions between the crust, oceans, and atmosphere (earth system science and global change). Life on Earth must adjust constantly to adapt to these changes in order to survive (ecology). In a larger context, Earth is just a rocky planet that has billions of counterparts all over the Galaxy (astronomy). The possible existence of extraterrestrial life and the potential consequence of contact with alien civilizations have major social implications (sociology and philosophy).

Study of astrobiology therefore gives students a broader view of science than traditional science courses and offers them a grand perspective of the frontier of science.

1.4.2 ASTROBIOLOGY AS A VEHICLE TO BROADEN THE MIND

While many students have the perception that science is dull and boring, astrobiology discusses topics that are of great interest to students and the general public. One example is extraterrestrial life. Most people have a simplistic view of extraterrestrial life, assuming it to be similar to ours and to the inhabited extraterrestrial worlds having geological structures, climates, and daylight cycles similar to those of the Earth. This naïve view is commonly depicted in popular science fiction novels and movies such as *Star Wars* and *Star Trek*. Astrobiology offers an opportunity to look deeper into these issues. Our science explores and shows that there are many possible evolutionary paths to life, and extraterrestrial life may have totally different appearances from terrestrial

living organisms. Exoplanets that harbor such life may have diverse atmospheric and surface conditions, as well as different daily and seasonal arrangements from Earth.

An unidentified flying object (UFO) is another very popular topic. Many assume that aliens visit us in mechanical flying objects with shining visible lights. Through the study of biological and cosmic evolutions, students in an astrobiology class will learn that any visiting alien civilization will be much more advanced than us and that their methods of visit are likely to be well beyond our present technological knowledge.

The above two examples of extraterrestrial life and UFO help illustrate the common pitfalls in popular thinking. Scientists are conservative in their methods but bold in their imagination. Others are careless in their methods but conservative in their interpretations of observed events.

The study of astrobiology also forces us to seek deeper and more fundamental meaning of seemingly obvious concepts, such as the definition of life. Although the distinction between life and non-life seems intuitively self-evident, a precise scientific definition that can be broadly applied to extraterrestrial life is not simple (see [Chapter 1.1](#)).

The study of alien worlds may have impacts on the understanding of our own Earth system. Our present awareness of global warming originated with the study of the greenhouse effect on the atmosphere of Venus. Will observations of other planets and planetary satellites help us learn more about past and future climate changes?

There are obvious religious implications on the question of extraterrestrial life. Does the existence of extraterrestrial life, in particular intelligent life, cause any conflict with existing religious doctrines? If such life exists, are humans really the chosen people created by God?

Astrobiology can also have a linkage to the past. If advanced intelligent civilizations are indeed common in the Galaxy, would they have already visited us? Is there any anthropological evidence for past visits by alien civilizations? It is possible that alien civilizations did visit the Earth, without us knowing it (Shklovskii and Sagan 1966)?

The exploration of other worlds by humans also raises ethical, political, and economic issues. Is it within our rights to visit, and possibly contaminate, other worlds? Should we be allowed to exploit the resources in the Moon and other planetary bodies? Will our visits to asteroids, planets, and planetary satellites disrupt the environment of these objects to the extent that it is irreversible? If we send returning probes or humans to other planets, we could be bringing back alien life forms that may pose danger to life on Earth. Colonization of Mars may require us bringing Earth-based plants and other species to the planet; what are the potential consequences? What kinds of safeguards or precautions we should exercise before engaging in these activities (Chon-Torres 2017)? Given the current high public interest in human inhabitation of the Moon and Mars, we need to have a thorough discussion on these issues before embarking on such endeavors.

The study of astrobiology can also serve as a vehicle for the discussion of possible development of human society in

the future. Over the last decade, we have seen tremendous progress in artificial intelligence. Will a time come when there will be no distinction between natural and artificial intelligence? Will our world be taken over by the intelligent machines? What will be the role of humans in such a society?

On a longer timescale, should humans be engaged in planetary engineering? It is conceivable that we could alter the atmosphere of Venus to make the planet habitable. Chemical or biological means can be introduced to convert carbon dioxide in the Venus atmosphere to oxygen, so that the surface temperature can be lowered and oxygen can be available for human respiration. Is planetary engineering inherently different from the way in which we have transformed planet Earth in the last several centuries?

The above examples on religion, ethics, social change, etc. can serve as excellent forums to bring in students in humanities, social sciences, engineering, and science together. A course in astrobiology will challenge students' minds and open their imagination to wider perspectives.

1.4.3 ASTROBIOLOGY AND OUR PLACE IN THE UNIVERSE

Humans have asked the question: "How important are we?" since the beginning of our existence. The search for answers to "where is our place in the universe" began as early as humans developed the intellectual abilities to think, and this quest is still ongoing. Five-thousand years ago, our ancestors already began careful observations of the heavens and recognized that celestial objects have regular patterns of behavior and are highly predictable. Extensive ancient monuments were constructed to mark the repeatability of celestial events such as the extreme north and south positions of sunrise and moonrise (Selin 2000).

The search for the relationship between heaven and Earth and the place of humans in it was the greatest driver for the development of intellectual thought. Through the use of simple observing instruments, our ancestors were able to achieve a highly sophisticated degree of theoretical understanding of the universe. Over 2000 years ago, ancient thinkers already knew that Earth was round and a free-floating object in space, not attached to anything. They also knew that the Sun's motion through the stellar constellation along the path of the ecliptic was responsible for the seasons. By adopting a model that puts the spherical Earth at the center of a giant celestial sphere upon which all stars reside, ancient astronomers were able to accurately predict the positions and times of sunrise and sunset at all locations on Earth. Ancient astronomers knew that the Moon shines by reflected sunlight and the phases of the Moon are the result of geometric relationship between the Sun, the Moon, and the Earth. Through observations and mathematical analysis, Greek astronomers were able to estimate the physical sizes of the Earth and the Moon and the distance to the Moon to great degrees of accuracy (Kwok 2017).

The integration of Ptolemy cosmology, Aristotle natural philosophy, and Christian doctrines gave rise to a model that humans are located between heaven (which is located outside

of the celestial sphere) and hell (which is located in the middle of the Earth). This system of belief was challenged only after the proposal of the heliocentric model of the universe by Copernicus (Kuhn 1957, Koestler 1959). The realization that Earth is just one of the planets and the possibility of existence of other worlds similar to our own, as raised by Giordano Bruno, greatly weakened the foundation of the Christian faith and the authority of the Church.

Recently, we are able to go beyond the model of the physical structure of the universe and incorporate the scientific study of life into the question of search for our place in the universe. The origin and evolution of life are considered in the context of the physical universe. We now believe that Earth is a tiny speck of dust in the vicinity of an ordinary star, one of about 100 billion stars in our Milky Way Galaxy, which itself is just one of 100 billion galaxies in the universe. We have learned that planets are common in our Galaxy (Lissauer et al. 2014, Kaltenegger 2017) and organic compounds are widely present in the universe (Kwok 2011). The fact that the building blocks of life are ubiquitously present suggests that life could also be ubiquitously present.

The historical evolution of our beliefs on this subject and the speculation of how things could develop in the future represent a fascinating topic of class discussion. Changing interpretations of the structure of the universe over human history have overturned established social structures and how we perceive ourselves in the context of the Earth and the universe. The discovery of extraterrestrial life will have an equal, if not greater, impact on society.

May be, the most significant implications on the question of “our place in the universe” and the search of extraterrestrial life are changing our perception of ourselves: not as citizens of certain nations, member of certain races, or adherents of certain regions, but as common inhabitants of planet Earth. The education value of this concept goes far beyond what any humanities or social science course can deliver.

1.4.4 CURRENT STATE OF SCIENCE EDUCATION

In most universities today, science is taught by discipline. Students enroll in programs or majors of a specific discipline such as physics, chemistry, or biology. Students often perceive these subjects as segregated and not related to each other. In research-intensive universities, emphasis is placed on preparing students for graduate work, earning a PhD degree, and becoming the next generation of researchers.

The emphasis on specialty training is particularly strong in Russia, Asia (China, Japan, and Korea) and certain countries in Europe. Students and young researchers are encouraged to dig deeper into increasingly narrower subject areas. In order to give students a broader education, many North American universities have out-of-major requirements to supplement the major courses. For example, it is common to have distribution requirements for undergraduate science students to take courses in humanities and social sciences, such as psychology,

economics, and history and for non-science majors to take science courses such as physics and biology. However, these courses are often introductory courses in these disciplines and are not designed specifically to be relevant to the out-of-major students.

An alternative approach to university education is to adopt a whole-person training philosophy, where the emphasis is to develop students as intellectual beings capable of analyzing the increasing complex problems of the modern world. The goal is not so much to impart factual knowledge of a particular discipline but to train students to be aware, to observe, to analyze, and to produce solutions to unfamiliar problems.

1.4.5 A NEW APPROACH OF TEACHING SCIENCE

Although the knowledge content of astrobiology is interesting in its own right, I am keener to use the teaching of astrobiology as a tool to develop students’ intellectual abilities. In our education system, science courses often focus on the description of current models. Courses in biology and chemistry are commonly laden with facts, and courses in mathematics and physics are filled with abstract derivations. It is not to say that these are not useful, but these may have missed an important element of science education. Most science courses inform students on our current interpretations on how things are, with little attention paid to how scientists came to the present points of view. In fact, science is about the process of rational thinking and creativity. What we consider to be the truth is constantly evolving and has certainly changed greatly over the history of humankind. The essence of science is not so much about the current view of our world but how we changed from one set of views to another. Our goal of science education should not be about the outcome but about the process (Preface, Kwok 2017). We should try to help students develop the ability to observe, deduce patterns, and hypothesize on the origin of these patterns. Understanding the process of scientific thinking benefits students in all areas of study, not just science students.

This approach of teaching was used by me to teach a common core course at the University of Hong Kong between 2010 and 2018 to about 100 students per year drawn from all faculties of the university. The content of the course is designed to inform the students that our world views are the result of observations, pattern recognition, logical deductions, predictions, and further experimentation. This process is applicable not only to science but also to our everyday lives. By going through the historical examples discussed in the course, students learn to be suspicious of authority, be less willing to conform to the current way of thinking, and be bolder to explore new ideas. These potential effects on students have far greater impact on their lives than any knowledge content that science courses may impart.

During my tenure as president of the Astrobiology Commission of the International Astronomical Union, I tried to promote this approach of science education and use

astrobiology as a tool to develop new ways of science teaching, in particular in the developing countries. As traditions are strong, change is not easy. However, the rapid development of the field of astrobiology offers a better opportunity as a vehicle for education reform than other more established or entrenched disciplines of science. Being at the wide-open frontier of interdisciplinary science, astrobiology can make a stronger case, so that the next generation of scientists be educated differently.

ACKNOWLEDGMENTS

My interest in astrobiology began when I first read the book “Intelligent life in the Universe” by Shklovskii and Sagan in 1973. Much of the content of the book is still relevant today.

1.5.1 ASTROBIOLOGY'S VALUE TO EDUCATION IN MAINSTREAM US CULTURE

Astrobiology explores our origins like no other part of NASA does, and the potential future discovery of extraterrestrial life will mark a major revolution in all of science, much like the Copernican revolution of the sixteenth century, in which we learned that we are not at the center of the universe. In this sense, astrobiology may be the most important and impactful investment that NASA has made. It is imperative that we mobilize astrobiology content across cultures and contemplative traditions toward making meaning of the search for and discovery of life elsewhere in the universe and furthering authentic dialogue around our origins.

Astrobiology is a multidisciplinary, diverse, and expansive endeavor, involving many seemingly disparate investigations. If astronomy, biology, chemistry, geology, paleontology, physics, and planetary science can be thought of as individual threads, then as the intersections of and spaces between these disciplines are explored by astrobiologists, the threads are brought together and woven into an interdisciplinary tapestry depicting a story of our origins, our place in the universe, and our search to find life elsewhere.

This interdisciplinary nature of astrobiology has special relevance in education. Astrobiology provides an umbrella, a larger context in which many fundamental science concepts such as gravity and volcanism can be taught. In alignment with teaching standards developed by states and professional education organizations in the US, such as the Next

Generation Science Standards (National Academies Press 2013), educators are required to teach these concepts, introduced at the appropriate time with respect to cognitive ability and conveyed at increasing levels of depth, as students progress through the grade levels. While discipline-based concepts are typically taught in isolation, at both the K-12 and college levels, it has been shown that learning outcomes are enhanced when concepts are tied together in a larger, interdisciplinary context, such as the search for life elsewhere in the universe (Jones 2010, Howes et al. 2013, Hye 2017).

The huge questions guiding astrobiology (Are we alone? Is there life elsewhere?) cannot be addressed by one scientific discipline alone. Each discipline is a contributor of its knowledge and methodologies, and astrobiologists must communicate across discipline boundaries and access each other's expertise in order to successfully address these vast and ancient questions (Hays 2015). This collaborative essence is also a valuable tool in education, as many of today's best instructional techniques employ problem-based and/or team-based approaches (Dochy et al. 2003, Laal and Ghodsi 2011).

The astrobiology community, as primarily funded by NASA, has capitalized on the unique value that astrobiology brings to education. Numerous learning materials such as curricula, hands-on activities, games, web interactives, online courses, films, and books, as well as programs for youth, teachers, and the general public, in places such as classrooms, after-school settings, and museums have been developed and implemented over the past 20 years (for more, see <https://astrobiology.nasa.gov/education/>). But there is much more value to be had.

1.5.2 ASTROBIOLOGY-AS-ORIGINS-STORY

To weave that tapestry story of our place in the universe, as described in the other chapters of this book, astrobiology starts at the first moments of our universe. Astrobiology traces our origins from the Big Bang as the source of hydrogen—the simplest element. Over time, nuclear fusion in the cores of the first stars turned that hydrogen into many of the rest of the elements, especially the ones that make up all life on Earth, including our very selves. Astrobiology follows those elements into planets and moons, studying the process of planetary system formation, in which the star and all the bodies that orbit it form together, from the same source material and at the same time.

Astrobiology investigates the relationship between life and its planet (or moon). It champions the idea of a planet as a “container” that facilitated the emergence of life as a transition from geochemistry to biochemistry, supplying the required raw materials and energies. And where did those raw materials come from? The cores of stars that lived out their lives long ago.

Astrobiology goes on to explore the dance between planet and life—the co-evolution wherein planet influences life’s evolutionary trajectory; then life innovates, adapts, and influences back; and on and on. It even looks into the relationship of all life at the molecular level, seeking to define the Last Universal Common Ancestor, at once appreciating the diversity—yet common ancestry—of all life, and the shared provenance of all things in the universe.

When we see the threads coming together in this way, it’s easy to recognize astrobiology as an origins’ story. Today’s scientific community is at the heart of a modern, secular culture that has advanced to the point of using its core methodologies to articulate an origins’ story. This is good and right. It is a natural, cultural phenomenon to seek to understand humanity’s place in the larger world, in the cosmos. Astrobiology is not the first origins’ story and perhaps won’t be the last, but it should claim its place in the great cannon of cosmologies and origin stories of humanity—what Joseph Campbell has called “mankind’s one great story” (Campbell 1991).

1.5.3 NEW DIMENSIONS OF VALUE TO EDUCATION—DUAL LEARNING

In terms of education then, seeing astrobiology as a cultural expression opens up whole new ways in which learning can be facilitated, beyond using it as an interdisciplinary context in which standardized, discipline-based concepts and skills can be more effectively taught.

Because most cultures have highly developed and intricate cosmologies and ways of knowing (aka methodologies to generate knowledge), astrobiology-as-origins-story (and its underlying way of knowing, the scientific method) can be utilized as a means of connecting to learners and bringing together people and ideas. In such connecting, the goal should never be to take something away from someone, to antagonize a pre-existing system of knowledge, or to disabuse any culture

or individual of knowledge they generated and hold dear, nor should it be to verify or validate cultural “myths” and beliefs. Such a perspective must also acknowledge and respect that each culture or contemplative tradition will have unique origins’ stories and content. Assumptions about similarity of material or ways of working across cultures must be checked.

In this approach of meeting learners where they are with respect to their origins’ stories and offering astrobiology-as-origins-story as another expression of “mankind’s one great story,” there is no value judgment woven into the paradigm, and therefore, no one body of knowledge can be proclaimed as better or truer. Instead, they co-exist in what is perhaps a new level of interdisciplinarity—a meta level—for astrobiology.

Rather than put origins’ stories at odds, it is possible to create—and my colleagues and I have co-created—an environment wherein two bodies of knowledge and ways of knowing are equal—a “dual-learning” environment that facilitates the learning of both (see [Section 1.5.5](#)). When both bodies of knowledge are presented as equal in a non-threatening, dominance-free paradigm, learners are motivated to gain knowledge about both, and neither is diminished. Learners are supported to examine the relationship between the two from their own perspectives and decide for themselves if there are resonances or irreconcilable differences. Either conclusion is valid, as, again, the point is not for one to dominate or be revealed as absolute truth.

Many Science, Technology, Engineering, and Mathematics (STEM) programs and the pursuit of STEM educational pathways and careers pressurize youth to leave their communities. In many cases, opportunities for American Indian/Alaska Native (AI/AN) youth such as taking part in an internship, pursuing advanced degrees, and accepting job offers require them to move away, off tribal lands. Those communities consequently experience a “brain-drain” phenomenon (Kapur and McHale 2005), while some cultural priorities and the desire of many young Native people are often to keep all tribal members, especially the best and brightest, at home and involved in tribal advancement and the preservation and perpetuation of cultural knowledge and language.

This mandatory exodus, even if the intention is for the student to return and be involved in tribal advancement, harkens back to the early “management” strategies of non-Native government organizations in the US, which instituted boarding schools, wherein Native youth were forcibly separated from their families to receive an education and were forbidden to speak their languages (Adams 1995). Thus, the modern STEM paradigm, which pulls Native youth out of their communities, reinforces, perhaps unawares, the attitudes and practices of colonization.

Today, Native youth at least have the choice to leave to pursue STEM (and other career paths), versus in the past, when they were forcibly put into the boarding schools, but why should Native youth have to choose at all between a STEM identity and a cultural identity? Why does it have to be an either/or situation? How can we move toward yes/and?

Experiencing a dual-learning environment can foster the simultaneous development of both cultural identity and

STEM identity and ensure content learning gains of both STEM and cultural concepts (Demmert and Towner 2003). It can also support Native youth to consider STEM approachable and non-threatening. But much remains to be changed and evolved toward decolonizing and deinstitutionalizing STEM, so that Native youth who do pursue it don't have to sacrifice their cultural identity in the process.

1.5.4 NASA AND THE NAVAJO NATION PARTNERSHIP

It was with this perspective of astrobiology-as-origins-story that I met the opportunity, when it came along in 2005, to work with the Navajo Nation. I was invited to participate in a seminal Round Table between NASA's Office of Education and the Navajo Nation, designed to engender dialogue around the question, Is the Navajo Nation interested in partnering with NASA on education initiatives? This kind of "asking first" approach demonstrates inherent respect for the sovereignty of the Navajo Nation and Diné culture, as well as lack of assumption that everyone wants what NASA/science has to offer.

The Round Table convened educators, tribal government officials, community leaders, medicine people, and other stakeholders from across the Navajo Nation. Through dialogue, it was ascertained that educational initiatives with NASA were indeed desired. In line with their emerging tribal legislation at the time, the Sovereignty in Education Act, and through a reexamination of Diné Fundamental Law, the value expressed was that scientific and cultural knowledge should be taught together, as equals. This value emerged as a core philosophy, inspiring the term "dual-learning environment," and began guiding what would become a long-term, multifaceted partnership, now in its 14th year. It was also made clear that NASA was not being invited into partnership to "fix" or "solve" anything but rather to represent science completely and accurately in a dual-learning paradigm.

1.5.5 CO-CREATION AND DUAL LEARNING IN ACTION

My Diné colleagues and I formed the NASA and the Navajo Nation project team, standing solidly upon the foundation laid down by the Round Table (Allen 2016). Numerous meetings and ceremonies led to the co-creation of the first educator guide, "Sq' Baa Hane' – Story of the Stars." Both cultural and scientific knowledge and stories relating to stars were explored, and the scientific content was chosen for its ability to align with the cultural content. The concept of stellar evolution, with a focus on the process of star formation and nuclear fusion as the source of heavier elements, was selected to be part of the hands-on activities in the booklet. The general theme of cycle/recycle is present throughout and is explored in more detail in the second educator guide.

The "Cycles in the Cards" activity, in particular, embodies the dual-learning environment and offers learners a potential connection between Diné origins' stories and those of science,

as told through stellar evolution. In this activity, cards are used (in sets of four) to represent all the parts and phases of creation and are laid down on a table in the order told in a Diné origins' story called "Dahadínísá / The Beginning." As the story unfolds, each of the four cards in each set is placed into a different section of the table, corresponding to the four cardinal directions: east, south, west, and north. Finally, all the cards are placed, and piles form in each area. Once this is completed, four cards representing four phases of a star's life cycle are each placed, one onto each pile, aligning to what is known about each direction.

A card with an image of a star-forming region such as contained in many nebulae is placed in the east direction; a card with an artist conception of a circumstellar disk, representing the early stages after a star is formed, is placed in the south direction; a card with an image of our Sun, representing the main sequence of a star's "life" is placed in the west direction; and a card with an image of a supernova remnant is placed in the north direction. In this way, the life cycle of a star and the process by which elements are created and made available to the next generation of stars and planetary systems map directly to the processes and knowledge inherent in the Diné origins' story. Indeed, if the scientific method can be seen as having four phases: inquiry/hypothesis, experimentation/observation, data collection/analysis, and conclusions/next questions, then these map into the pattern as well.

As the partnership grew and years passed, another educator guide was co-created, and numerous workshops for Diné teachers and summer camps for Diné youth were co-implemented. The team also held a "Cultural Immersion Experience" for managers of academic and federal education programs, designed to serve Native youth, with the goal of potentially altering programmatic designs that don't reflect a full appreciation of the needs of those whom they are intended to serve.

The second educator guide, "Tł'ehonaa'éí Nihemá Navajo Moon," deepens the dual-learning philosophy. In it, the scientific concepts of planetary system formation, the electromagnetic spectrum, and spectroscopy find resonance with the Diné concept of K'é, a system of relationship and kinship, and with the knowledge embedded in the Diné cradleboard.

In the teacher workshops and student summer camps, the dual-learning environment is anchored by the presence of both a scientist and a medicine man. In the camps, field sites that are at once geologically significant and culturally sacred are visited, and both experts share knowledge and stories on the trails. Reflecting upon the experience at Canyon de Chelly National Monument, one student remarked, "Both the rocks themselves and the petroglyphs tell a story." Of Chaco Culture National Historic Park, where the scientist teaches about the Western Inland Seaway that was once there and the students learn about the former human occupants of the area, another student reflected, "At Chaco, the people may be gone, but the spirits are still there...and the ancient sea is gone, but the rocks record its presence."

Current efforts are focused on the development of a new hands-on activity, wherein the aspect of the Diné cosmology

that involves a progression through four worlds and a scientific timeline from the Big Bang to the present day are brought together. The team is also exploring new field sites and developing new curricula for future summer camps.

In all these ways, the dual-learning environment is thus co-created, and learners are free to find and/or generate connections between the two bodies of knowledge and the two ways of knowing. Our team is presently in the process of publishing data collected from these programs, which assess the extent to which both cultural and scientific concepts are learned, as well as the extent to which learners have made connections between the two.

1.5.6 MORALS OF THE STORY?

I have learned from the indigenous knowledge and scholarship to which I've been exposed that the universe is relational, meaning that the fundamental context in which all things exist is one of community, interconnectedness, and relationship (Thayer-Bacon 2002, Cajete 2010). In my view, the origins story, as told through astrobiology, and the epistemology through which it has been developed share this understanding of relationality. And I'm not the only one. As Carl Sagan has said, "The cosmos is also within us. We are made of starstuff. We are a way for the cosmos to know itself."

The methodologies of science may be reductionist, but the output, especially in the case of the current scientific thinking about our cosmic origins and the emergence, evolution, and diversity of life on Earth, is systemic, holistic, and relational in nature. What could be more relational than Newton's Third Law of Motion, which states that every action has an equal and opposite reaction, or than the main principle of the First Law of Thermodynamics that matter and energy are neither created nor destroyed, only transformed? If astrobiology-as-origins-story is the output, can we move beyond to identify outcomes or morals of the story?

There are clear themes or concepts resident in astrobiology-as-origins-story that I think of as teachings or lessons from the science. The knowledge that the atoms that make up our Earth and us were made in a star that lived and died long ago intimately connects us not only to the universe and its cyclical processes but also inextricably and immutably to the solar system, the Earth, and to one another. As Neil de Grasse Tyson says, "We are all connected...to each other—biologically, to the Earth—chemically, to the rest of the Universe—atomically." We can also look at the process of stellar nuclear fusion, the process by which most atoms heavier than hydrogen were made, and see creative potential in the harshest environment imaginable, the hyper-pressured core of a star.

Planetary system formation as a phenomenon concurrent with star formation shows us that all the material in the star, planets, moons, asteroids, comets, etc., in our (and any given) solar system formed from a common source (nebulae, the giant molecular clouds) and according to the same processes. Herein lies more evidence of connectivity and relationship. If we find life elsewhere in our solar system, for example, on Mars or on Enceladus, in this way, we'll be related to it, too.

As humans, we think of the conditions in which early life may have emerged as "extreme," such as the high temperatures of hot springs or vents, the crushing pressures and lack of sunlight on the seafloor, an atmosphere without free oxygen, and bombardments at the surface. We continue to investigate such extreme environments here on the modern Earth and study how life innovated and adapted in order to spread and survive and thrive in these environments.

We look at the co-evolutionary relationship between life and Earth and see times when the environmental conditions presented life with challenges, and in turn, life innovated new biochemical strategies and influenced the environment. This is perhaps most perfectly illustrated by the microbial invention of oxygenic photosynthesis ~2.5 billion years ago, through which oxygen was put into the atmosphere for the first time, likely paving the way for multicellular life and the Cambrian explosion, and the asteroid impact at the K/T boundary ~65 million years ago not only wiped out the dinosaurs but also opened up environmental conditions that ultimately gave rise to the time of mammals. And it continues today, as we humans and our industries emit carbon dioxide and other greenhouse gases into the atmosphere, causing environmental conditions to change again. How will life on Earth respond?

In looking at the origin and evolution of life in this way, the themes of life's resiliency, tenacity, and ability to innovate new strategies—under environmental pressure—to make a living and grow are clear. Again, we can see the theme of creative potential in times of disruption, adverse conditions, and even catastrophe. And the idea of cause/effect and the relational nature of the universe are on full display.

This knowledge is begging for us to act accordingly. Neil de Grasse Tyson goes on to say, "Whatever you do, say, or even think influences others, and they influence you." Interconnectedness and relationality can show us the way to respect and stewardship. If we impact or harm one part of the system, there will be reverberations throughout the system, and we will eventually feel the repercussions ourselves. This has implications in how we approach the discovery of life elsewhere—will we see it as other and unrelated or embrace it as family and strive to protect and preserve it? There are implications too in how we behave toward our planet and, most importantly, how we treat one another.

1.5.7 ASTROBIOLOGY FOR THE INCARCERATED

Within the perspective of astrobiology-as-origins-story representing a relational universe, it stands to reason that our actions have consequences, for which we must take responsibility. There is perhaps no place more exemplary of consequences than a prison or jail. There is also perhaps no place more rich with transformative potential. What shifts might we see if astrobiology-as-origins-story and the themes, lessons, and teachings therein are shared as educational programs for incarcerated populations?

Founded in 2016, Astrobiology for the Incarcerated (AfI) is a partnership between NASA's Astrobiology Program, the Initiative to Bring Science Programs to the Incarcerated (INSPIRE) at the University of Utah, and the Sustainability in Prisons Project (SPP) at the Evergreen State College in Olympia, WA. The partnership leverages the prior work, experience, and expertise of INSPIRE and SPP, as well as much larger studies of exposure to educational programs behind bars, which show a large reduction in the likelihood of returning and an equally large increase in post-release employment (Davis et al. 2013). The AfI team and I bring astrobiology lectures to incarcerated adults and hands-on astrobiology activities to incarcerated youth across the US. We will also be deploying astrobiology imagery via short-format films into special housing units where live programming isn't allowed.

The goals are that the story, teachings, and images will broker connections for inmates to the cycles of the cosmos, our common origins, and the overall idea of a relational universe and that those connections will result in a greater capacity for positive relationship. When, in 1969, NASA provided us our first glimpse of Earth from space (in the image that became known as "Earthrise"), a reframing of our perspective catalyzed a movement of environmental stewardship (McGuinness 2009). In a similar vein, astrobiology-as-origins-story can help inmates contemplate their place in the world and inspire stewardship of self and relationships. The AfI team is currently in the process of collecting data from a pilot of our activities to assess the impact of our efforts on the inmates in terms of knowledge gains and attitudinal shifts.

1.5.8 CONCLUSIONS

The questions of astrobiology—the pursuit of knowledge about our origins, life on Earth, and the possibility of life elsewhere in the universe—are not exclusive to science. We must tread lightly, as we bring the scientific stories of our place in the universe and the teachings therein into "first contact" with those of other cultures and contemplative traditions. We must be relational and approach with humility and respect. Using astrobiology-as-origins-story and the teachings within it in educational environments should be undertaken with even more care; science should not be wielded as a sword to cut down or diminish other bodies of knowledge or epistemologies. Rather, we can create a safe space, promote their co-existence, and let them speak and listen to each other. We can be present to that unfolding and hear what is being said. As have I, you may find that these bodies of knowledge and ways of knowing have more in common than not. The etymology of the very word "universe" is telling us, if you listen closely enough, that no matter what ways of knowing we use, we are all speaking "one verse," telling "one story," and singing "one song."

2.1.1 INTRODUCTION

This chapter presents various perspectives on defining life. First, an overview of the most common approaches to defining life is given, accompanied by a selection of definitions of life that illustrate these approaches. Some definitions of life also address the origin of life. Advantages and disadvantages of minimal versus expanded definitions of life are evaluated. Finally, borderline cases of life (such as viruses) are addressed.

2.1.2 BACKGROUND ON DEFINITIONS OF LIFE

One of the key goals of astrobiology is to define life, which is important not only for understanding the origin and evolution of life on Earth but also for the search for extraterrestrial life. Many definitions of life have been proposed. They are given in a chronological collection of 95 definitions from 1855 to 2002 (Popa 2004), 77 life definitions from 1871 to 2002 (Popa 2014), and 78 definitions from 1999 to 2000 (Pályi et al. 2002). Although a large number of definitions of life have been proposed, none is universally accepted (Popa 2014). While each definition addresses some key features of life, none appears inclusive of all the features. Minimalistic definition of life was also sought (Trifonov 2011), as well as the universal definition of life, which would be applicable to extraterrestrial life also (Ruiz-Mirazo et al. 2004). Many inclusive definitions describe what life does but do not state what life is. Our ability to define life is also dependent on our understanding of the origin of life, which is a subject to controversies (Peretó 2005). A comprehensive definition of life should

also address its origins. A philosophical problem exists that we may not know enough about the theory of life to define it (Cleland and Chyba 2002, 2007). Currently, the NASA's definition of life is used most often. It is: "Life is a self-sustained chemical system capable of undergoing Darwinian evolution" (Joyce 1994, 2002; cited in Popa 2004, 2014). A comprehensive definition of life should also address the borderline cases, such as viruses. The latter are in the twilight zone of life, according to Villarreal (2004).

The task of defining life has also been undertaken by the philosophers, alone or in cooperation with scientists (Cleland and Chyba 2002, 2007; Gayon 2010; Malaterre 2010; Tirard 2010; Tirard et al. 2010; Weber 2015). Some scientists applied philosophical principles in defining life and the origin of life (Kolb 2005, 2007, 2010, 2012, 2016; Perry and Kolb 2004). These examples testify to the interdisciplinary nature of astrobiology, which now solidly includes philosophy as a discipline (see Chapter 1.1 for the discussion on the interdisciplinarity of astrobiology).

Definitions of life often reflect the original disciplinary training of the authors or their current investigational area of expertise and their understanding of the origins of life. Examples include chemically oriented authors (Benner et al. 2004; Benner 2010). Specific questions that were examined include types of polymers that support Darwinian evolution (Benner 2010), a repeating dipole as a universal structural feature for the catalysis in water, universal structural features of metabolites in water, and the charge requirement for folding of the genetic materials with repeating charges, among others (Benner et al. 2004). These examples provide us with chemical descriptors for life.

To define life, one must understand it first, at least at some level. The ultimate experimental way to understand life is to make it in the laboratory. Work on the synthetic life has been quite successful (Venter 2007, 2013; Ball 2016). While we still do not have synthetic life produced *ab initio*, much progress has been made, such as the synthesis of a minimal bacterial genome (Hutchinson et al. 2016). Philosophical aspects of the synthetic biology are recently reviewed, from chemical and ethical points of view (Schummer 2016). New molecular biology tools, such as the Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) gene-editing method, provide additional ways to tinker with the building blocks of life (Callaway 2016).

In the next section, different ways to define life are addressed.

2.1.3 DIFFERENT WAYS OF DEFINING LIFE AND FACTORS INVOLVED

Defining life is important for astrobiology, specifically for understanding biology and the origins of life on Earth, in searching for the putative extraterrestrial life, and for placing the artificial life in a context of the biological life.

In general, different types of definitions exist (Churchill 1986, 1990; Gupta 2015). Examples include lexical, stipulative, and operational definitions. A lexical definition explains the meaning of a word as it is currently used and given in the dictionaries. A stipulative definition assigns a meaning to a word, with the objective of clarifying arguments or discussion in a specific context. A stipulative definition represents an explicit decision to use a word in a given way. Since stipulative definitions represent proposals to use a word in a certain way, they can be judged as useful or not, clear or not, but not as true or false. Operational definitions are often used in the experimental sciences. An operational definition states the meaning of a term by connecting its proper use to some observable condition (Churchill 1986, 1990). Scientific definitions are typically stipulative. One example is the NASA's definition of life: "Life is a self-sustained chemical system capable of undergoing Darwinian evolution" (Popa 2004, 2014; Gayon 2010).

Some definitions of life are expanded dictionary definitions of life, in which the additional description is added for the use by specialists. Some other definitions aspire to capture only the perceived essential characteristics of life, which are then specified. Most valuable definitions attempt to include the origins of life. Many definitions are the mixtures of these types.

Defining life is often influenced by the three historical conceptions of life. They are: life as animation (Aristotle), life as mechanism (Descartes), and life as organization (Kant) (Gayon 2010). Some contemporary definitions of life can be easily traced to these three conceptions.

Philosophical visions about life, such as holism (generalism), reductionism (minimalism), vitalism and spiritualism, and mechanistic reductionism and dialectical materialism, also influence the process of defining life (Popa 2010, 2014). The holism regards life as a collective property. It considers

its function and purpose. The reductionism aspires to explain life by the fundamental and minimalistic mechanisms and forces. The vitalism and spiritualism view life as the result of some esoteric force or supernatural will, which are beyond the power of observation and understanding. Contemporary science rejects vitalism and spiritualism. However, the latter views may still be present in the contemporary thinking about life, but in a non-transparent way. Élan vital may be substituted by another concept that is difficult to define or decipher but sounds less vitalistic ("spontaneous emergence of organizational complexity," as one example). Mechanistic reductionism and dialectical materialism consider life as a fully anticipated phenomenon, which is the result of the laws of nature (Popa 2010). These philosophical views may be revealed in the definitions of life.

Life is often defined by a list of properties that are common to all life. Such list typically includes chemical components, thermodynamic properties, metabolism, compartmentation via a semi-permeable membrane, reproduction and replication, and a combination of such properties (Gayon 2010).

Autopoiesis is a concept proposed and developed by Maturana and Varela as the sole requirement for life (Maturana and Varela 1980). Autopoiesis (from Greek roots, meaning self-making) refers to life's continuous production of itself. Autopoiesis involves metabolism, which is believed to be essential for life (Margulis and Sagan 1995). An autopoietic unit is defined as an open system that is capable of sustaining itself because of an inner network of reactions that regenerate the system's components (Maturana and Varela 1980; Luisi 2006, 2016). Maturana stated: "When you regard a living system you always find a network of processes or molecules that interact in such a way as to produce the very network that produced them and that determine its boundary. Such a network I call autopoietic." Luisi lists three criteria for autopoietic system: (1) boundary of its own making; (2) self-maintenance; and (3) self-generation via a network or reactions that are generated by the system itself. If these criteria are fulfilled, the system is alive (Luisi 2016).

There are individual life forms and entities that are considered alive but cannot reproduce, such as sterile organisms. Also, self-reproduction of individuals may not be possible if the type of reproduction must include a partner, such as in the sexual reproduction. Likewise, individual humans at the life stages during which they are not fertile, such as babies and very old people, are not capable of reproducing. The requirement for reproduction is clearer when put in the context of species, rather than an individual. Various stages on the path of the life cycle of the individuals and borderline cases of life can all be covered by the term "life forms," even though these forms may not exhibit all typical characteristics for life (Liesch and Kolb 2007; Kolb and Liesch 2008).

In his article titled "Why is the definition of life so elusive? Epistemological considerations" Tsokolov analyzes the problems of defining life (Tsokolov 2009). The problems include attempts to define life with terms that may not be clearly defined. Examples include the terms "complexity" and "self-organization." Defining life via living and with terms

that seem intuitively understandable but are not sufficiently defined (e.g., complexity) may create confusion. Many definitions of life are descriptive, since they use a list of various characteristics of life. Such lists often include the uptake of nutrients and energy from the environment, metabolism, growth, reproduction, adaptation, heredity, autocatalytic reactions, chirality, compartmentation, disequilibrium, decrease in entropy, feedback loops, homeostasis, and genetic codes. Such descriptions are not ideal, since they may include terms that are not necessary or sufficient for life and that may not be characteristic of all living systems. The author also considers defining “minimal” life. For example, a minimal living cell has certain properties. If all the properties are not present, the system is not yet living. If more properties are present, the system is not minimal. The author shows the “minimal life” on a scale for continuous evolution from inanimate to living. However, the scale is arbitrary, since the borders in the continuity are arbitrary. The author also considers the concept of “arbitrarily alive” for various borderline cases of life.

Another important characteristic of life is its apparent purposefulness, which is called teleonomy (Pross 2012). It refers to the general behavior of living beings, in which they act in their own behalf and follow their “agenda,” such as feeding and reproducing. Teleonomy is evident at all levels of life, from the single-cell to multicellular levels. As one example, bacteria “swim” toward a high-glucose region, in search for food. Pross points out the similarity between the teleonomic character of life and life’s élan vital, which is a discredited concept. This is the case even when élan vital is replaced with seemingly scientific terms, such as “emergent properties of complex systems.” Pross (2003, 2012) places teleonomy on a scientifically transparent basis in his proposal of physico-chemical characterization of teleonomy via dynamic kinetic stability (DKS).

Life cycles of even the most primitive life are complicated. They include at various stages life forms that by themselves may not have properties of fully developed life. Kolb and Liesch (2008) included these forms in their definition of life: “Life is a chemical phenomenon which occurs in space and time as a succession of life forms which combined have a potential to metabolize, reproduce, interact with the environment, including other life forms, and are the subject of natural selection.” However, a question remains about the identity of individual life forms and how they relate to the fully developed life. This is best handled via the philosophy of identity, which is described in the next subsection.

2.1.3.1 PHILOSOPHICAL PROBLEM OF IDENTITY AND ITS APPLICATION TO THE DEFINITION OF LIFE

The identity problem is an old philosophical problem, which has been applied to defining life (Kolb 2010). To start with, “The Ship of Theseus” paradox, described by Plutarch in 75 ACE, raises the question of whether a ship that has all its parts replaced, plank by plank, remains the same ship. This paradox can also be applied to the living organisms. For example, one can raise questions if an organism stays the

same despite its cell turnover and if a cell that has its constituent molecules replaced in a catabolic/metabolic cycle remains the same. Different ways to handle this problem have been proposed (Kolb 2010). The identity or sameness is covered here. Identity is what makes an entity definable, recognizable, and distinguishable from other entities. When one looks at a living entity at this particular moment, in its present space, and compares it with what it was in the past when it was different (such as during its developmental life stages), and possibly also in a different space, one faces a problem in defining its identity. Either one can say that its identity remains the same, although the living entity was qualitatively different in the past, or that it is different. The latter option means that the living entities would have to have an infinite number of identities, over a continuum of time and the associated space. This would not be useful. One way out of this problem is to use the so-called numerical identity, by which an individual living entity is numerically the same, namely “one”; however, at any time and point in time/space, it may exist as a different life form. Identity of living entities during a spatiotemporal succession of its life forms can be handled by considering the identity over time (Gallois 2003, 2016). Gallois proposed that things can be identical at one time but distinct at another time. This would represent “occasional identities.” Gallois also addressed the identity issues in the case of a dividing amoeba, the subject that was discussed and further developed by Kolb (2010). The consideration of the identity problem has resulted in a new definition of life: “Life of an organism is the sum of its life forms over a period of time. We set the integral of time from the birth of the organism to its death” (Kolb 2010).

In the next section, selected examples of definitions of life are provided, together with their focus and strengths.

2.1.4 REPRESENTATIVE EXAMPLES OF TYPES OF DEFINITIONS OF LIFE AND THEIR FOCUS AND STRENGTHS

In this section, selected examples of definitions of life are listed. Each definition is followed by a short statement about its focus and strength. Definitions are listed in no special order. Note that the bibliographical source for a number of these definitions is Popa (2004).

Life 1a: the quality that distinguishes a vital and functional being from a dead body; b: a principle or force that is considered to underlie the distinctive quality of animate beings (compare vitalism); c: an organic state characterized by capacity for metabolism, growth, reaction to stimuli, and reproduction ... 5 a: the period from birth to death (Merriam-Webster’s Collegiate® Dictionary, Tenth Edition, 1993). This is an example of a lexical definition of life.

Life as a system capable of (1) self-organization, (2) self-replication, (3) evolution through mutation, (4) Metabolism, and (5) concentrative encapsulation (Arrhenius, 2002; source Popa 2004). Strength:

It gives a list of essential properties of life and is comprehensive.

Life is the process of existence of open non-equilibrium complete systems, which are composed of carbon-based polymers and are able to self-reproduce and evolve on basis of template synthesis of their polymer components (Altstein, 2002; source Popa 2004). Strength: It is specific about thermodynamic and chemical requirements.

Life may be described as “a flow of energy, matter and information” (Balscheffsky, 1997; source Popa 2004). Strength: It includes flow of information.

Life is an expected, collectively self-organized property of catalytic polymers (Kauffmann, 1993; source Popa 2004). Strength: It includes catalysis and self-organization; life is expected.

Life is a self-sustained chemical system capable of undergoing Darwinian evolution (NASA’s working definition of life; Joyce 1994, 2002; source Popa 2004). Strength: It includes Darwinian evolution and self-sustainability as criteria for life.

Life is defined as “a material system that can acquire, store, process, and use information to organize its activities” (Dyson, 2000; source Popa 2004). Strength: It includes information.

Any living system must comprise four distinct functions: (1) increase of complexity; (2) directing the trends of increased complexity; (3) preserving complexity; and (4) recruiting and extracting the free energy needed to drive the three preceding motions (Anbar, 2002; source Popa 2004). Strength: A focus on complexity.

Any system capable of replication and mutation is alive (Oparin, 1961; source Popa 2004). Strength: It gives key properties of life.

Life is self-reproduction with variations (Trifonov 2011). Strength: This is a minimal definition of life. It is like Oparin’s definition (Oparin 1961; source Popa 2004).

Life is *metabolizing material informational system* with the ability of *self-reproduction* with *changes (evolution)*, which requires *energy* and *suitable environment* (Trifonov 2011). This is a composite definition of nine groups of defining terms that were used in 123 definitions of life. Strength: It is comprehensive.

Life is a chemical system capable of transferring its molecular information independently (self-reproduction) and also capable of making some accidental errors to allow the system to evolve (evolution) (Brack, 2002; source Popa 2004). Strength: Chemical accidental errors enable evolution.

Life is synonymous with the possession of genetic properties, that is, the capacities for self-replication and mutation (Horowitz, 2002; source Popa 2004). Strength: A focus on key properties of life.

Life is what the scientific establishment (probably after some healthy disagreement) will accept as life (Friedman, 2002, paraphrasing Theodosius Dobzhansky; source Popa 2004). Strength: It reveals a drawback of stipulatory definitions, which can change.

Life is a new quality brought upon an organic chemical system by a dialectic change resulting from an increase in quantity of complexity of the system. This new quality is characterized by the ability of temporal self-maintenance and self-preservation (Kolb, 2002; source Popa 2004). Strength: It includes the origin of life as the result of abiotic-to-biotic transition via a dialectic change, and as such is expected.

Life is a chemical phenomenon that occurs in space and time as a succession of life forms that combined have a potential to metabolize, reproduce, interact with the environment, including other life forms, and are the subject of natural selection (Kolb and Liesch 2008). Strength: It includes life forms; comprehensive.

We propose that life of an organism is the sum of its life forms over a period of time. We set the integral of time from the birth of the organism to its death (Kolb 2010). Strength: It includes life forms of an organism.

It’s alive if it can die (Lauterbur, 2002; source Popa 2004). Strength: It includes death as a criterion for life.

No physiology is held to be scientific if it does not consider death an essential factor of life. Life means dying (Engels ca. 1880; source Popa 2004). Strength: It includes death in defining life.

Life (L) is a total sum (Σ) of all acts of communication (C) executed by a sender-receiver at all its levels of compartmental organization. Thus $L = \Sigma C$ (De Loof 2015). Strength: It includes communication as a criterion for life.

Life is synonymous with the possession of genetic properties. Any system with the capacity to mutate freely and to reproduce its mutation must almost inevitably evolve in directions that will ensure its preservation. Given sufficient time, the system will acquire the complexity, variety, and purposefulness that we recognize as alive (Horowitz, 1986; source Popa 2004). Strength: It gives the essential properties of life, and it includes purposefulness.

The characteristics that distinguish most living things from non-living things include a precise kind of organization; a variety of chemical reactions that we term metabolism; the ability to maintain an appropriate internal environment, even when the external environment changes (a process referred to as homeostasis); and movement, responsiveness, growth, reproduction, and adaptation to environmental change (Vilee et al., 1989; source Popa 2004). Strength: It gives a detailed list of the essential properties; it includes homeostasis.

Any definition of life that is useful must be measurable.

We must define life in terms that can be turned into measurables and then turn these into a strategy that can be used to search for life. So, what are these? (1) structures; (2) chemistry; (3) replication with fidelity; and (4) evolution (Nealson, 2002; source Popa 2004). Strength: A focus on measurables to define life.

Life is a metabolic network within a boundary (Maturana and Varela, 1980; reformulated by Luisi, 1993; source Popa 2004). All that is living must be based on autopoiesis, and if a system is discovered to be autopoietic, that system is defined as living; that is, it must correspond to the definition of minimal life (Maturana and Varela 1980). Strength: It gives autopoiesis as a criterion for life.

A living system is a system capable of self-production and self-maintenance through a regenerative network of processes that takes place within a boundary of its own making and regenerates itself through cognitive or adaptive interactions with the medium (Damiano and Luisi 2010; this is a reformulation of the original Maturana and Varela definition of living; Maturana and Varela 1980). Strength: Focus on autopoiesis.

Life is a historical process “as the mode of existence of ribosome encoding organisms (cells) and capsid encoding organisms (viruses) and their ancestors” (Forterre 2010). Strength: This definition includes viruses.

The selection of the definitions of life reflects their diversity and different approaches. They justify Popa’s statement: “We may never agree on a definition of life which will remain forever subject of a personal perspective. The measure of one’s scientific maturity may actually be his/her latest definition of life and the acceptance that it cannot be ultimate” (Popa 2010).

2.1.5 MINIMAL VERSUS EXPANDED DEFINITIONS: PROS AND CONS

In his paper titled “Vocabulary of definitions of life suggests a definition,” Trifonov analyzed the vocabulary of 123 definitions of life (Trifonov 2011). The analysis revealed nine groups of defining terms. A composite definition of these is: *“Life is metabolizing material informational system with ability of self-reproduction with changes (evolution), which requires energy and suitable environment.”* Out of these nine groups, (self) reproduction and evolution (variation) appear to be a minimal set for a concise and inclusive definition: “Life is self-reproduction with variations.” This definition is quite similar to Oparin’s definition: “Any system capable of replication and mutation is alive” (Oparin 1961; source Popa 2004).

Trifonov’s paper elicited lively responses. Some were critical of his approach, some attempted to supplement the minimal definition of life, and some presented their

own views on the matter. Examples of the responses to Trifonov’s paper are given, with selected arguments: (1) complexity could be used as a basis for defining life (Jagers op Akkerhuis 2012); (2) whether or not viruses are alive, they are clearly on a continuum between living and non-living; the existence of such a continuum complicates the search for an all-purpose definition of life (Hansma 2012); (3) life is a process, not a system (Di Mauro 2012); (4) all known biological replicators exhibit digital character, since they are polymers consisting of multiple types of monomers; digital properties are necessary for life (Koonin 2012); (5) the definition includes self-replication, which is an activity, but does not specify any quality that the agent needs to satisfy; thus, life simulations can be classified as actual forms of life (Macagno 2012); (6) vocabulary analysis does not adequately address complex words, which may not be often used, such as “cryptic information” and “energy dissipative systems” (Popa 2012); and (7) a disappointing feature of the minimal definition of life is its failure to connect with the problem of the origin or emergence of life (Tang 2012).

As pointed out by Tang, good definitions of life should connect with the emergence of life (Tang 2012). Higgs has addressed this subject in his paper titled “Chemical evolution and the evolutionary definition of life” (Higgs 2017). He suggests that a good place to put the conceptual boundary between non-life and life is between the chemical evolution and the biological evolution.

A question may be posed if a minimal definition is better than a more expanded one. The quest for a minimal definition reflects a desire to identify the essential requirements for life, which would be both necessary and sufficient for it. However, the minimal definition works by considering the lowest common denominator for life. Thus, when considering all life from bacteria to humans, highly developed intelligence of humans as a criterion for life is not included, since bacteria do not have it (Kolb 2007). This impoverishes our thinking and the overall insight of what it means to be alive at every level of life. Minimal definitions are not usually suitable to include borderline cases for life. More elaborate definitions, which include a lengthy list of the life’s characteristics, may be more useful in describing different types of life and perhaps even the gray areas of life. A disadvantage may be that at least some of these characteristics are non-essential.

In the next subsection, another philosophical approach to the definition of life, the application of Aristotelian principles, is presented.

2.1.5.1 APPLICATION OF ARISTOTELIAN PRINCIPLES TO THE DEFINITION OF LIFE

This discussion is based on the paper “On the applicability of the Aristotelian principles to the definition of life” (Kolb 2007). Here, it is specifically geared toward the examples of the definitions of life from this chapter and the arguments’ *pro* and *con* for the minimalistic definition of life. Aristotle considered a living thing by reference to a list of characteristic “life functions,” such as self-nutrition, growth, decay,

reproduction, appetite, sensation or perception, self-motion, and thinking. In “*De Anima*,” Aristotle states: “Some natural bodies are alive and some are not—by ‘life’ I mean self-nourishment, growth, and decay.” Even today, life is often defined via a list of its characteristics, as seen in the examples given in [Section 2.2.4](#). In his “*Categories*,” Aristotle developed a theory of classification of existing things. Aristotle placed an individual living organism higher in the classification than its species or genera. The reason for his belief is that the individual substance does not lose its qualities as it becomes part of a species and genera, but the converse is not true. Thus, manhood, which would be a generic description of the properties of all men in the species, is not contained in the primary substance, which is an individual man. General is not present in specific, and the abstract is not present in the real. This has a direct relevance to the question if minimalistic definitions of life, which may be abstract, are better than the descriptions of the real-life characteristics. Aristotle’s arguments are still valid today.

2.1.6 BORDERLINE CASES OF LIFE: ARE VIRUSES ALIVE? ANSWERS PROVIDED VIA DIALETHEISM AND FUZZY LOGIC

Some biological forms or entities do not exhibit critical features of life, such as self-reproduction and metabolism. Such examples include viruses, which can reproduce only with the help of their host, and they do not carry out metabolism themselves. Because of these deficiencies, and their relative simplicity, viruses are generally not considered to be alive by a large majority of the definitions of life. Some scientists state explicitly that viruses cannot be considered alive, since they are not autopoietic (Margulis and Sagan 1995; Luisi 2016). However, Forterre disagrees and sees viruses as biological entities (Forterre 2010). In his article “Defining life: The virus viewpoint,” Forterre suggests the following definition of life, which includes viruses: life is a historical process “as the mode of existence of ribosome encoding organisms (cells) and capsid encoding organisms (viruses) and their ancestors” (Forterre 2010). Viruses do replicate, albeit with the assistance of the host, they evolve and have evolutionary relationship with the host (Villarreal 2005), are ancient, and may have a link to the origins of life (Villarreal 2014), among other properties that are typically considered biological. The discovery of a giant virus that falls ill through infection by another virus (a “virophage”) has been used to suggest that viruses are alive, since they can get sick (Pearson 2008). The question if viruses are alive or not is still not resolved to everybody’s satisfaction. Villarreal saw viruses in a twilight zone of life (Villarreal 2004). Villarreal’s classic paper on the subject so far has not been surpassed. However, progress has been made in understanding viruses in general and if they are alive. For example, Forterre notices that viruses are no more confused with their virions and that they are viewed more often as complex living entities (Forterre 2010).

When considering that most of the definitions of life do not include viruses as alive, one should also reassess the process of making definitions in general. Most definitions of life are stipulative. Most of the experts in the field decide that the definition of life should capture the properties of most of life. Since viruses do not share the key features of most of life, such as self-reproduction and metabolism, they are not considered alive. Such a decision is practical, since viruses are indeed borderline cases. Stipulative definitions in general exclude cases in gray areas. Likewise, in the lexical definitions and in other definitions in which a list of various properties of life is given, only the most common properties are given. These definitions tend to cover the lowest common denominator in all life, from lowly bacteria to highly intelligent life. Bacteria do not exhibit high intelligence, so the latter property is typically not included in the definitions of life (Kolb 2007). In case of viruses, one goes even lower on the complexity scale, as compared with bacteria.

Another important factor in answering the question if viruses are alive or not is that definitions of life are often built based on the distinction between living and non-living. Aristotelian classical logic, which allows for only two answers, true and false, can deal only with the alive and non-alive options. However, some believe that there is no sharp boundary between these two options, but, instead, there are degrees and modes of “liveness” (the state or quality of having a life) (Gayon 2010). Thus, in addition to “alive” and “non-alive,” a category of “more-or-less-alive” is introduced (Bruylants et al. 2010; Gayon 2010; Malaterre 2010). This requires a departure from the Aristotelian logic. Examples include application of fuzzy logic (Cintula et al. 2017), according to which there would be degrees of being alive (alive = 1; non-alive = 0; partially alive = higher than 0 up to 1) (Bruylants et al. 2010; Malaterre 2010), which can be applied to viruses, and dialetheism, which we address next.

Dialetheism (Priest 1995, 2006; Priest and Berto 2017) does not follow the Aristotelian logic. Priest examines the limits and boundaries of the mind, thought, concepts, expressions, descriptions, conceptions, and knowing. These limits and boundaries cannot normally be crossed; yet, they may be crossed under the circumstances of transitions. Transcendence beyond these limits may create contradictions. Priest believes that some contradictions may be true and gives a simple example of a true contradiction. He considers a person leaving the room through an open door to go outside. At some point in this transition, as the person exits the room by passing through the open door, the person will be both inside and outside the room. It is important to note that this is true only for the transition situation. Thus, both the statement and its negations could be true. This belief is termed dialetheism (from Greek a two-way truth) (Priest 1995, 2006). Dialetheism would allow for both alive and non-alive options to apply to viruses (Kolb 2010). Viruses are considered non-alive based on the criterion that they cannot self-reproduce. This is true for the virion form of viruses. However, when virions penetrate their hosts, their

reproduction becomes possible via the host. Thus, in their hosts, viruses become alive, if we accept assisted reproduction as fulfilling the reproduction criteria for life. Thus, it appears that viruses can be both non-alive and alive, which is a contradiction in the Aristotelian logic. However, if we accept dialetheism, we can propose that viruses can be both non-alive and alive, as they are transitioning from the virion phase to the reproductive phase inside their hosts.

However, the non-Aristotelian logic is necessary only if one sticks to the presently available definitions of life, which exclude viruses. If additional definitions of life are formulated to include viruses, and if they become accepted, the approach of multivalued logic may become obsolete.

Finally, definitions evolve, in a predictable way. For example, stipulative definitions, which represent proposals to use a word in a certain way, can be expanded to include new findings. As more people accept the expanded stipulative definitions, they may become more widely used and, in some cases, can even become lexical (Churchill 1990). If definitions of life are formulated to include the most current knowledge of life and its borderline cases, they will become generally accepted. This is not the case at this time.

2.1.7 CONCLUSIONS

Different methods of defining life are reviewed. Examples of definitions of life are given, and their strengths are described. Minimalistic definitions of life are important, since they presumably capture the essence of life. More elaborate and descriptive definitions are also valuable. They are more suitable for describing diverse life entities than the minimalistic definitions. Descriptive definitions do not try to exclude life properties that may be deemed as non-essential, which may be wise. Problem in classification of the borderline cases of life, such as viruses, is briefly reviewed. A part of the problem resides with the definitions themselves, which address most life but not its gray areas. This problem may be surpassed if one departs from the Aristotelian logic, which would allow only two states, alive and non-alive, and uses the non-Aristotelian logic, such as dialetheism and fuzzy logic. Dialetheism allows for the states of being both alive and non-alive during the transitions, and the fuzzy logic assigns the state of life on a scale of 1 (alive) to 0 (non-alive) and the cases in between (less than 1 and higher than 0). Definitions may evolve to address new knowledge about life and its borderline cases. At some point, such inclusive definitions of life will be universally accepted, but this is presently not the case.

ACKNOWLEDGMENTS

Special thanks are due to Ben Clark for his detailed review of this chapter and many helpful comments. Donald A. Cress and Joseph Pearson have provided useful input about different definitions, as formulated in logic.

2.2.1 INTRODUCTION: WHY A DEFINITION OF LIFE?

The need for, and a proposed version of, an operational definition that intends to capture the essence of life in its most fundamental terms was presented at the ALIFE IX Conference in Boston (Clark 2004). This chapter draws heavily on the workshop-tutorial materials of that conference. However, those materials were not included in the published conference proceedings, and for that reason, the survey of previous attempts of defining life by Trifonov and his sources did not include this viewpoint (Trifonov 2011, 2012). What follows entails updates of the concept and its relevance to the work of Trifonov and those who have provided published comments on his work. In addition, this chapter addresses the reticence by some scientists and philosophers to accept the premise that a definition of life (DoL) is possible (Cleland and Chyba 2002, 2007) or useful (Szostak 2012; Tessera 2012).

Definitions of life now appear profusely in the philosophical, biological, and now even the computer literature. Biologists often independently construct lists of favorite characteristics of life as they best know it. For decades, a typical

biologist's approach has been to narrow down favorite attributes to a half dozen or so to advocate the keystones of a living system (Oparin 1965; Mazia 1966; deDuve 1991; Hickman et al. 2001; Koshland 2002). One problem has been that there is no general consensus—only three or four of these key attributes appear on all lists. A greater problem is that there are at least 104 attributes of life in the literature, many of which are non-essential, such as irritability.

Most DoLs have not been sufficiently generalized and universalized (GU) for application to alien life or artificial constructs of new forms of life (generalized, in the sense of being applicable to all currently known forms of life and non-life; universalized, by encompassing conceivable new or novel forms of life). Some DoLs seem simpler, yet are not universal. For example, the so-called NASA DoL, “Life is a self-sustained chemical system capable of undergoing Darwinian evolution,” (Joyce 1994) is precise and succinct but prescribes that the search for life, for example, on Mars, be focused on evidence for chemical functionality and an apparent requirement for independence (“self-sustained”). Furthermore, the assumption that only Darwinian evolution can be employed by an alien form of life is both fundamentally unprovable and difficult to observe.

2.2.2 NEED FOR A DEFINITION OF LIFE

The need for a DoL is sometimes questioned. “We’ll know it when we see it.” The Viking missions to Mars in 1976 adopted specific criteria but obtained inconclusive results on possible metabolic-like activities of chemically stimulated samples of Martian soil, leading to a controversy that persists to this day as to whether these missions did or did not detect life.

Billion-dollar class space missions to Mars, Europa, Titan, Enceladus, Ceres, and other planetary objects of astrobiological interest are aimed toward the ultimate objective of detecting life or evidence of past life or prebiotic activity. At these costs, it is incumbent upon astrobiologists to provide measurements whose results can be traced to well-defined fundamental objectives. Certainly, a more-accepted definition of what constitutes life as compared with non-life, including guidance on criteria that may be used to uniquely infer the presence of life activities, is needed for the fiduciary accountability of budgeting public funds for space exploration, both within and beyond our solar system.

A DoL is also of profound importance to understanding nature’s transition from inanimate milieu to the first organism. The Origin scenario remains unknown but cannot be well investigated without some concept of what is being sought.

Finally, for the sake of intellectual clarity and pedagogical responsibility to the student, it is time for biologists writing the textbooks of the future to come up with something better than: “Life is cells; cells are compartments containing proteins, nucleic acids, and other biochemicals; cells divide; read further to learn the difference between mitosis and meiosis.”

2.2.3 ELUSIVE THEORY OF LIFE

A proposal that defining life be postponed until “a theory of life” comes into being (Cleland and Chyba 2002, 2007) takes as its analogy the historical delay in recognizing that the chemical composition of water is H_2O . This line of reasoning can be challenged on several grounds. Water is a specific substance, whereas it is clear that life is a phenomenon, with many different manifestations in bulk chemical makeup.

The statement that water is H_2O , and vice versa, embodies an entire hierarchy of hidden sub-definitions. We must know that H_2O is a *molecule*; that molecules are made of *atoms*; that *quantum mechanical* (QM) rules govern the energetics and stability of *chemical bonds*, which in this case are *covalent*; that the bonding is related to QM configuration *orbitals of electrons* surrounding a charged *nucleus*; etc., etc., etc. Italicized terms in the preceding sentence require lengthy definitions, some of which will lead to additional new terms recognized only by specialists. Even QM theory has not yet been successfully applied to quantitatively predict all the physicochemical properties of water.

The thought has been that “ H_2O ” explains the substance “water.” It does not. In its form most valuable to life, water is a liquid. But it also may exist as one of several ices (amorphous or specific crystalline habits), as gaseous vapor, as a supercritical fluid, or even as a plasma. Much more serious

is that even in the ultrapure state, the liquid substance is not solely H_2O molecules. Rather, its pH is 7.0, which means that small but definite amounts of H^+ and OH^- are intimately associated with it. These “non- H_2O entities” cannot be removed. Are they water or not? The chemist would say they certainly are not—they are hydrogen and hydroxyl ions—and would further complicate the story with species such as H_3O^+ and processes such as hydrogen bonding. Owing to the ever-present galactic cosmic ray flux plus emissions of additional ionizing radiation from long-lived natural radioisotopes in soil and rock, the physicist would then point out other species that are present in this water substance, including peroxides and the solvated electron. Do we really understand all that is there to know about this substance? No, but this does not mean that we cannot define what it is for now, perhaps taking extra care to distinguish between water, the molecule (H_2O); water, the liquid (aqua); the various forms of ice; etc. Yet, every human on planet Earth is intimately familiar with water substance, its powerful effects as the dominant fluid of nature, as well as its extraordinary values to humanity, including its absolute necessity for sustenance (typically by drinking).

We may not yet understand the origins of life, but we also do not yet understand the origin of our oceans of water on Earth—whether it is mainly due to endogenous sources such as lava and magmatic degassing of rock in the Earth’s mantle or to exogenous delivery of cometary ices and hydrous asteroids during terminal accretion of the planet.

Another example of definition difficulties is “the flu.” We all are well aware of the influenza, regardless of whether we have ever directly experienced it. As a potential scourge to humanity, it is second to none. It drove to its end the First World War, but by exacting a tragic toll of 20 million human lives. Any attempt at a strict definition of “influenza” immediately encounters two critical difficulties. A broad range of outward attributes (i.e., symptoms of the disease: fever, body aches, loss of appetite or intestinal distress, and general weakness and malaise) render diagnosis difficult, especially in the face of numerous other similar but distinctly different infectious diseases (e.g., the common cold). The manifestations of influenza are thus inexact. In addition, the core cause of the disease, the influenza viral genome, comes in many different RNA sequences. As a zoonose, the next dangerous flu epidemic is likely to involve a totally new invention, a genotype never before spread on planet Earth. We cannot specify its precise composition. However, we can specify most of its sequence and many of its properties in advance. And we understand the general phenomenon in terms of how it operates, how it comes about, and how to classify it (an orthomyxovirus). The lack of a formula as precise as H_2O or lack of an unambiguous symptoms fingerprint (attributes list) does not put off a whole suite of on-going activities, ranging from investigations of its functions, studies of its etiology, and a continual search to detect new forms as soon as they appear for preparations for prevention of infectious disease in humans. Likewise, bacteria, protista, and metazoa are far more resistant to definition by their composition than simple viruses.

2.2.4 DATA BASE FOR GENERALIZATION

The full inventory of species in the biosphere constitutes a broad and diverse Data Base of Life. It is sometimes stated, however, that we cannot understand the nature of life because “we have only one example of it.” This refers, of course, to the surprising discoveries in similarities in the biochemical fundamentals of all known living organisms. A restricted set of nucleotides and amino acids, and especially their polymers, permeate our terrestrial biosphere. The mechanics of our genetic underpinnings seem to be nearly the same in all organisms, great or small, ancient or modern.

This point of view neglects, however, the astounding diversity of phenotypes that spring forth from these biochemical and genetic foundations. Seahorses and thoroughbred race horses—one a fish and the other a mammal—have little in common except the shape of their heads and the nature of their cells. Conversely, bacteria and archaea have morphologies and sizes that fall within a very restricted universe of modalities. Similar-appearing organisms can differ dramatically in terms of which energy sources they utilize (solar photons, or a wide range of chemical redox couples) and ecological interactions (independent vs. various degrees of symbioses: parasitism, commensalism, and mutualism). Life in its breadth is far more astonishing than what the science fiction writers for *Star Trek* and *Star Wars* have so far been able to imagine. Diversity in shape, size, and functionality, just in our single biosphere, provides countless examples of different implementations of life.

A wide variety of phenotypes of organisms is recognized as alive, in contrast to certain natural but unrelated phenomena having similarities. A few key examples are provided in [Table 2.2.1](#).

In the first column are numerous organisms and ecological units that are undeniably “alive,” both in common usage and scientific acceptance. In the second column, “not alive,” a set of opposite cases, is presented, some of which have been previously considered “alive” by at least some cultures, but all of which, under the illumination of scientific understanding, are phenomena or objects that are not categorized as being in the realm of the living. The third column is a set of cases about

which there has been uncertainty or debate but which can in fact be categorized by this DoL. It is the first two columns that were mainly utilized to construct this GU DoL.

Reproduction cannot be the sole criterion for life. Crystals reproduce and so do fires and even lightning—in all three cases, accelerated by auto-catalysis. These phenomena also transduce energy (“metabolize”) and grow in size. In contrast to the beliefs of the ancients, we now clearly understand the science, albeit imperfectly, behind all three phenomena. They are not life. To overcome the nettlesome problem that these are not alive, we must invoke some other property. In this DoL, the choice is to recognize that all known life forms contain an instruction set that is tied to their reproductive uniqueness and metabolic activities. These instructions are advantageously kept separated from structure and the numerous required and optional functionalities (von Neumann 1966; Poundstone 1984; Benner 2010); however, in principle, they need not be physically distinct—e.g., one-biopolymer cell (Benner 1999) and the RNA World (Pressman et al. 2015).

Reproduction also is not the essence of all living organisms. The classic example is the mule, an offspring of donkey (male) and horse (female), which itself is sterile because of a miss-match in ploidy between the two parental species. In many eusocial insect communities, the workers are non-reproductive (ants, bees, and wasps), yet they are the organisms that are essential for the propagation of the colony.

2.2.5 GENERALIZED AND UNIVERSALIZED DEFINITION OF LIFE

A simple definition of lightning is “an electrical discharge in air, arising naturally.” Yet, the phenomenon of lightning is anything but simple. Cumulonimbus cloud formation; aerosol physics; electrostatics of charging; Maxwell’s equations of electromagnetism; ionization potentials; coronal and arc discharges; streamers; bifurcation ratios; excited states of atoms; photon production and propagation; etc., all come into play.

Similarly, simplified DoLs are “system with evolvable self-replication” or “reproduction with heritance.” Yet, life

TABLE 2.2.1
Cases in the Data Base (Columns Not Meant to Always Correlate)

Alive	Not Alive	Questionable
<i>Homo sapiens</i>	Hair, fingernails, urine	Comatose human, Frankenstein monster
Amoeba	Fire, volcanoes, lightning	Organs, bone, erythrocyte
<i>Drosophila melanogaster</i>	Rivers, clouds, earthquakes	Virus, viroid, mitochondrion
<i>Bacillus subtilis</i>	Crystals, minerals	Crystal defect pattern
Lichen	Weathering rinds	Spore, cyst, seed
Birds and bees	Nest, honeycomb	Prions, organelles
Butterflies and trees	Cocoon silk, cellulose	DNA, srTn, exons, introns
Endoliths	Chondrite	Martian meteorites
Rainforest	Mahogany table	Mother Earth
Microbial mats	Fossil stromatolites	Computer virus, evolutionary algorithms
Coral reef	Coral jewelry	Replicating robots

on Earth is gloriously complex and proficient in its ability to survive, to transform, and to spread. As previously described (Clark 2001a, 2002), the fundamentals of life can be generalized and then universalized by stripping away dependencies on the specificities of terrestrial organisms, such as physical configurations (morphologies), scales of size or time, biochemical modalities, and even chemistry itself.

The DoL adopted here is in two parts because of recognition of the need to distinguish specialist organisms, which may have no *direct* role in reproduction, from the essential reproductive unit. To highlight this distinction, we combine the two individual words of “life” and “form” into a single, all-representative word encompassing the minimum reproductive set of organisms, the Lifeform (Lf). We formulate separate definitions for Life, Lifeform, and Organism. Accordingly, **Life** is any phenomenon of reproduction and activity that has the following characteristics:

A Lifeform is a single *organism*, or a collection of specialist organisms, whose ability to reproduce is enabled by a set of indispensable yet modifiable *instructions* embedded in the Lifeform.

Although this statement is simple and succinct, it alone is insufficient as a DoL because of the question of what, exactly, is an *organism*. It furthermore leaves unanswered whether there can be non-reproductive organisms. For example, in the case of humans, a very large fraction of the population consists of non-reproductive persons—including pre-puberty children, non-sexually active adults, males and females with age-related cessation of fertility, and persons born sterile or who become infertile, etc.—who are all nonetheless “alive” and enormously contributive to the success of the Lf. Thus, the following is essential to complete this DoL:

An Organism is any *physical entity* produced by a Lifeform that can, in a *suitable environment*, affect the *flow and/or conversion of energy* to perform active functions guided by a subset of the Lifeform’s instruction set.

By definition, an organism is “alive.” Some organisms are not reproductive, and some Lfs need more than one type of organism (as in sexual reproduction) to produce a single new organism. The act of reproduction is typically non-trivial. It can require the active functions of accumulation and sequestration of raw materials, their processing into useful materials, an elaborate construction process, and the mechanics of separating the new organism from the parent organism(s). Many organisms on this planet today are multi-tasking bundles of prodigious and manifold functionalities.

The organism is guided by instructions, but not all instructions are necessarily embedded in each individual organism. Forms of communication, such as mating rituals and the worker bee’s waggle dance, are in-effect instructions via which an organism’s activities are beneficial to the Lf. The ubiquitous sensing and response systems built into most organisms will automatically influence their activities, based upon environmental conditions and stimuli.

Biological reproduction is the process of copying the instructions and using them in the production of a new organism. The newly created instructions may be, for example, a faithful (cloned) or mutated copy of previous instructions or created by combining copies of instructions from two or more organisms (e.g., sexual reproduction and horizontal gene transfer).

The Lf encompasses the fundamental unit of biological reproduction.

Our definition emphasizes that environment is critical. Although most organisms are highly efficient under certain conditions, they may enter into a cryptobiotic or dormant state for ultimate survival and will succumb (die) if their environment causes damage, such that they cannot be revived. It is not just physicochemical aspects of the natural environment that are critical but also ecological features—the abundance and types of other organisms that compete directly or indirectly or that provide nutrients or a favorable environment.

It may be difficult to detect whether an entity is alive if it is simply dormant. Likewise, it may also be difficult to determine if an organism that was formerly alive is now dead rather than dormant. The condition of death may be considered as an irreversible transition to a state where an organism is no longer able to control energy to perform useful functions. The only way to ascertain this state may be, in certain cases, by providing it with an optimum, suitable environment.

The reason instructions are so crucial is that crystals, as one example, can suffer dislocations and other defects that propagate because of growth via templating. They contain no instructions per se. These differences are important for distinguishing between the substances that can grow by templating and those that can grow by spontaneous assembly but without instructional content. However, in view of self-replicating transposons (srTns) and viruses, the main distinction must be that the structural templates (genomes) encode critical instructions, which, once decoded, manifest separately from the template itself.

Compared with other definitions, certain specific departures of this DoL from others are notable. The phrase “in a suitable environment” not only makes explicit that which is not always implicit but also emphasizes the importance of organisms that can only live given the existence of other, different organisms or completely different Lfs.

2.2.5.1 THIS DEFINITION IS GENERALIZED

Extreme parasites such as viruses are sometimes considered not to be alive because of a false premise that most organisms are generally independent. The vast majority actually depend upon predation, parasitization, mutualism, or commensalism. Like well-structured computer programs, these hierarchies can be nested several layers deep—a man keeps a dog, the dog harbors worms, the worms contain bacteria, and the bacteria are infested by plasmids and phage. All are alive. Most astoundingly, the non-coding DNA that infiltrates so many genomes has been found to contain “mobile elements”—proliferating short sequences of DNA, some of which encode the keys to

their own reproduction. It is therefore the conclusion of this GU DoL that sfTns and the like are alive, representing simply another, deeper level in the broad scheme of life.

Parasites vastly outnumber primary organisms, and in that sense, they can be considered even *more* successful. Only a few classes of microbes (e.g., certain anaerobic chemo- and photo-lithoautotrophs) are fully independent of other organisms or their products. For example, the term “free living cell” is often applied to cells that may not be parasitic on a living organism but nonetheless are highly dependent on the availability of nutrients which are in the environment only because of the activities of other organisms. Thus, the synthesis of a minimal bacterial genome by knocking out all genes not required for growth has reduced the number of “essential” genes to less than 500, but the laboratory growth medium used in such investigations is rich in small-molecule metabolites, including vitamins and glucose (Hutchison et al. 2016). Truly independent life grows successfully on substances existing in the geosphere, hydrosphere, and/or atmosphere that were never metabolized by other organisms.

In the notable effort by Trifonov in 2011 to cull a minimalist DoL from 123 definitions by other workers, including the extensive compilations and analysis by Popa in 2004 and more recently in 2015, he at first summarizes properties close to those herein in a definition-1 of life, including the phrases “informational systems,” “self-reproduction,” “metabolizing ... energy,” and the often neglected “suitable environment” (Popa 2004, 2014; Trifonov 2011; Kolb 2018). However, Trifonov then eliminates several of these attributes to postulate a streamlined definition-2, that life is “any system capable of replication and mutation.”

However, any such definition-2 lacks identification of key requirements to the reader, as also pointed out in comments by others (Egel 2012). By not identifying the need for some input of energy, it neglects the fact that the reproductions performed by life would otherwise violate the inevitable increases in entropy (Schrödinger 1944), as specified in the Second Law of Thermodynamics. Invoking mutation without specifying the transmission and replication of a content of “information,” where the mutable elements (genes) are stored, neglects the breakthrough discoveries of DNA and RNA as the informational molecules at the heart of life on Earth. And eliminating the important condition of a “suitable environment” would seem to render “not alive” status to all dormant organisms, non-reproductive organisms, and highly parasitic organisms. Thus, although we agree with Trifonov (2011, 2012) that the more streamlined version-2 definition is the most fundamental core essence of life, it is not preferred because of the lack of recognition of the key components cited earlier.

An even greater departure from previous work is the distinction between organisms and what is defined here as the Lf, which highlights that for some forms of life, a collection of different organisms is needed to create a reproductive unit, for example, the male/female pair in those species locked into obligatory bisexual reproduction.

A class that is most instructive includes the example of the worker honey bee. Only the queen and drone honey bee can

accomplish reproduction, while the vast number of bees in the hive community are female “workers,” whose reproductive organs are non-functional. Nonetheless, the worker bee is very much alive by virtue of any number of traits, including vigorous metabolism, the ability to sting, purposeful unnatural movement (counter-current flight), and even intelligence. Here, we term such an entity an organism, but not an Lf. Instead, the Lifeform (as one word) is the assemblage of queen-drone-worker honeybee.

In the case of obligatory parasitism, the host is part of the Lf, willing or not. Thus, an organism can contribute to more than one Lf in certain cases.

A final detail is the difference between organisms and their non-living products. Considering the bird, its nest, and an egg, the first and third are alive, but the second is not. What is special about the nest? Passivity, but especially the lack of instructions. The nest was built, most obviously, according to a plan. This plan, a subset of instructions, is embedded in the bird, not in the nest. As a result, the nest is evidence of an organism as a biomarker but is not an organism itself. We can call such products *Tools* of the organism, to discriminate against non-useful products such as excreted wastes. Tools may be passive (shell, fur, and ant stick) or active (venom and triggered spines). The erythrocyte (red blood “cell”) is not only non-reproductive but also contains no genome or other instructions, and in this DoL, it is not considered alive, because even though it performs a metabolic function, it has no genome and none of the instruction set. Likewise, even though tractors or self-driving automobiles can control energy to perform functions, they are not alive, because they do not contain even a portion of the genome (instruction set) of the humans, who created them.

2.2.5.2 THIS DEFINITION IS UNIVERSALIZED

In order to universalize this definition, the key statements are carefully divorced from the plethora of important capabilities that so many of the most successful organisms on Earth have developed, yet that might not be essential in a less-competitive world. Even if a fundamentally different form of life once existed on Earth, it surely was subsumed (and/or consumed) by the prolific, versatile, and prodigious organisms of our current biosphere. Alternative chemistries for life have been proposed, and various forms of artificial life are possible, in which the relative importance of the roles of chemical and physical phenomena is reversed. Based upon terrestrial life, we recognize a need for organics and liquid water, yet our planet is atypically well endowed with these ingredients compared with many other bodies in this and assuredly other solar systems. In Table 2.2.2, a number of attributes that may *not* be essential to all forms of life in the universe are listed.

In order for any DoL to be fundamental, the one-hundred or so attributes of life must be derivable from it. For this GU DoL, some attributes are intrinsic (e.g., reproduction implies growth and organization, and growth implies capture of matter and energy). Most other attributes have been shown to be the plausible outcomes of evolution. Although a DoL that

TABLE 2.2.2
Some Attributes a Universalized DoL Does Not Explicitly Require

- Scale: Neither on size, nor on speed or time of existence
- H₂O or liquid water
- Organic chemistry or even chemistry
- Conventional nutrients or common energy sources
- Homeostasis or self-repair
- Mobility or motility
- Responsivity, sensors
- Hierarchical structure, intrinsic complexity
- Independence of other LFs
- Intelligence
- Other *vital* factors: Life imperative, volition, purpose, soul, Gaia, or “The Force”

ignores evolution is almost unthinkable (although some do), it is nonetheless the case here that evolution is a capability, not an essence, because the replication of instructions is unlikely to be error-free. The acquisition of valuable attributes and the invention of new features and strategies by prolonged evolution include everything from motility to senescence, from apoptosis to phototrophy, and from homeostasis to morphogenesis.

2.2.6 FORMALISM OF THIS DEFINITION OF LIFE

If a DoL cannot be considered definitive without stringent specification, an approach would be to express it mathematically. The definition for water stated as “H₂O” is actually an equation:

or,

Life is a process. As Poundstone has discussed, it is a recursive process (Poundstone 1984). Similarly, this DoL can be expressed mathematically, as a recursive relationship. With separation of dependent and independent variables:

$$I_{n+1} = r(I_n, O_n, E)$$

$$O_{n+1} = R(I_{n+1}, O_n, E)$$

where O_n is the parent organism with embedded instruction set I_n ; the O_{n+1} and I_{n+1} are the progeny organism and instructions, respectively; E represents environmental factors; and r and R designate appropriate functions of these variables. These relationships are meant to capture the process that the instruction set to produce the progeny is from a copy of the instruction set of the parent, which is then operated on by the parent organism to produce the progeny organism. In biology, copying the genome (instruction set, I) is often called

replication (r), while making copies at the organism level is often termed reproduction (R).

Generalizing to the case where multiple organisms, j_{\max} , are required to constitute the reproductive unit,

$$I_{n+1} = r(I_{n,j}, O_{n,j}, E)$$

$$O_{n+1} = R(I_{n+1,j}, O_{n,j}, E)$$

where the r and R functionalities include assimilation of all contributory organisms and instructions ($j = 1$ to j_{\max}).

The LF can similarly be expressed mathematically as the set of O and I :

$$L_f = \{O_j, I_j\}$$

realizing that the I_j is embedded in the O_j and that some organisms contain minimal instructions, whereas others (e.g., viroids and sRNA) are naked instructions.

2.2.7 APPLICATIONS OF THIS DEFINITION OF LIFE

This DoL can be applied to several questions, issues, and opportunities related to various forms of life.

2.2.7.1 ALIEN LIFE

When astronomers and planetary scientists search for H₂O in other places of our universe, they observe for such characteristics as the emission or absorption spectra of H, OH, and H₂O (respectively Lyman alpha, in the far ultraviolet [UV] wavelengths; bond stretch at near-to-mid infrared [IR] wavelengths; and rotational bands at microwave frequencies). These are special attributes of the water substance, as are phenomena such as expansion upon freezing, high specific heat, high latent heats for phase transformations, sharp melting points, and specific crystalline phases when solid.

Likewise, searches for extraterrestrial life will generally settle on certain attributes that are most amenable to measurement and reasonably indicative of living functions. The Viking life-detection instrument results remain inconclusive, but in the main because of a highly restricted set of criteria based upon chemical reactions, which, although indicative of metabolism in tested Earth soils, are now thought by many to reflect the presence of thermally labile but highly reactive inorganic chemical components in a Martian soil whose composition is exotic by terrestrial standards. In fact, nearly all attempts to identify life by one or a few attributes can be shown to have pitfalls, as delineated elsewhere (Clark 2001b, 2003, 2018). The important lesson to recognize is the difficulty of establishing that something is alive under remote or robotic *in situ* experiments. Searches for life must accordingly include a robust number of tests for multiple attributes or else for the core characteristic of reproduction with instructions.

2.2.7.2 ORIGIN OF LIFE

A recurring quandary in the hypotheses and experimental investigations into the progression of abiotic evolution to the first *bona fide* Lf is how to judge whether an entity that is on the path to become “alive” actually has reached that state. Different camps of scientists studying prebiotic evolution embrace concepts of “metabolism-first,” “replication-first,” “compartmentalization-first,” and various combinations of these. Others promote the idea that it is not even possible to define what life is and hence avoid making judgments (Cleland and Chyba 2002, 2007). It has also been pointed out that such definitions are difficult to employ in studies of the pathways to the origin of life (Szostak 2012; Tessera 2012).

However, a useful analogy is to compare “alive” and “not alive” to the common concepts of “daytime” and “nighttime.” Although we clearly recognize the difference between day and night, there are the intermediate states of “dawn” and “dusk,” when the Sun is neither all the way present nor totally absent. These intermediate states are somewhat difficult to define rigorously, without being arbitrary, yet we do not have difficulty in recognizing both day and night. Thus, the allusion to “we will know it when we see it” is not so arbitrary, as sometimes seems, in that systems being investigated could be deemed “alive,” “not alive,” or “incipient.”

Another example of intermediate states may be drawn from the common concepts of solid, liquid, and gas. When asked, most educated persons would judge an ice cube as being in the solid phase. Yet, we know that if such a solid is placed into a sealed chamber that is kept cold while being evacuated and then closed off from the pump with a valve, a sensitive pressure gauge will measure a gradual increase in pressure as the ice sublimates and the chamber is filled with a vapor, whose equilibrium concentration is dictated by the temperature of the ice. Thus, what is considered to be in the solid state is also partly in the gaseous state. Furthermore, if a light is shone on the ice, or a small amount of a suitable salt is sprinkled onto its surface, the system now manifests all three phases—solid, liquid film, and gas vapor. Yet, there are many measurement methods that can determine which regions are best described as being in which phase. Most difficult to define, however, is the thin-film liquid phase, which is intermediate between the other two phases. Perhaps, the expedient and most correct path to follow is to explicitly describe the phases for which a determination is not conclusively apparent. Likewise, as an abiotic chemical system evolves from non-living to creating living entities, the various stages could be described without recourse to pre-determined nomenclature which could be inadequate, misleading, and/or superfluous.

The motivation often seems to have been to be able to state with precision whether life has been created at some certain point, or not, in the laboratory or by prebiotic nature itself. Certainly, when some reproductive entity finally became firmly established on Earth, it was a tipping point in that the evidence suggests an unbroken chain for several billion years in which the biosphere evolved and flourished. However, in analogy with the human reproductive cycle, is the critical

tipping point ovulation, or ejaculation, or fertilization, or embryogenesis, or fetal development, or birth of baby, or puberty, and so forth? Clearly, these are all “critical events” to borrow a phrase from space exploration. In a successful space mission to Mars, there are multiple critical events ranging from rocket launch, spacecraft separation, navigation to Mars, atmospheric entry, and landing to deployment of instruments and sample-processing equipment. Virtually, all critical events are essential for the overall success of the mission.

Perhaps, the most constructive approach to assessing the origin of life is to continue focusing on the various scenarios and series of critical events that must occur until achievement of the final, fully capable reproductive system. This system must include not only the physical form necessary but also the functional capabilities and the information package that enable it to evolve as it spreads and thus always produce some organisms that can survive one or more of the plethora of insults that the exogenous environments will hurl at them.

2.2.7.3 COMPUTERS AND NETWORKS

“Soft Life” is taken to be that generated by software. Once the final software program step is written, debugged, and properly executed in a code whose overall functionality includes reproduction enabled by instructions and active control of a flow of energy, the criteria for life have been met. Of course, such soft entities do need a suitable environment, which entails a computer, server, or mobile electronic device. In addition, in order for the progeny programs to spread, there needs to be inter-computer connections, preferably a large network (e.g., the Internet). As has been advocated by some, software programs that operate in computers in effect create physical entities, since they occupy physical locations in memory elements and affect the flow, for example, of read-write energy. What is often called “virtual life” is not ethereal, after all. Even as they multiply in memory via a program simulating population growth, or as a “computer virus” (CV) propagated over a network, various physical phenomena occur (electromagnetic waves, electrical currents, and switched states of magnetic domains), creating new physical entities independent of their parent. Computer viruses are alive, not as parasites of organic bodies but as the inanimate tools of *technosapiens*, the “suitable environment” of interconnected general-purpose computers. True, they readily are migrated from one physical assemblage to another, as the computer manages its storage space, but at any instant, they exist in at least one copy in a physically specifiable form. This DoL is invariant with time-scale. Teleportation may not be possible for metazoans, but it is commonplace for computer organisms.

Evolutionary algorithms are not reproductively proliferative, in general, and hence are not alive by this DoL. They do accomplish evolution in the sense of adaptation by feedback, and they often are designed to mimic biologically known enhanced methods for speeding evolution, such as chromosome crossovers and gene duplications. Self-expanding program codes are also well known and relatively simple to generate but generally represent growth rather than reproduction.

2.2.7.4 CREATING CHEMICAL LIFE IN THE LABORATORY

Laboratory efforts at Test Tube Life may formally satisfy this DoL and also the NASA DoL by way of explicitly demonstrating Darwinian evolution. Already more than three decades ago, the Spiegelman team achieved accelerated evolution in the test tube to create new variants of the RNA virus *Qβ* (Spiegelman et al. 1965; Mills et al. 1967). Much of the current work on this general topic, for example, by several groups (Rasmussen et al. 2004, 2016; Joyce 2007; Powner et al. 2011; Robertson and Joyce 2012; Pressman et al. 2015; Islam and Powner 2017; Sutherland 2017; Szostak 2017), focus on achieving results consistent with concepts of the RNA-World model, using success criteria similar or identical to the NASA DoL. Correspondingly, the use of informational macromolecules and suitable translation chemistries satisfies the first part of the GU DoL given previously. By using molecular evolution for achieving enhanced efficiencies in catalysis of one or more functions of the system and by providing substrates from which energy can be extracted, these experiments also satisfy the second part of this definition. However, the “suitable environment” is an artificial one, not a natural one, and the ultimate challenge will be to develop an assemblage of molecules that conceivably have resulted from a natural environment that at one time (or more) occurred on the early Earth. Although originally highly contrived, these approaches are showing considerable progress.

Rebuilding of functional viruses and genomes for cells by using purely *in vitro* systems is an example of synthetic biology investigations that are actively creating new versions of life.

2.2.7.5 CITIZEN SCIENCE

This DoL is more easily discussed with the lay public than many, if not most, definitions posited previously. Some DoLs are actually obtuse even to the science community. Although it is not a requirement imposed on scientists, in general, to use popular terminology, it is worth acknowledging that research into the origins of life, although fascinating, is seldom at an intrinsically high priority for funding through public support.

In this definition, an analogy to a soccer team could be made—the “Lifeform” is the team itself, and the players are the “organisms.” Other organisms in this Lf are the coaches and support personnel. The opposing team is another instance of the same type of Lf. The referees constitute a totally different Lf but are parasitic on the soccer teams. There are also artifacts/tools, such as the soccer ball, the playing field, turf, line markings, and goal. A set of formal rules constitutes instructions that are essential to defining and guiding the game of soccer. These instructions are subject to revision, that is, evolution. Of course, we don’t see any of these Lfs actively reproducing, but we know in fact that, somehow, they do, because there appears to be more and more soccer teams all the time. Likewise, it is rare to observe many organisms actively reproducing in nature, because those acts are rare compared with daily life. Yet, they somehow always occur, or the Lf would not persist.

A DoL should also pass the reasonableness test. Thus, to say that a mule is not alive because it cannot self-reproduce seems to fly in the face of common intuition. Furthermore, little children are eminently alive, yet not capable of reproduction.

And to say that a virus is not alive, despite the fact that the professionals who conduct the scientific study of viruses are biologists, biochemists, geneticists, and medical and pharmacology researchers, seems likewise to violate the common-sense logic of any thoughtful external observer.

2.2.7.6 MACHINE LIFE

Finally, we must most seriously contemplate machine life and its potential ramifications. This GU DoL is fully consistent with the concept of a “mesorg,” a mechanized, electronics-based, software-driven organism. To be classified as being “alive,” such a machine must include enabling instructions sufficient for its own reproduction. Robots, regardless of type—industrial, recreational, or financial—are distinctly not alive, because none of the instructions for their manufacture are embedded within them. The production of robots is not recursive. Indeed, the concept of “six-sigma” manufacturing is to strive for exact duplication of a specific product, fully faithful to a standard design. On the other hand, as a result of product development engineering, a new model that is only a variant of a previous robot (or any artifact) may be put into production.

In this sense, products evolve at the hands of humans. As such, they remain under strict control by their creators. Furthermore, if the designs, procedures, and software, carefully locked away somewhere in a safe (or server), were somehow destroyed, there would be no possibility of faithful reproduction of the same product, except possibly by reverse engineering. A widespread Lf, on the other hand, confers massively parallel redundancy, with distributed organisms capable of propagating the basic design.

A mesorg need not, by virtue of “a suitable environment,” fabricate all of its own components from scratch—it is not necessary to construct electronic devices by extracting silicon from silica sand, to invent new software languages and subprograms, or to reinvent wheels, gears, and latches. Hardware designs and software can be borrowed and then modified until the transition occurs, such that reproduction occurs in a manner that is controlled, at least in part, by instructions embedded in each mesorg itself. This departure from the “complete description” specification in the von Neumann/Poundstone views of life is an important extension (von Neumann 1966; Poundstone 1984); however, it in no way is in disagreement with their penetrating insights overall.

With a mere modicum of intelligence, somewhere between a honeybee community and an assembly worker in a human factory, a mesorg could strike out on its own. Darwinian- and Lamarckian-type evolutions could occur, including the potential for speciation. From a minimalist mesorg, initially highly dependent upon *technosapiens*, such evolution as well as pirating could evolve measures of progressive independence, just as humankind has achieved an amazing degree

of success in taming its own environment. Although such an Lf might always be dependent on the technologies of humankind, it would nonetheless be alive and could exhibit many of the attributes of other Lfs and organisms.

2.2.8 ETHICS OF CREATING NEW LIFEFORMS

The chain of sequential propagation with every progeny slightly or significantly different from its parent(s) creates ever-expanding lines of independent diversity. Changes that are beneficial to Lf XYZ may be competitive or otherwise threatening to one or more other organisms, including its own parents. Thus, we reach the attribute most usually not explicit, although many of us are aware of it implicitly. That attribute is conspicuously self-centric with respect to our own Lf. Variously called hazardous, dangerous, or deleterious, that attribute is certainly not the essence of life. But it is an attribute of several natural Lfs, the predators and parasites of humankind, as well as what we do to our supporting species (crops and domestic animals).

All artificial Lfs, whether wet, soft, or hard, have the potential to do damage to the biosphere and therefore require sober control. Genetically engineered organisms and machines that could become alive should be a concern to *Homo sapiens*, just as are those many forms of life that are already problematical (from viruses to microbes to mosquitoes to dangerous animals) and that we either protect against, domesticate, or have exterminated.

ACKNOWLEDGMENTS

Any novel formulations above are the responsibility of the author, but an enormous body of work by numerous researchers underlies the basis for the discussions, clarifications, and examples herein. The encouragement, thoughtful review, and editorial assistance by V. M. Kolb are gratefully acknowledged.

2.3.1 INTRODUCTION

This chapter presents the current state of the art in creating microorganisms with synthetic genomes. Cloning of bacterial genomes in yeast as centromeric plasmids and transplantation of genomes from one bacterial species to another are described. Methods of DNA synthesis and genome assembly, as well as progress on automation of DNA synthesis, are reviewed. The classification of genes as non-essential, quasi-essential, or essential and identification of those required for minimal life are discussed. Synthesis of a minimal bacterial genome and its installation into a compatible cytoplasm to produce a minimal synthetic cell are described. Progress with synthetic yeast chromosomes is reviewed. Finally, a digital-to-biological converter (DBC) that uses DNA sequence information stored in a computer to direct the automated production of biological materials such as DNA, RNA, proteins, and bacteriophages is described.

2.3.2 DEFINITION AND BRIEF HISTORY OF SYNTHETIC CELLS

Cells are the fundamental units of life. They reproduce and carry out multiple chemical processes by virtue of the genetic information carried in their genomes. Recent advances in DNA

synthesis now make it possible to synthesize entire genomes of some single-cell microorganisms. A synthetic cell is one that is controlled by such a chemically synthesized genome. It will generally contain various features that do not occur naturally, such as changes in codon usage, modular design, and addition or removal of genes. Cells whose genomes are copied from natural DNA templates by using DNA polymerases or cells with genetic modifications introduced by genetic engineering, even if some parts of the genome were made synthetically, are not included.

Although a synthetic cell could be of any type, it is currently feasible to synthesize only the genomes of single-cell microorganisms, specifically bacteria and yeast. Generally, the properties of bacteria are completely determined by information carried in their DNA genomes. Thus, whether a synthetic cell is created by installing a synthetic genome into an existing recipient cell and replacement of the recipient genome, or alternatively, was somehow created entirely from non-living cell parts plus a synthetic genome, the result would be the same (Figure 2.3.1). Examination of the resulting cell after several generations of growth would not reveal the path by which it was created. This holds strictly for bacteria and archaea but may not precisely hold for eukaryotes, since mitochondria also contain essential information, and epigenetic information such as DNA methylation patterns may not be easily reproduced in the synthetic genome.

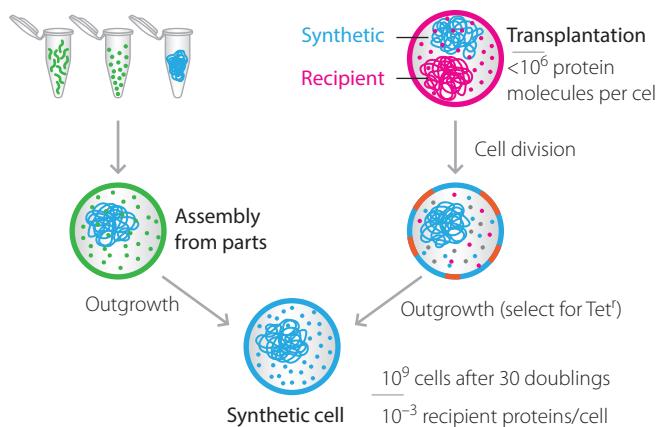

FIGURE 2.3.1 The final synthetic cell is the same, regardless of the path by which it was created. The path on the left involves assembling the synthetic cell from non-living parts, including the synthetic genome. The non-living parts might be those specified by the synthetic genome or by the recipient cell or any other set of parts compatible with assembly of a living cell programmed by the synthetic (blue) genome. In the path on the right, a synthetic genome (blue) is transformed into a recipient cell (red), followed by genome segregation and outgrowth of daughter cells containing only the synthetic genome. After many doublings, the original parts of the recipient cell have been replaced by those specified by the new (blue) genome. The original parts of the recipient cell (red) are diluted following loss of the recipient (red) genome. A mycoplasma cell contains fewer than a million protein molecules. Thirty doublings following the loss of the recipient genome will produce $\sim 10^9$ daughter cells. So, after 30 doublings in the absence of the recipient genome, a typical cell will contain no protein molecules at all from the original recipient cell.

Synthetic cells are currently made from genes that are found in existing natural organisms. No one yet has the knowledge to create genes *de novo* specifying proteins or RNA with new functions; however, this may change at some point in the future. The design of synthetic cells is thus entirely dependent on knowledge of the genetic repertoire of existing organisms. The first complete gene complement of a living cell, that of *Haemophilus influenzae* Rd, was determined in 1995 (Fleischmann et al. 1995). Since then, thousands of organisms have been sequenced, and the repertoire of genes and genomes in GenBank is enormous.

Sequencing technology has evolved rapidly, especially with the development of highly parallel, chip-based next-generation sequencing (NGS) (Attia and Saeed 2016). However, DNA synthesis capability lags far behind. In 1970, Khorana and coworkers were the first to develop the chemistry for synthesizing DNA and apply it to the synthesis of the gene for yeast alanine transfer RNA (tRNA) (Agarwal et al. 1970), but it was not until 2002 that a full genome, that for the 7.5 kb polio virus, was synthesized as a DNA molecule that could be transcribed to make the RNA genome of the virus particle (Cello et al. 2002; Wimmer 2006). In 2003, the bacteriophage phiX174 genome (5.3 kb) was synthesized by

whole-genome assembly from 256 oligonucleotides (Smith et al. 2003). Only in the past dozen years has DNA synthesis advanced to the point that small bacterial genomes can be made in the laboratory by chemical synthesis (Gibson et al. 2008a, 2010a; Hutchison et al. 2016).

The smallest known bacterial genomes belong to the genus *Mycoplasma*. The smallest among these is *Mycoplasma genitalium*, a wall-less bacterium that inhabits the human urogenital tract and can be grown independently in the laboratory. Its genome was synthesized in 2008 and was propagated as a yeast centromeric plasmid (Gibson et al. 2008a). In 2010, the *Mycoplasma mycoides capri* genome was synthesized and activated by transplanting into the closely related *Mycoplasma capricolum* to yield a synthetic cell, syn1.0, that differed only slightly from the wild-type cell (Gibson et al. 2010a). The syn1.0 genome was subsequently used to create the first nearly minimal genome, as described in [Section 2.3.6](#) (Hutchison et al. 2016).

2.3.3 PROPAGATION OF GENOMES IN YEAST (*SACCHAROMYCES CEREVISIAE*)

Sections of a bacterial genome can be synthesized in the test tube, but since DNA is fragile and shears easily when handled in solution, it is impractical to assemble complete genomes in solution. The discovery that complete bacterial genomes can be propagated as centromeric plasmids in yeast cells has solved this and other problems in the generation of synthetic genomes (Gibson et al. 2008a; Benders et al. 2010). Propagation of bacterial genomes in yeast has become invaluable because:

1. A complete synthetic genome can be assembled by recombination in yeast from overlapping synthetic genome segments that share terminal DNA sequences.
2. Propagation in yeast permits cloning of a synthetic genome by selecting single yeast colonies. This is important because the production of synthetic DNA is an error-prone process and cloning is essential to ensure a pure source of the desired sequence.
3. Growth of yeast carrying a synthetic genome provides a source of a cloned synthetic genome for further experiments, including sequence verification.

To clone a bacterial genome (or segments thereof) in yeast, it is generally necessary to add several genetic elements. These may be combined into a tri-shuttle vector (Benders et al. 2010) that includes:

1. A yeast selectable marker. The *HIS3* gene has usually been used, and the genome has been introduced into a histidine auxotroph of yeast, lacking a functional *HIS3* gene. Growth on medium lacking histidine allows the selection of yeast cells stably carrying the bacterial genome.

2. A yeast centromere. *CEN3* or *CEN6* may be used. This allows the bacterial genome to duplicate and segregate as a chromosome in the yeast nucleus.
3. A yeast origin of DNA replication or autonomously replicating sequence (ARS).
4. Sequences required for replication and selection of the cloned bacterial DNA in *Escherichia coli*, for example, the pUC19 origin and the *TetM* gene. The *TetM* gene also serves as a selectable marker to allow isolation of bacterial cells into which the vector has integrated.
5. Such vectors also sometimes carry a transposase gene to facilitate random integration into the genome.

A synthetic genome can be assembled by transforming yeast with a set of overlapping synthetic DNA fragments that span the entire genome (Figure 2.3.2c). The ends of fragments adjacent on the genome overlap, typically by 40–200 bp. One of the fragments contains the yeast vector (described earlier). These fragments assemble by genetic recombination between their overlapping terminal sequences. A synthetic *M. genitalium* genome was assembled from as many as 25 overlapping fragments in this way (Gibson et al. 2008b), but typically synthetic mycoplasma genomes have been assembled from 8–10 segments.

It is also possible to clone complete genomes, isolated from bacterial cells, into yeast (Figure 2.3.2a and b). A yeast vector carrying a transposase gene can be introduced into the bacterial cell by polyethylene glycol (PEG)-mediated transformation

or by electroporation, depending on the type of cell (Figure 2.3.2a). Following transformation, cells with the integrated vector are selected by plating in the presence of tetracycline. Individual colonies are picked, and the integration site can be determined by sequencing from the vector into the adjacent genomic sequence. Because colonies with the integrated vector are selected, one can be sure that the vector is not disrupting any gene or other sequence that is necessary for viability of the cell. The genome can be released from the cell by lysis of the bacteria in agarose plugs, to prevent shearing of the genome during lysis. Then, the genome can be released from the agarose plug by melting and treating with β -agarase. Next, the genome is introduced, by PEG-mediated transformation, into a yeast strain carrying an auxotrophic marker in the *HIS3* gene. Selection of yeast carrying the bacterial genome is accomplished by selecting yeast colonies on a -His plate (Benders et al. 2010).

As an alternative to random integration of a yeast vector, the vector can be designed to recombine with the bacterial genome at a specific location (Figure 2.3.2b). If the genome is cleaved at the designed vector integration site, then recombination is facilitated when the isolated cleaved genome is co-transformed with the yeast vector.

Genomes can be transferred directly from bacteria to yeast under conditions that promote cell fusion (Karas et al. 2014). In some situations, this is a useful alternative to transplantation of an isolated DNA genome.

The completeness of a bacterial genome carried in yeast can be verified by using multiplex polymerase chain reaction

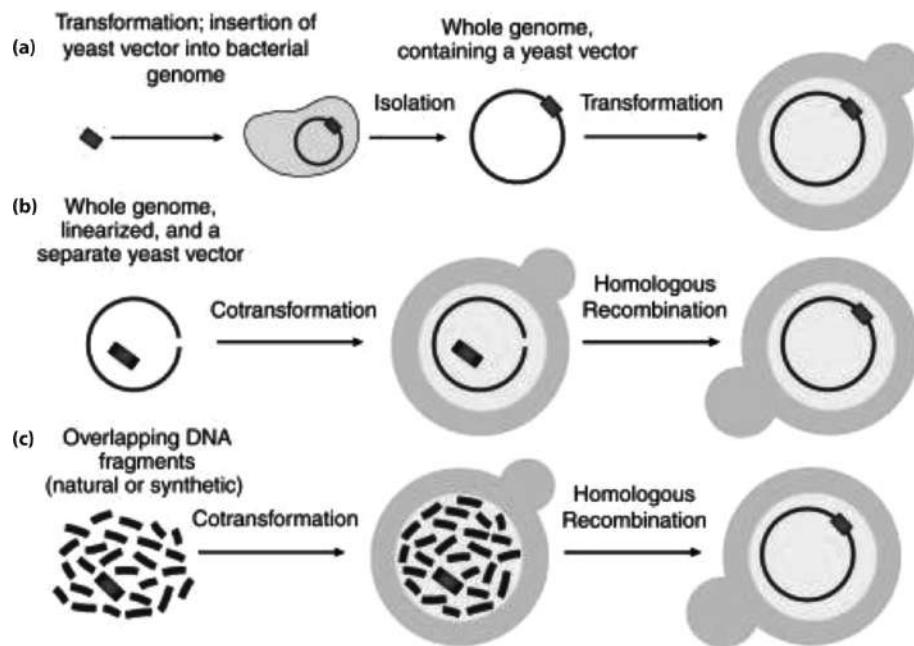

FIGURE 2.3.2 Three methods for cloning mycoplasma genomes in yeast. In order to be propagated by yeast, upon transformation, the bacterial genome must contain several yeast sequences (vector, black bar). (a) These can be incorporated into the bacterial genome by transformation of the bacterium. (b) Alternatively, they can be inserted by co-transformation of yeast with the vector and the bacterial genome. In this case, the two must share overlapping sequences, so that yeast can combine them by homologous recombination. (c) The bacterial genome can also be cloned by assembling multiple overlapping fragments.

(PCR) to detect junctions between adjacent overlapping segments. The mycoplasma genome is inherently quite stable when propagated in yeast. However, to avoid deletions in the mycoplasma genome, unnecessary propagation of the genome in yeast should be avoided.

The cloning of bacterial genomes into yeast has been accomplished for a variety of bacteria, including several *Mycoplasma* species (0.6–1.1 Mb) (Benders et al. 2010), *Acholeplasma laidlawii* (1.5 Mb) (Karas et al. 2012), *Prochlorococcus marinus* (1.6 Mb) (Tagwerker et al. 2012), and *H. influenzae* (1.8 Mb) (Karas et al. 2013). For genomes with a higher G + C content, it has been necessary to insert ARS elements into genomic sequences to permit cloning of large segments (Noskov et al. 2012).

2.3.4 TRANSPLANTATION OF GENOMES FROM ONE SPECIES TO ANOTHER

A bacterial genome can be propagated in yeast and gently extracted, but it is of little value unless it can be activated in a suitable recipient cell. The process of genome transplantation has been developed at the J. Craig Venter Institute (JCVI) to achieve activation of complete synthetic genomes. So far, transplantation has only been reported in several species of the genus *Mycoplasma* (Lartigue et al. 2007; Labroussaa et al. 2016) and in the closely related mollicute *Mesoplasma florum* (Baby et al. 2018). Other bacterial genomes could be engineered in yeast cells and then transferred piecemeal into bacterial cells by using genetic recombination.

In genome transplantation, a donor genome is prepared by gently lysing cells embedded in agarose plugs. The cells can be mycoplasma or yeast cells, carrying either a natural or a synthetic genome. The genome to be transplanted carries a selectable genetic marker such as a drug-resistance gene (typically *TetM*) to allow selection of cells carrying a transplanted genome. Cellular proteins are digested in the agarose plug, and then, the plug is digested with β -agarase. Recipient cells for the transplantation are usually a different mycoplasma species than the donor genome and are tetracycline-sensitive. The recipient cells are grown under standardized conditions, washed, and resuspended in calcium chloride. The donor genome preparation is mixed with the recipient cells under transformation conditions by using PEG. Growth medium is added, and the cells are incubated at 37°C for several hours. The cells are then washed and plated on solid medium containing tetracycline, under selective conditions.

Under selection for the tetracycline-resistance marker (*TetM*) on the donor genome, the recipient cell genome is lost following repeated rounds of cell division. All cellular components are replaced by those coded by the donor genome, as shown in Figure 2.3.1 (right-hand pathway). Tetracycline-resistant colonies carry only the transplanted genome, which can be verified by genome sequencing. Typically, the donor genome is either *M. mycoides* or a synthetic genome based on *M. mycoides* genes and the recipient is *M. capricolum*. These genomes are easily distinguishable at the sequence level.

The published synthetic genomes, such as JCVI-syn1.0, JCVI-syn2.0, and JCVI-syn3.0, have all been verified by complete genome sequencing (Gibson et al. 2010a; Hutchison et al. 2016).

2.3.5 CHEMICAL SYNTHESIS OF DNA

Synthetic biology is genetic engineering that uses chemical synthesis of DNA as the major method for constructing genetic parts. Breakthroughs in low-cost, accurate, and rapid DNA synthesis are having wide-reaching implications for the growing synthetic biology community. Cost, accuracy, and speed have been major inhibitory factors to the development of the field and to widespread applications. Synthetic biologists are synthesizing and expressing genetic elements to provide a sustainable means for producing desirable products such as new and improved therapeutic drugs, vaccines, biosensors, biofuels, biochemicals, food ingredients, and cosmetics. With chemical synthesis of genes, pathways, and genomes becoming faster, more precise, and only pennies per base pair, the technology is becoming more prevalent. Researchers are picking promoters, genes, terminators, and regulatory sequences from vast genomic and metagenomic databases and beginning to experiment with various pathway constructions on an empirical basis. This, in turn, is significantly accelerating progress, reducing development time, and increasing the probability of success in developing valuable products derived from synthetic DNA.

DNA can be synthesized in the laboratory, either enzymatically or chemically, but there is an important difference. Enzymatic synthesis requires template DNA, whereas chemical synthesis does not. This lack of necessity for a template allows tremendous flexibility in the design of new sequences. For example, codon usage of a gene can readily be changed, or genes from any source can be added, deleted, or rearranged in a genome in any fashion compatible with life.

Chemical synthesis of DNA always starts with oligonucleotide building blocks of a few dozen nucleotides in length that are made by chemical joining of single nucleotides. All the DNA in a synthetic genome is derived originally from chemically synthesized oligonucleotides. Duplex DNA molecules of several hundred base pairs in length are made by joining oligonucleotides together. Subsequently, duplex DNA molecules are joined to form larger and larger DNAs in steps that employ enzymatic synthesis; however, the precursor DNA is from synthetic oligonucleotides. The steps in producing genome-sized DNA molecules are described in Sections 2.3.5.1 through 2.3.5.5 and Figure 2.3.5.

2.3.5.1 OLIGONUCLEOTIDE SYNTHESIS

Oligonucleotides are the building blocks of synthetic biology. They are the starting material, from which genes, pathways, and even genomes are synthesized, and these, in turn, enable products, such as medicines, biofuels, and biochemicals, to be developed. Khorana developed chemistry for oligonucleotide synthesis in the 1960s (Khorana 1968, 1972; Caruthers et al. 1972). His

original methods were greatly improved during subsequent decades (Caruthers 2013). Currently, DNA oligonucleotides are most frequently made inexpensively by computer-controlled solid-phase automated synthesizers. To make a desired oligonucleotide, phosphoramidite 2'-deoxynucleoside dA, dC, dG, and T building blocks are sequentially coupled to the growing oligonucleotide chain in the order specified. The product is then released from solid support, deprotected, and collected. Oligonucleotides always contain a low frequency of errors, because coupling steps are not 100% efficient and accurate, and thus, achieving error-free synthetic oligonucleotides becomes the most significant factor as the oligonucleotides are assembled into larger DNA molecules.

Oligo providers, such as Integrated DNA Technologies (IDT), offer individual tubes of oligos, which contain a unique sequence, at a price of ~\$0.10/base. The cost remains high owing to inefficient reagent use during the chemical synthesis process. Oligos are generally produced at the nanomole scale, which translates to consumption of only 0.01% of each oligo with oligo assembly methods. Microarray chip technologies offer a low-cost source of oligonucleotides and have the potential to significantly decrease the overall synthesis costs by more than an order of magnitude (Kosuri et al. 2010). However, these oligos are of very low concentration and in a single, complex mixture containing thousands of unique oligonucleotides, which make them difficult and unreliable to process and consequently reduce turnaround time.

Although oligonucleotide synthesis is drastically better than what it was 40 years ago, this process continues to produce a fraction of unintended DNA sequences, which will be more prevalent in longer synthetic DNA fragments. Excluding microchip DNA technologies, which traditionally have significantly higher error rates, the synthesis error rate for the assembly of standard oligonucleotides is generally about one error per 1000 bp. Thus, it should be expected that if oligonucleotide errors are not weeded out early on in the building process by, for example, cloning and sequencing or with an error correction procedure, most, if not all, DNA fragments above 10 kb will contain errors. Cloning and sequencing procedures that identify error-free DNA products or subassemblies can be very effective but reduce turnaround time and increase DNA synthesis costs.

2.3.5.2 ASSEMBLY OF OLIGONUCLEOTIDES TO MAKE PIECES OF DUPLEX DNA

Recent methods, including our own, have reduced the bottlenecks for the assembly of oligonucleotides into genes and genes into pathways and genomes. Overlapping oligonucleotides (oligos), typically 20–50 nucleotides in length, are generally assembled into larger duplex DNA molecules by either of two methods. If adjacent oligos perfectly overlap each other without gaps, they can be ligated together to form assemblies of varying size, up to a few hundred base pairs in length (Smith et al. 2003). If the oligos overlap with

single-stranded gaps, then polymerase cycle assembly (PCA) is used. This is essentially set up as a PCR, except that there is no amplification, since all of the oligos are at approximately the same concentration, including the terminal 5'-oligos. If the terminal two 5'-oligos are in excess over those in the interior of the assembled product, then both assembly and some amplification can take place.

Synthetic Genomics, Inc. (SGI's) Archetype™ software is configured to allow for a DNA sequence to be instantly converted into a synthesis paradigm, starting from the overlapping oligonucleotide sequences that need to be synthesized. In general, oligonucleotides are designed to contain (1) 30-bp overlaps between adjacent 60-base single-stranded (ss)DNA oligos; (2) 40-bp overlaps between adjacent dsDNA fragments; (3) universal primer-binding domains for PCR amplification of the assembly intermediates; and (4) restriction sites to release the primer-binding domains following PCR amplification.

Adjacent oligos are combined ~50 at a time to build ~1.5 kb DNA fragments. Following oligo assembly and PCR amplification, error-containing DNAs are selectively removed by an endonuclease (identified in Archetype™ by SGI's scientists) to reduce error rates caused by imperfect oligonucleotide synthesis. This "error correction" process starts by denaturing and annealing the PCR products. Because the majority of the DNA molecules in the population contain the correct DNA sequence at every position, heteroduplex DNA will be formed at sites containing a substitution, deletion, or insertion.

These regions are recognized and cleaved by the endonuclease. Because intact molecules amplify more efficiently than nuclease-digested DNA, PCR can be used to enrich for error-free synthetic fragments. It has been found that this error correction procedure can reduce error rates by 1–2 orders of magnitude per round. For example, one round of error correction can reduce the average number of errors per 30 kb construct from about 30 to 3 or 0.3. If necessary, multiple rounds of error correction will be used. These methods allow one to avoid using a biological intermediate, such as *E. coli*, to filter out error-containing DNA, which slows down the DNA construction process.

2.3.5.3 ENZYMATIC ASSEMBLY OF PIECES OF DUPLEX DNA: FROM SMALL TO LARGE

Following error correction and PCR, the synthetic DNA fragments are separated from their primer-binding domains by restriction enzyme digestion to expose overlapping sequence with adjacent fragments. Several *in vitro* enzymatic reactions capable of assembling genome-size molecules from multiple overlapping DNA fragments have been previously described (Gibson et al. 2009; Gibson 2011). The simplest of these recombination methods can be carried out as a single isothermal reaction. The assembly reaction mixture in this system (commonly referred to as Gibson Assembly) contains a 5' exonuclease, a DNA polymerase, and a DNA ligase working in

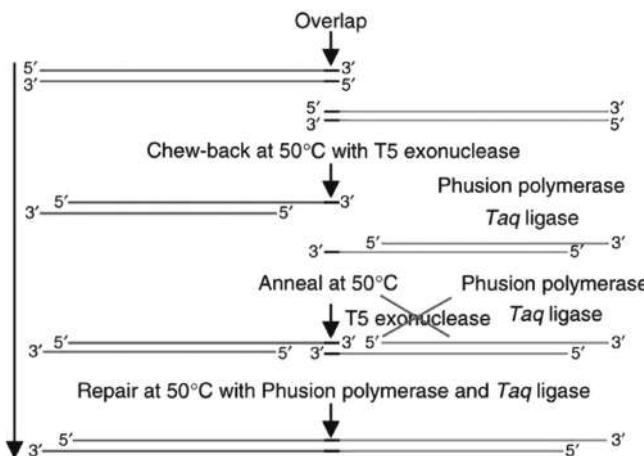

FIGURE 2.3.3 Two adjacent DNA fragments sharing terminal sequence overlaps (black) are joined into a covalently sealed molecule in a one-step isothermal reaction. T5 exonuclease removes nucleotides from the 5' ends of double-stranded DNA molecules, complementary single-stranded DNA overhangs anneal, Phusion DNA polymerase fills the gaps, and *Taq* DNA ligase seals the nicks. T5 exonuclease is heat-labile and is inactivated during the 50°C incubation.

harmony to accomplish the seamless joining of multiple DNA fragments during a brief 50°C reaction (Figure 2.3.3).

Other *in vitro* methods that are both seamless and sequence-independent include circular polymerase extension cloning (CPEC), In-Fusion (Clontech®), uracil-specific excision reagent (USER), and sequence- and ligation-independent cloning (SLIC) (Hughes and Ellington 2017). Although these methods have been useful in the assembly of DNA up to the size of small genetic pathways, they have not been used in the construction of larger DNA molecules such as whole genomes. The Gibson Assembly system does not rely on thermocycling to bring overlapping parts together, and the assembled sub-fragments are covalently joined with DNA ligase, reducing the likelihood of fragmentation of large DNA molecules. In addition, ligated DNA assembly products are more efficiently moved into host organisms such as *E. coli*. Gibson Assembly was used to rapidly synthesize the entire 16,520-bp mouse mitochondrial genome from 600 overlapping 60-base oligonucleotides (Gibson et al. 2010b). It was also used in combination with yeast assembly to synthesize syn1.0 and syn3.0.

2.3.5.4 AUTOMATION OF DNA SYNTHESIS

A variety of DNA synthesis and assembly methodologies that lead from oligonucleotides up to whole chromosomes have been previously developed. Since first reporting on the Gibson Assembly method, several improvements have been made, including (1) increased robustness of the reactions by redesigning how oligonucleotides assemble; (2)

FIGURE 2.3.4 The BioXp DNA printer. The desired gene sequence is submitted to sgidna.com. Custom reagents are received, the BioXp is loaded, and the run is begun. Oligonucleotides are assembled, and errors are corrected. After the run is completed, the duplex DNA tiles are collected.

increased synthesis speed by assembling more oligos at once; and (3) increased accuracy by introducing an endonuclease-based, error-correction step. By reducing error rates, speed is increased, in turn, as cloning and sequencing requirements are reduced or eliminated. By improving the robustness of these procedures, it was found that the processes described earlier were highly amenable to automation. With this in mind, a “DNA printer” was developed, called the BioXp (Figure 2.3.4); it combines these workflows to build highly accurate synthetic genes. The synthetic DNA fragments that are produced on the instrument can be stitched together by Gibson Assembly to build larger DNA constructs.

2.3.5.5 ASSEMBLY OF A SYNTHETIC BACTERIAL GENOME

The procedures described previously can be combined to generate complete synthetic bacterial genomes, as shown in Figure 2.3.5. A typical workflow may be as follows: (1) Gibson Assembly of 1.5 kb BioXp products, five at a time, into a vector, and then transformation into *E. coli*; (2) identification of error-free 7 kb “cassettes” on an Illumina MiSeq DNA sequencer; (3) yeast assembly of as many as 20 cassettes to generate sub-genomic assemblies; (4) rolling circle amplification (RCA) from positively screened yeast clones to generate microgram quantities of DNA *in vitro*; and (5) whole-genome assembly in yeast from the RCA-generated material.

This whole-genome synthesis workflow was used to create the syn3.0 minimal genome and can currently be carried out in less than 3 weeks, which is about two orders of magnitude faster than the first reported synthesis of a bacterial genome by our group in 2008.

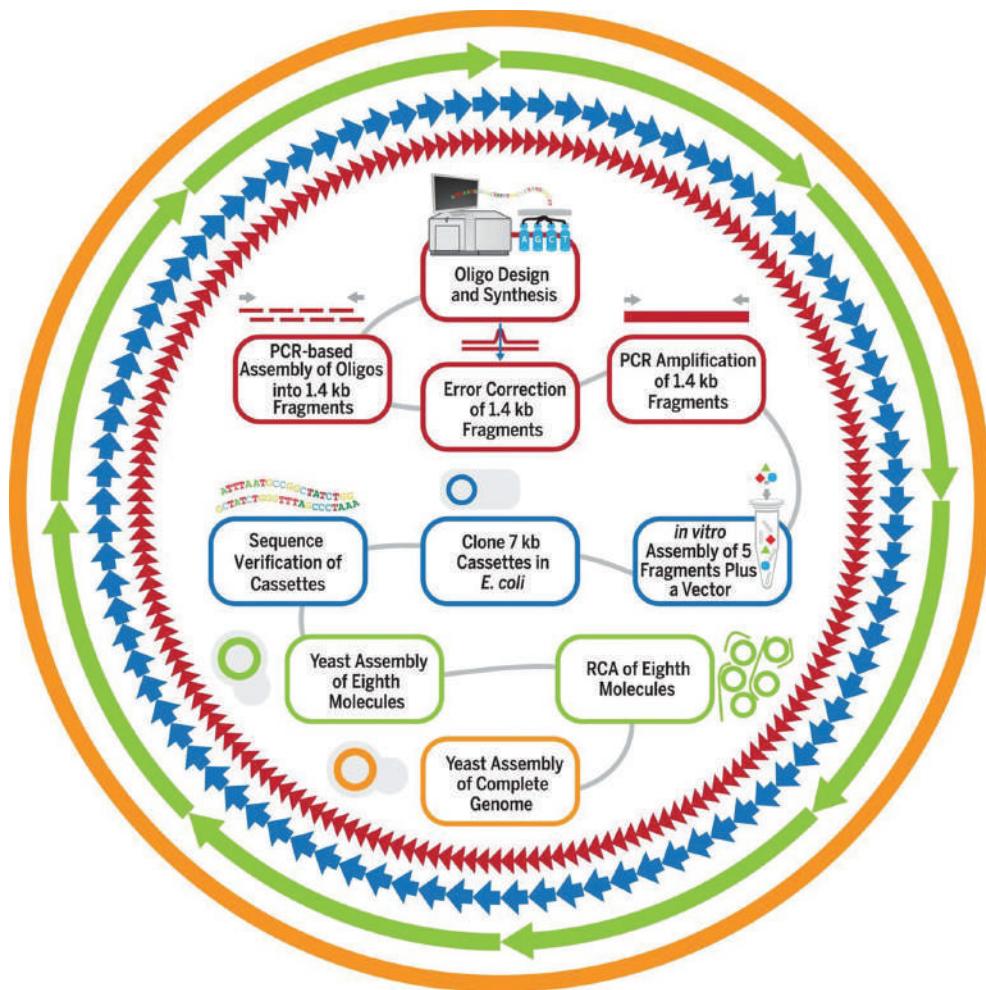

FIGURE 2.3.5 Strategy for whole-genome synthesis. Overlapping oligonucleotides are designed, chemically synthesized, and assembled into 1.4 kb fragments (red). Following error correction and PCR amplification, five fragments are assembled into 7 kb cassettes (blue). Cassettes are sequence verified and then assembled in yeast to generate eighth molecules (green). The eight molecules are amplified and assembled in yeast to generate the complete genome (orange).

2.3.6 MINIMAL SYNTHETIC BACTERIAL CELLS

Scientists have long sought to understand the minimal genetic requirements for life (Morowitz 1984; Fraser et al. 1995; Mushegian and Koonin 1996). There is no unique solution to the set of genes required for a minimal cell. The set will be determined by cell type, cell architecture, and the growth environment. For example, *E. coli* can be minimized for growth in either a rich or a minimal medium. Fewer genes will be required in the rich medium. Eukaryotic cells have complex inner structures and organelles requiring more genes than bacteria with relatively simple architectures.

In attempting to define a minimal set of genetic functions for life, it makes sense to start with a natural cell that already has a small genome. Mycoplasmas have the simplest architecture and smallest genomes among the known bacteria and are considered ideal targets for minimization. They have undergone reductive evolution in the restrictive environments of

animal hosts and have lost many genes that would be required in harsher surroundings. The 580 kb genome sequence of *M. genitalium* was determined by Fraser et al. (1995). It has the smallest genome of any known natural cell that can be independently grown in the laboratory. With only 485 protein-coding and 43 RNA-coding genes, the question immediately arose as to how many of these were essential. In 1996, Mushegian and Koonin compared the gene contents of the first two sequenced bacteria, *M. genitalium* and *H. influenzae*, with the idea that if there was a core set of genetic functions necessary for life, each of the genomes would contain that set. They found 256 orthologous genes in common and suggested that as the minimal set (Mushegian and Koonin 1996). To test this experimentally, Hutchison et al. (1999) introduced global transposon mutagenesis for identifying non-essential genes in *M. genitalium* and the closely related *Mycoplasma pneumoniae* and estimated that there were between 265 and 351 essential genes in *M. genitalium*. In a follow-up study,

individual *M. genitalium* clones with single-gene transposon knockouts were isolated. The total number of different viable-gene knockouts approached 101 asymptotically (Glass et al. 2006). In the 1999 study, the authors proposed that one way to determine the minimal requirements for life would be to “create and test a cassette-based artificial chromosome.” However, DNA synthesis was not sufficiently developed at that time to pursue this “bottom up” approach.

By 2008, DNA synthesis was sufficiently advanced to completely synthesize the 580 kb *M. genitalium* genome and propagate it as a yeast centromeric plasmid (Gibson et al. 2008a), but attempts to activate the genome by installation in a recipient cell were unsuccessful. Concurrently, the somewhat-larger natural 1.1 Mb genome of *M. mycoides capri* was successfully installed into a related mycoplasma strain, *M. capricolum*, by transplantation (Lartigue et al. 2007).

The stage was thus set to create the first synthetic cell. Synthesis of the *M. mycoides* genome was carried out in stages as described previously and shown in Figure 2.3.5. The synthetic genome with slight modifications from the natural genome was assembled and propagated in yeast. The genome was then recovered from yeast and transplanted into *M. capricolum* to produce the synthetic cell syn1.0 (Gibson et al. 2010a). Although possessing a considerably larger genome than *M. genitalium*, syn1.0 became the target for minimization. The genome could be propagated and genetically manipulated in yeast, and the genome was readily recoverable from yeast and transplantable to obtain cells at various stages of minimization.

2.3.6.1 CLASSIFICATION OF GENES AS ESSENTIAL, QUASI-ESSENTIAL, OR NON-ESSENTIAL

How does one design a minimal genome? The key is to be able to identify non-essential genes that can be removed without effecting viability. Genes can be classified into three categories based on whether inactivation results in cell death, impaired growth, or no discernable defect (Smith et al. 1996; Badarinarayana et al. 2001; Lluch-Senar et al. 2015; Hutchison et al. 2016).

A gene is essential if when inactivated, the cell cannot be indefinitely propagated. The cell may continue to divide for a time, but once the essential gene product is sufficiently diluted among the progeny, no more growth occurs. In this case, the gene specifies an essential function that is not supplied by any other gene in the cell. On the other hand, if this essential function is supplied by each of two different genes, either one of these two genes is classed as non-essential. They form a synthetic lethal pair (Dobzhansky 1949). Only when one of the two is inactivated does the function reveal itself as essential. A highly redundant genome will appear to have few essential genes, even though it has many essential functions.

A gene is non-essential if it can be inactivated without affecting the viability or growth rate of the cell. It can specify either a non-essential genetic function or an essential genetic function. In the latter case, as discussed previously, it

is dispensable because another gene in the cell supplies the same essential function.

A third class of genes is called quasi-essential. When inactivated, these genes result in impaired growth. The degree of growth impairment can vary from modest to severe. Inactivation of a quasi-essential gene in a cell results in its gradual loss from a culture when grown competitively with cells having mutations in non-essential genes.

Genes are usually inactivated by deletion or by disruption with a transposon. Global transposon mutagenesis by using the Tn5 transposome (a protein-DNA complex of the transposase and the transposon) carrying a selectable antibiotic marker is widely used (Hutchison et al. 2016). In a single transformation experiment, a population of thousands of individual cells with single Tn5 insertions can be produced. These are plated on selective solid medium to obtain the population of viable cells with Tn5 inserts. This initial population (P0) is then passaged several times in liquid medium. During passage, slower growing cells with Tn5 insertions in quasi-essential genes gradually decrease in number relative to the normally growing cells with Tn5 inserts in non-essential genes. After the fourth passage (P4), usually amounting to about 40–50 generations of growth, the culture will mostly contain cells with Tn5 insertions in non-essential genes. Quasi-essential genes contain relatively fewer Tn5 hits in P4 than in P0. Locations of the Tn5 insertions in the genome sequence are typically determined by sequencing the junctions between Tn5 and the genome sequence (Hutchison et al. 1999, 2016).

In Figure 2.3.6, a section of Tn5 insertion map illustrating the three categories of genes is shown for syn1.0. There are 432 non-essential, 229 quasi-essential, and 240 essential genes in syn1.0 by this assay. The quasi-essential genes are further divided into three sub-groups (ie, i, and in), based on the degree of growth impairment.

2.3.6.2 STEPWISE SYNTHESIS OF A MINIMAL CELL

Without prior knowledge of the final minimal content of essential and quasi-essential genes, minimization is best carried out in a series of design, build, and test (DBT) cycles, as illustrated in Figure 2.3.7 (Hutchison et al. 2016). The syn1.0 genome was divided into eight approximately equal pieces, such that each could be designed, built, and tested for viability in the presence of the other seven wild-type pieces. An initial DBT cycle was based on available information from the literature, from deletion analysis, and from incomplete transposon mutagenesis information. Synthesis of each of the eight pieces yielded only one feebly viable segment. A second DBT cycle utilized information on quasi-essential genes and successfully yielded all eight viable pieces. However, when the eight pieces were joined together, the genome was not viable on transplantation. Only certain combinations of the designed pieces in combination with the other pieces taken from syn1.0 were viable. The reason for this became apparent when it was discovered that certain essential functions were carried redundantly by two different genes, each on a separate piece of the genome. These pairs of synthetic lethal genes (Dobzhansky 1949) had been

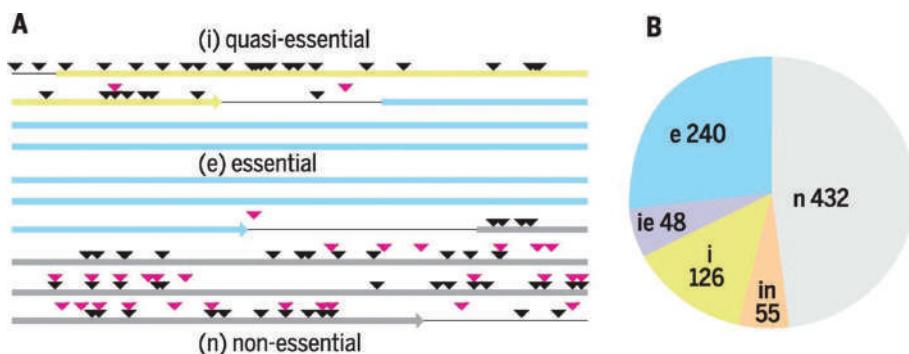

FIGURE 2.3.6 (a) Examples of the three gene classifications based on Tn5 mutagenesis data. The gene *MMSYN1_0128* (dark blue arrow starting at the right end of the top line) has P0 Tn5 inserts (open bars) and is a quasi-essential “i” gene. The next gene (*MMSYN1_0129*) has no inserts and is an essential “e” gene. The last gene (*MMSYN1_0130*) has both P0 (open bars) and P4 (red bars) inserts and is a non-essential “n” gene. (b) Number of syn1.0 genes in each Tn5 mutagenesis classification group. “i” genes are divided into three categories, “ie,” “i,” and “in,” depending on the degree of growth impairment. The “n” genes and “in” genes are candidates for deletion in reduced-genome designs.

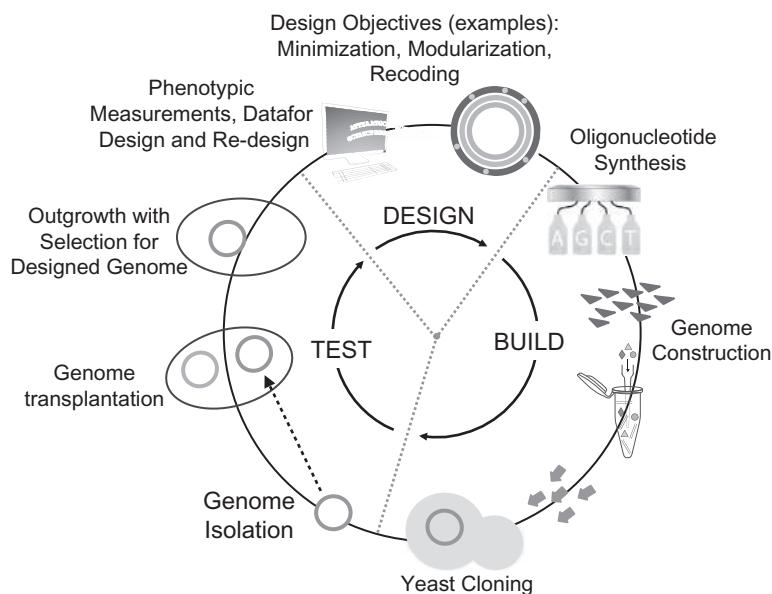

FIGURE 2.3.7 The JCVI design-build-test (DBT) cycle for bacterial genomes. The design objective is genome minimization. Starting from syn1.0, a reduced genome is designed by removing non-essential genes, as judged by global Tn5 gene disruption. Each of eight reduced segments is tested in the context of a 7/8 syn1.0 genome and in combination with other reduced segments. At each cycle, gene essentiality is re-evaluated by Tn5 mutagenesis of the smallest viable assembly of reduced and syn1.0 segments that give robust growth.

considered non-essential, since one member of the pair could be removed without effect. However, if both were removed, the cell lost the essential function and died. Restoration of one member of each synthetic lethal pair allowed all eight pieces to be combined into a viable cell. This cell, syn2.0, was examined by Tn5 mutagenesis, and an additional 42 genes were identified as apparently non-essential. These were removed in a third DBT cycle to yield syn3.0, a close approximation to a minimal cell (Hutchison et al. 2016). The syn3.0 genome is 531 kb in size and has 438 protein-coding and 35 RNA-coding genes (Figure 2.3.8).

Comparison of syn3.0 with the starting syn1.0 cell revealed several differences. Its doubling rate in culture was about 3 hours compared with 1 hour for syn1.0. Colonies

were similar in appearance on solid media but were about half the diameter. In static liquid culture, syn1.0 remained in suspension, whereas Syn3.0 formed a mat in the bottom of the culture tube. The most striking changes were observed microscopically. Syn1.0 appeared as uniform spheres with a diameter of about 400 nm. Syn3.0, in contrast, was strikingly pleiomorphic in appearance, with long filaments, large vesicles, and a spectrum of sphere sizes, both smaller and larger than syn1.0 (Figure 2.3.9). Apparently, some genes affecting cell division and morphology were deleted in syn3.0, without compromising viability.

How close is syn3.0 to a minimal cell? Comparison of the non-essential gene content for the four mycoplasmas *M. genitalium* (580 kb) (Glass et al. 2006), *M. pneumoniae* (816 kb)

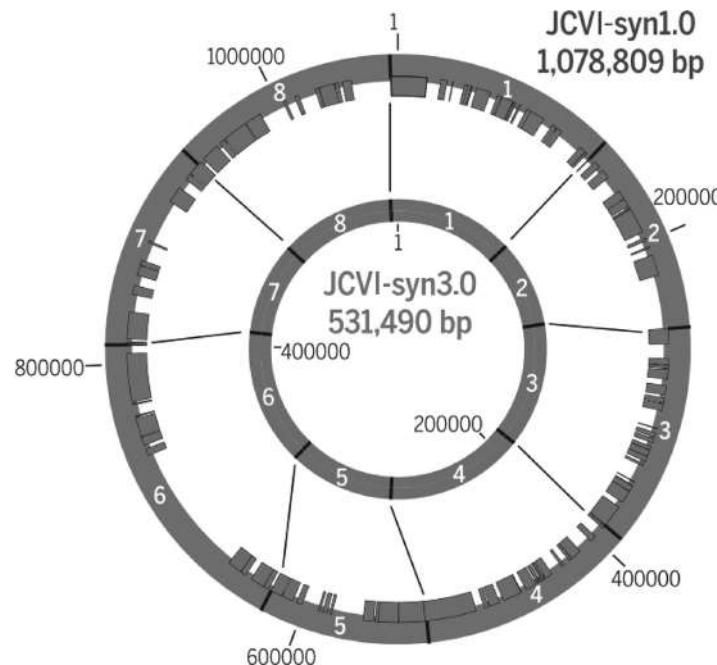

FIGURE 2.3.8 Comparison of the syn1.0 (large circle) and syn3.0 (small circle) genomes showing the division of each into eight segments. The bars inside the large circle show regions that were retained in syn3.0.

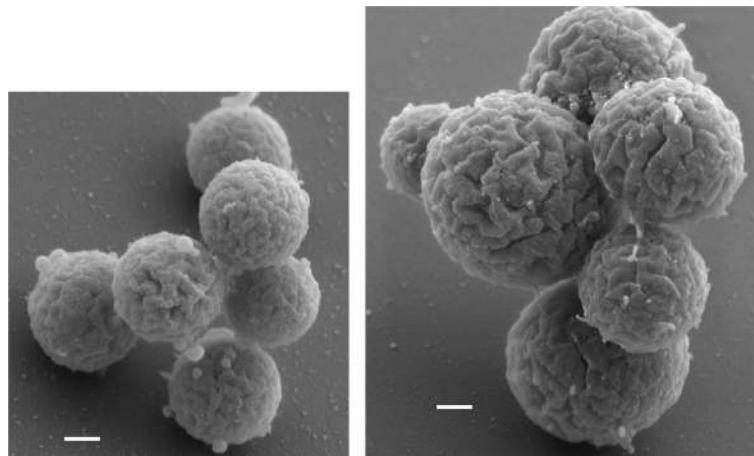

FIGURE 2.3.9 Electron micrograph of a cluster of syn1.0 cells showing uniform spheres (left), and a cluster of syn3.0 cells showing spheres of varying sizes (right). Scale bar is 200 nm.

(Lluch-Senar et al. 2015), *Mycoplasma pulmonis* (963 kb) (French et al. 2008), and *M. mycoides* JCVI-syn1.0 (1080 kb) (Gibson et al. 2010a) shows that the number of non-essential genes varies directly with genome size (Figure 2.3.10). When non-essential genes are plotted against genome size, extrapolation to non-essential genes = 0 yields a minimal genome size of about 423 kb. Plotting non-essential genes versus total genes yields an extrapolated value of 412 genes when non-essential genes = 0. Based on these extrapolated values, syn3.0 is not yet minimal. However, as a working minimal cell, it is important to retain a reasonable growth rate. The Syn3.0 genome is already substantially smaller than that of *M. genitalium*, yet its doubling time at 3 hours is five times

faster. Removal of more genes might inevitably result in slower growth.

2.3.6.3 GENETIC REQUIREMENTS OF A MINIMAL CELL

The syn3.0 genome is 531 kb in size and has 438 protein-coding and 35 RNA-coding genes compared with the 1079 kb syn1.0 genome with 862 protein-coding and 39 RNA-coding genes. Table 2.3.1 lists six major gene functional categories as well as the sub-categories under each major category. Genes involved in expression of genetic information such as transcription and translation are mostly retained; only 22 genes were deleted, whereas 195 genes were kept in syn3.0. Genes involved in

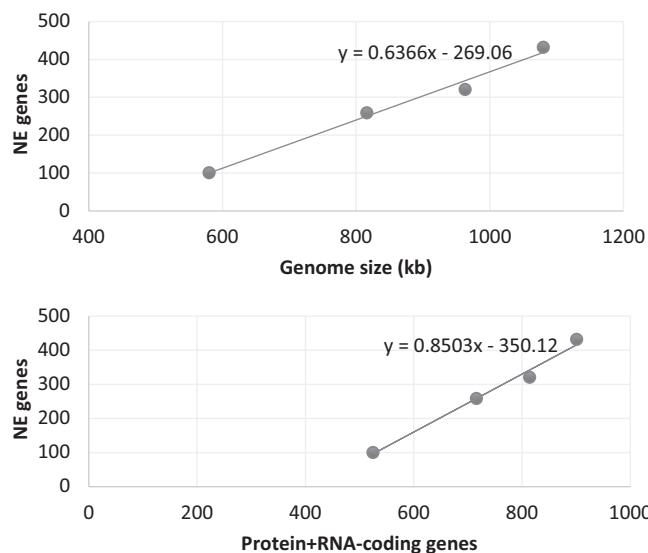

FIGURE 2.3.10 Non-essential (NE) protein-coding genes were determined by transposon mutagenesis in *M. genitalium* (580 kb), *M. pneumoniae* (816 kb), *M. pulmonis* (963 kb), and *M. mycoides* JCVI-syn1.0 (1080 kb). Plotting NE genes versus genome size yields an extrapolated value of 423 kb for the minimal genome size when NE = 0. Plotting NE genes versus total genes yields an extrapolated value of 412 genes when NE = 0.

preservation of genome information such as DNA replication and cell division were also largely retained; 34 genes were kept in syn3.0, and 13 genes were deleted. Among the genes involved in cell membrane structure and transport, 92 were retained and 77 were deleted from syn3.0. Only 73 genes involved in metabolism and energy production were retained, and 109 genes were deleted. A total of 73 genes specified mobile elements and DNA restriction systems, and these were all completely dispensable. Finally, among genes that could not be assigned to functional categories, 79 were retained and 134 were deleted.

All sequenced organisms currently contain a substantial fraction of genes with unknown or imprecisely known functions. In syn3.0, 65 genes are of unknown function (although seven genes have functional assignments as lipoproteins or membrane proteins) and 84 have generic functional assignments. Among the generics, the majority have been assigned to functional categories and belong to families such as hydrolases, ATPases, ATP transporters, etc., but their precise substrates are not known. In Table 2.3.1, only 79 genes have not been assigned to a functional category in syn3.0. Fifty-eight of these are of unknown function, and 21 are generic. A major goal for the future is to assign precise functions to those genes with unknown or generic functions. Only then will a complete understanding of life be possible (Alberts 2011).

2.3.7 SYNTHETIC YEAST CELLS

An international consortium of scientists from the USA, China, the UK, Singapore, and Australia has undertaken DNA synthesis of the yeast *Saccharomyces cerevisiae* genome (Annaluru et al. 2015; Richardson et al. 2017). *Saccharomyces*

TABLE 2.3.1
A List of All the Syn1.0 Genes Either Kept or Deleted in Syn3.0

Functional Category	Keep	Delete
Expression of Genome Information	195	22
Ribosome biogenesis	14	1
Transcription	9	0
RNA metabolism	7	0
Protein folding	3	0
Translation	89	2
RNA (ribosomal RNAs [rRNAs], tRNAs, small RNAs)	35	4
rRNA modification	12	3
tRNA modification	17	2
Regulation	9	10
Preservation of Genome Information	34	13
DNA topology	5	0
Chromosome segregation	3	0
DNA metabolism	3	0
DNA replication	16	2
DNA repair	6	8
Cell division	1	3
Cell Membrane	92	77
Protein export	10	0
Lipid salvage and biogenesis	21	4
Cofactor transport and salvage	21	4
Efflux	7	3
Membrane transport	31	32
Transport and catabolism of non-glucose carbon sources	2	34
Cytosolic Metabolism	73	109
Glucose transport and glycolysis	15	0
Nucleotide salvage	19	8
Metabolic processes	10	10
Redox homeostasis	4	4
Proteolysis	10	11
Lipoprotein	15	72
Acylglycerol breakdown	0	4
Mobile Elements and DNA Restriction	0	73
Unassigned	79	134
Total	473	428

cerevisiae has been extensively characterized genetically. It has 16 linear chromosomes, approximately 12 megabases of non-redundant sequence, and 6000 genes (Engel et al. 2014). Complete synthesis of the genome is within reach of current DNA synthesis capability and is currently well underway.

Yeast researchers have agreed on certain design features for the synthetic chromosomes. Only conservative changes will be made to ensure that the synthetic yeast will have the same fitness and normal growth of the wild-type cells. No destabilizing elements will be included to ensure genome stability and avoid rearrangements. The synthetic yeast will also have genetic flexibility to facilitate future studies. A complete design of the yeast genome incorporating these and other features was recently announced (Richardson et al. 2017).

Chromosome III was the first to be synthesized and installed (Annaluru et al. 2014). Design changes included TAG/TAA stop codon replacements; deletion of introns, mobile elements, and silent mating loci; and deletion of subtelomeric regions. In addition, 98 loxPsym sites were inserted to enable genome scrambling. The designer chromosome was synthesized in 12 “minichunks” with alternating selectable markers. Native chromosome III was replaced by 11 successive minichunk transformation rounds by using the high recombination frequency of yeast. Chromosome III size was reduced from 316,617 to 272,871 bp, without detectable loss of fitness of the synIII yeast strain.

So far, all of the yeast chromosomes have been designed and six (II, III, V, VI, X, and XII) have been synthesized (Richardson et al. 2017; Wang et al. 2018). When all the chromosomes have been synthesized and installed to create a synthetic yeast cell carrying the Sc2.0 genome, the focus will be on producing a yeast cell with a minimal genome, a truly daunting task. With around 5000 estimated non-essential genes mixed in and around at least another 1000 essential genes, how many can be removed without substantially compromising viability? One approach will be to introduce Cre recombinase into the cell to promote “scrambling” of genes and segments flanked by loxPsym sites (Shen et al. 2016). Survivors would be sequenced to discover genes and segments that can be deleted. Only yeast with small deletions are likely to be viable. This “top down” approach seems unlikely to proceed quickly, as the number of possible combinations is huge. However, much is likely to be learned. With the rapid progress in automated DNA synthesis, a bottom-up approach might ultimately prove to be the winner.

2.3.8 A DIGITAL-TO-BIOLOGICAL CONVERTER

In his book “Life at the Speed of Light,” J. Craig Venter speculates on the possibility of biological teleportation (Venter 2013), the sending of DNA sequence information for a life form to a distant planet, and then recreating the living organism by means of a machine located at the destination. As a step toward this goal, his company, SGI, has recently developed an automated machine called a digital-to-biological converter (DBC) that can receive digital sequence information stored on a computer and use it to direct the automated production of DNA, RNA, proteins, or virus particles (Boles et al. 2017). The efforts to create synthetic cells have led to the development of ways to write DNA faster, more accurately, and more reliably. Because of the robustness of these technologies, the process could be automated to move workflows out of scientists’ hands and onto a machine. In 2013, the first DNA printer, the BioXp, was built (Figure 2.3.4).

The next step was to develop a prototypical DBC, an essential first step to bringing on-demand and distributed manufacturing in biology to fruition. Unlike the BioXp, which starts with premanufactured small pieces of DNA (oligonucleotides), the DBC instrument was designed to receive digitized DNA code and convert it into whatever biological materials

the code specified, which could be DNA, RNA, proteins, viruses, or even living cells.

To build the DBC, scientists worked together with software and instrumentation engineers to collapse multiple laboratory workflows into a single box. This included software algorithms to predict what DNA to build; chemistry to link the G, A, T, and C building blocks into short stretches of DNA; enzymatic assembly reactions to stitch those DNA fragments into much longer ones; and biology to convert DNA into other biological entities such as proteins (Boles et al. 2017).

A schematic diagram of the prototype is shown in Figure 2.3.11. It made therapeutic drugs and vaccines that, when tested, were as good as those from traditional methods. Laboratory workflows and processes that once took weeks or months were now carried out in only 1–2 days, without any human intervention, and were simply activated by the receipt of an email that could be sent from anywhere in the world.

Less than 200 years ago, it could take several weeks to get a one-way written message to someone. This all began to change in the 1840s with the invention of the fax machine—the first device that could transmit an image over a wire. The DBC can be compared to the fax machine, but rather than receiving images and documents, the DBC receives the instructions for printing biological materials.

Consider how fax machines have evolved. The prototype of the 1840s is unrecognizable compared with the fax machines of today. In the 1980s, most people still didn’t know what a fax machine was, and it was difficult to grasp the concept of reproducing an image instantly on the other side of the world. But, nowadays, smartphones can do everything that fax machines can do, and this rapid exchange of digital information is taken for granted.

Digital-to-biological converters will be useful for distributed manufacturing of medicines, starting from DNA sequence. A day can now be imagined when it is routine for people to have a DBC connected to their home computer or smartphone as a means to download their prescriptions such as insulin or antibody therapies or for farmers to instantly download the most updated therapies for infested vegetables, fruits, and livestock.

It is easy to imagine DBCs located in strategic places around the world for rapid response to disease outbreaks such as the flu. For example, the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia, could prevent a flu outbreak by emailing a DNA sequence for a vaccine against it to DBCs in developing countries on the other side of the world, where a vaccine is manufactured on the front lines. This flu vaccine could even be tailored to match the specific strain circulating in that area. Sending DNA for instructing vaccines around the world in a digital file, rather than stockpiling those same vaccines and shipping them out, promises to save thousands of lives. With the cost and turnaround times to read DNA dropping exponentially, one can imagine the DBC being central to precision medicine, where every hospital in the world has a DBC to manufacture treatments tailored to a patient’s DNA, at the patient’s bedside.

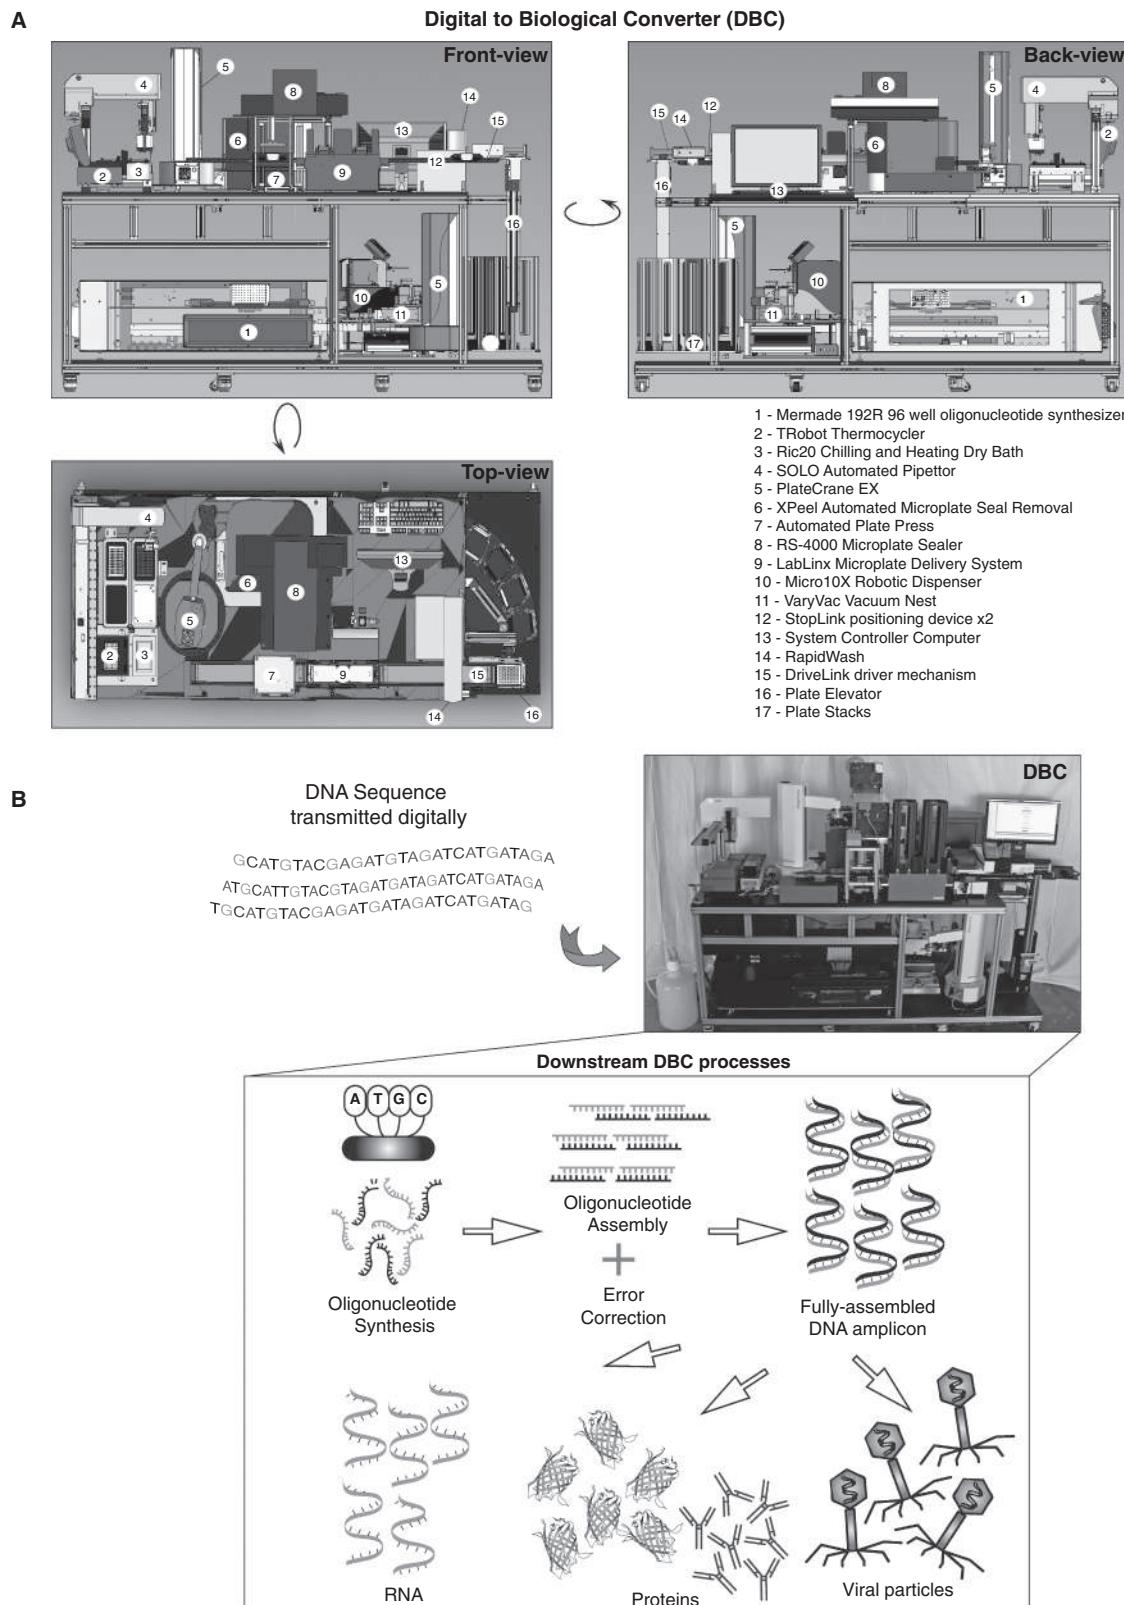

FIGURE 2.3.11 The digital-to-biological converter (DBC) constitutes fully integrated instruments and underlying software that are coordinated to perform a series of tasks without human intervention. Before a run, the DBC is preloaded with reagents required to make a designated biopolymer from digitally transmitted DNA sequence. The DBC process commences by generating overlapping oligonucleotide sequences that are subsequently chemically synthesized. These oligonucleotides are then assembled and processed to build a high-quality synthetic DNA amplicon. This DNA amplicon may be further converted into RNA, proteins, or viral particles by user-designated instructions. Examples of products generated on the DBC include influenza virus genes, antibody polypeptides, an RNA vaccine, and ϕ X174 viral particles.

The applications go as far as the imagination will go. One can imagine DBCs being placed on other planets. Scientists on Earth could send the digital instructions to the DBC for a new medicine to treat an infectious disease or to make the planet more habitable for humans. This could include digital instructions to assemble synthetic organisms that make oxygen, food, fuel, and building materials. With digital information traveling at the speed of light, it would take only minutes for those instructions to be sent from Earth to Mars, compared with months to physically deliver those samples on a spacecraft.

For now, one must be satisfied beaming new medicines across the globe, fully automated and on-demand to save lives from emerging deadly infectious diseases and to create personalized cancer medicines for those who do not have time to wait.

2.4.1 INTRODUCTION

With an expertise in the philosophies of science and language, I turned my focus to the philosophy of biology and life sciences in the mid-1980s. I found it interesting that the results of the philosophy of science debates did not reach any biological discipline, although philosophy of science is the essential discipline for the foundations and justifications of scientific theory building and methodology. At the center of these more than half-a-century lasting debates was the question how to define a scientific sentence in contrast to metaphysical ones. “Scientific” meant empirically based, experimentally testable, and theoretically formalizable, because mathematics was assumed to be the only exact science that could depict material (physical and chemical) reality (Whitehead and Russel 1910–1913; Goedel 1931; Carnap 1939).

The crucial question remained how to construct sentences that are scientific and not metaphysical, that is, the question how to define language, the ultimate prerequisite of any human utterance. The debate lasted from 1920 to 1980, with its most prominent proponents such as early Wittgenstein,

Carnap, Hilbert, Russel, Whitehead, Goedel, Shannon, Weaver, Turing, von Neumann, late Wittgenstein, Austin, Searle, Chomsky, and Habermas (Witzany 2010). The results of these debates are part of the history of science:

- The concept of a coherent axiomatic system with error-free logical sentences is impossible, in principle.
- The concept of an exact scientific language was a pipe dream.
- Natural languages do not speak themselves; there are always real-life individuals in populations that generate and use such languages to coordinate and organize the real-life world, and the usage of natural languages is, therefore, part of communication, that is, a kind of social interaction.
- Living agents that use natural languages are principally able to generate new sign sequences that cannot be predicted or deduced from former ones and for which no algorithm is available, in principle.

- The meaning (semantics) of the signs and sign sequences in natural languages depends on the real-life context (pragmatics) within which signs are used and not on its syntax.

As a consequence, formalizable, that is, mathematical, theories of (context-free) languages are not an appropriate tool for explaining the essential features of natural languages used in communication processes. They cannot identify the context dependence of meaning and its deep grammar that helps to transport different and even contradictory meanings to the superficial grammar, both represented by identical sign sequences. Additionally, describing the social character of real-life organisms is not within their expertise, because social interacting organisms don't behave like formalizable abiotic elements, and, for the inherent feature of generating new sequences, new behavior, and new interactional motifs, no algorithm is available in principle (Witzany 1995, 2010, 2011a). As we will see at the end of this contribution, this must have serious consequences in the explanatory model on how to describe the sign-mediated interactions in non-cellular early RNA-world and emergence of the genetic code, genetic information, and its regulation.

2.4.2 EMPIRICAL FACTS ABOUT COMMUNICATION

2.4.2.1 COMMUNICATION IS SOCIAL INTERACTION

Communication designates social interaction. Social interacting living agents need some tools so that interaction may lead to coordination and organization of common behavior to reach goals. In contrast to physical-chemical interactions on an abiotic planet, communicative interactions on biotic planets are mediated by signs. Such signs must be uttered by bodily expressed movements, phonetics, audiovisuality, tactility (e.g., vibrational), or odor (semiochemical). This means that sign-mediated utterances may also be transported as body movement patterns (e.g., series of gestures).

The use of signs in communicative interactions must be learned somehow (Morris 1946). This means that the use must follow an acquired competence. The competence of living agents is inherited or learned or both. In any case, it needs some social interaction experience to trigger this competence into an actual available behavior. In concrete real-life social experiences, living agents learn to designate a message for non-self agents in a real-life context. In social experiences, living agents learn to use more than one sign and combine multiple different signs into sign sequences to communicate complex content. Social experiences are the essential background to learning contextual, combinatorial, and content-based rules on how to use signs in social interactions (Witzany 2000).

2.4.2.2 COMMUNICATION IS SIGN-MEDIATED ACCORDING TO RULES

Communication is a kind of social interaction. It is an empirically proven fact that communication could not be invented by a singular living agent for one time only once. Communication

needs signs to communicate context-relevant content. Such signs can be combined in a line-up to sign sequences. The use of signs needs some competence to combine sign sequences correctly. This competence of rule-following depends on social interaction experience (context). Communication is the essential interaction to common understanding of content (meaning). Social interaction experience is embedded into a cultural background history.

2.4.2.3 MEANING DEPENDS ON CONTEXT

The meaning of a sign sequence or a “word” or any other sign used to communicate is a social function (Mead 1934). The behavioral reaction to a communicative utterance emerges semantic meaning. Not to forget that natural communication depends on the context. Also, meaning-generating social events are context-dependent. For example, the humble dance in bees gives direction and energy costs in food gathering. Exactly the same dance figures are used during the hive search, where context transports the completely different meaning of an appropriate hive (Witzany 2000). Another example: The sentence “Shooting of the hunters” in human communication may transmit the message that hunters shoot and, conversely, that hunters are shot. Without context, contradictory semantics of sign sequences cannot be identified. Syntactic analyses alone are insufficient to identify semantic content (Witzany and Baluška 2012b).

2.4.2.4 COMMUNICATION INITIATES DE NOVO GENERATION

Communication as rule-governed sign-mediated interactions are different from interactions in a purely physical-chemical world without any biotic agents. In such interactions, signs and rules of sign use as well as sign-using living agents are not existent. In contrast, communicating living agents share a limited repertoire of signs that are used according to a limited number of rules that must be followed to generate correct sign sequences to designate context-dependent content. Most interesting is the fact that such rules—although rather conservative—may be changed in extreme cases or if adaptation is necessary. Rule-following by living agents is rather flexible in contrast to natural laws to which living agents abide strictly. This means that communication is the essential tool to generate new signs, sign sequences, new rules for sign use, and generation of new content according to unexpected contextual circumstances (Witzany 2015). Communicating living agents are able, in principle, to generate new communicative patterns for better or innovative adaptation to a new and unforeseeable situation.

2.4.2.5 EXPERTISE ON LANGUAGE AND COMMUNICATION

Curiously, many biologists are not very familiar with the current definitions of “language” and “communication,” although they are commonly used in molecular biology to speak about “genetic code,” “code without commas” (Crick et al. 1957), “nucleic acid language,” “recognition sequences,” “transcription,” “translation,” “amino acid language,” “immune responses,” “intercellular communication,” etc. The above-listed theoretical and

empirically tested results on “language” and “communication” have been ignored until today. If we speak now about (1) the three categories of signs (index, icon, and symbol); (2) the three complementary non-reducible levels of semiotic rules’ syntax, pragmatics, and semantics; and (3) communication as rule-governed sign-mediated interactions, it can easily be seen that all these categories are nearly unknown in biology, especially in molecular biology, cell biology, genetics, bioinformatics, and related disciplines (Schroedinger 1944; Brenner 2012; Eigen 2013).

All the previously summarized characteristics of communication processes are results of empirical investigations (Habermas 1984, 1987; Austin 1975; Searle 1976; Tomasello 2008). These are no hypotheses or theoretical constructions but empirically proven facts. Some derive from investigations on cognition differences between apes and humans, some from investigations of communicative interactions and speech acts, and some from investigations of language constructions and applications. There is no doubt that language, communication, and social interacting living agents are within the expertise of empirical social sciences.

In the last 100 years, there has been an abundance of theories and concepts on language and communication by natural sciences, such as mathematics, physics, chemistry, information theory, cybernetic systems theory and its derivatives, “mathematical theory of language,” “cognitive revolution,” and “artificial intelligence” (Wiener 1948; Shannon and Waever 1949; Turing 1950; Chomsky 1964, 1965; von Neumann 1966; Nowak and Krakauer 1999). With the results of pragmatic action theory, all of them have been essentially falsified, because none of them could coherently explain the steps from a single biotic agent to a commonly shared understanding as a prerequisite for common coordination and organizational behavior or “how to make the move from a state of private consciousness to a state of mutual agreement and cooperation” (McCarthy 1984).

In this respect, this contribution will demonstrate that communication is the main characteristic not only of humans but also of life generally, based on a common methodological assumption

of natural sciences and social sciences by presenting empirical data that can be proved by experiments and observations.

2.4.3 BIOCOMMUNICATION IN ALL DOMAINS OF LIFE

If communication is the main characteristic of life, it must be possible to identify communicative actions throughout all domains of life. Until the middle of the last century, language and communication were thought to be special tools of only humans. Meanwhile, we know an abundance of examples of non-human languages and communication processes.

Therefore, the description of communication processes must be valid in principle in all organisms, from the simplest akaryote up to the humans. Whereas we identified main characteristics of communication, its (1) social character, (2) dependence on signs according, (3) the three kinds of rules (combinatorial, context-specific, and content-coherent), we must draw our attention from the decades-long narrative suggested by information theory and systems theory, that is, the sender-receiver narrative (coding-decoding), which was wrong in several aspects, as outlined elsewhere (Witzany 1995). Communication is not only an information-transfer process but more than this interaction, mediated mainly by utterances represented by signs. If we speak, or any other organism uses signs to signal something, we do something (Austin 1975; Searle 1976; Habermas 1994).

Interactions between living organisms that are based on signs (signals, icons, and symbols) used according to combinatorial, context-dependent, and content-coherent rules are the very fundamental techniques to coordinate any common behavior and organize division of labor. Although the lifeworld of organisms is rather restricted to their species-specific habitats, symbiotic partners, geologically determined niche constructions, the signals they share, and the behavioral motifs they like to use, we can find communication in all organisms of all domains of life (Witzany 2011c, 2012a, 2014a, 2017a; Witzany and Baluška 2012a; Witzany and Nowacki 2016) ([Figure 2.4.1](#)).

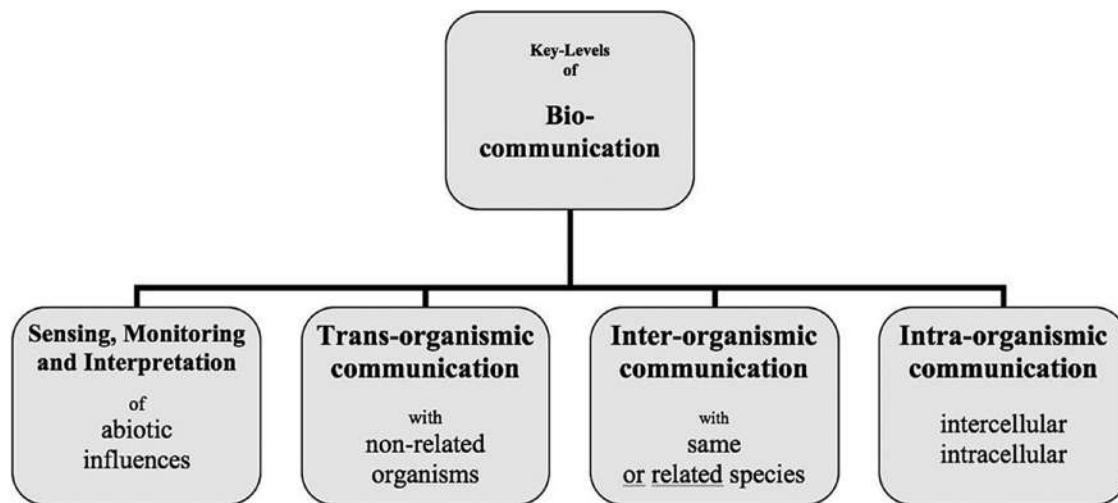

FIGURE 2.4.1 The biocommunication approach identified four levels in which cellular organisms are involved since the start of their life until death.

But biocommunication is not restricted to a species-specific lifeworld. Additionally, we must think of cell-cell communication processes in parallel within the organismal bodies, between tissues and organs, to coordinate interactions of the whole body. Last but not least, from the organisms that communicate within their body and between the same or related members of their species, we can also find communication processes between non-related organisms, as in attack and defense behaviors or more than this in an abundance of symbiotic and symbiogenetic interactions (Witzany 2006).

2.4.3.1 HUMANS AND THEIR ANCESTORS

To learn a natural language means to communicate basic everyday needs with community members. This is how we learn what a word means. “The meaning of a word is its use” (Wittgenstein 1953), or Ch. S. Peirce: to identify “...meaning, we have, therefore, simply to determine what habits it produces” (Peirce 1923). We can understand words and their sequences, because we have learned a practice of interaction, which includes learning from the community as to which words are combined with which customs or interactional patterns.

Although great apes understand many aspects of social interactions in their lifeworlds, including causal and intentional relationships, there is a crucial difference from human understanding: In contrast even with human infants, great apes cannot participate in shared intentionality or co-operative communication (Tomasello 2008; Bohn et al. 2016; Engelmann et al. 2017).

Another crucial difference between humans and great apes is that humans designate situations and entities for other people in a language-like manner. These other persons then try to understand why active agents want to share information and why they want them to know this could be relevant to them. Besides the ability to participate in shared intentionality, this requires a variety of complex and recursive logical conclusions about the intentions of others.

The empirical result is that although several animal species can represent situations and other entities cognitively in an abstract way, only humans can generate actively distinct perspectives of the same situation. Additionally, only humans draw social recursive conclusions that are self-reflexive also with regard to the intentional states of others. Also, several animal species evaluate and feed back their actions in respect of their intentional goals, but only humans evaluate their behavior with respect to the normative perspectives of others or their group identity.

The individual intentionality changed into co-operation by means of a common intentionality, which made new forms of cognitive representation, that is, perspectivistic and symbolic, possible. The conclusions changed into social recursive ones, which means they focused not on individual perspectives but on the perspective of all group members.

This new form of co-operation within common intentionality emerged from common goals (not individual ones) and commonly shared attention. These are the ingredients of social coordination, which is different from individual coordination with each other. Group hunting in great apes is characterized by the fact that each individual ape tries to catch the prey. This

means the group behavior remains in the “ego-status” for every individual. But the so-called co-operative turn in humans means that the group members now act in a group perspective without “ego-status.” The decisions that are taken focus on group benefit, not individual benefit. This was the result of experiments with 3-year-old children, in contrast to great apes, which remain in the “ego-status,” although they act together in groups. The children co-operated in several experimental setups, and it was shown that the common goal is so important that individual children who reached their goals early did not stop their actions until all the others had reached their goals. Similar behavior could not be observed in great apes (Tomasello 2008; Bohn et al. 2016; Engelmann et al. 2017).

Additionally, humans communicate with others about content that is not actually present. This means language must serve as symbolic (conventionally derived) representation of information that is not actual but abstract. This is a crucial difference from their ancestors (Bohn et al. 2015).

The speech acts in humans differ fundamentally from their evolutionary ancestors. We can differentiate superficial grammar and deep grammar in human speech acts, or, in the words of John Searle, the founder of speech act theory, we can find locutionary acts done by utterances (designated by their grammatical-semantic sequence); illocutionary acts (what we want to do with what we say), which cannot be identified through analyses of the words that are said but depend on mutual expectations, intentions, emotions, roles, etc.; and the performative speech acts that are characterized by what is done by the one who is addressee of what is said. Especially the illocutionary speech act is nothing that can be identified easily in great apes. Also, in humans, there is no algorithm available to identify such crucial determinants of what is expected and intended. So, natural human communication in everyday life and colloquial speech are nothing that can be computed or predicted easily.

Natural signs used by humans are not only auditory and visual (gestures) but also body movements and tactile. Beyond conscious sign generation, there are inherent unconscious messages transported, as in all other animals by semiochemicals, that is, pheromone and other hormone-like odors, although odor receptors and related tissues are largely lost during retroviral infection events in the African primate populations prior to the chimpanzee-human split (Villarreal 2009). This caused a strong selective pressure to evolve alternative communication tools to perpetuate social life and social order without pre-dominant odor determinants. Additionally, we must not forget that 95% of the cells that a human body assembles are persistent settlers, in most cases, symbionts, as demonstrated on the skin or in the human gut, without which humans cannot survive. Natural signs produced by humans to the symbionts depend on cell-cell communication in tissues and organs.

2.4.3.2 BEES

To take an example for communication as the main characteristic of animal life, we can take any species from this kingdom. More appropriate would be animal species that obviously share a coherent swarm behavior, as represented by some fish, insect,

or bird species. I will take bees for example, because, for successful investigation of bee language and communication, Karl von Frisch received the Nobel Prize in 1973. If we speak about language and communication, we usually think of humans that talk to each other and communicate to organize common goals and to coordinate common behavior (von Frisch 1971).

But since Karl von Frisch received Nobel Prize for detection and investigation of bee languages and dialects, broader research communities and experts in bee breeding noticed that even non-human social animals might communicate to reach complex behavioral patterns. Since Karl von Frisch's work, it has been evident that the highly complex social behavior of bee swarms is organized and coordinated by sign-mediated interactions, that is, communication. If communication processes are disturbed, they may have fatal consequences for bee colonies, especially if we think of special bees' behavior such as foraging, their search for a new hive, and the semantics of bee dances. As in every other natural language, the same sign sequences may have different meanings in different contexts. This means that bees with a limited repertoire of signs can transport different messages, which trigger different response behaviors, with far-reaching consequences (Witzany 1995).

As in every other natural language, bee languages also differ in habitat-dependent dialects. Small groups may generate specific signs according to niche adaptations, which are not present in other habitats, or similar signs may transport different meanings. For example, when mixing Austrian and Italian bees from certain regions, von Frisch exemplified that a special bee movement pattern (dance) that represents the distance to a nutrition field meant 100 meters for Austrian bees but 500 meters for Italian bees, which led to struggle between both groups, because one group did not find what was designated.

Most interestingly, the language of honey bees in colder hemispheres is the only known non-human language that uses body movements that represent symbolic signs.

Natural signs in bee languages are moving patterns, "dances" of various kinds, and motifs that transport all differentiated messages being relevant for social bee life to the other swarm-members. Besides this, hormonal (semiochemical), tactile, vibrational, and even visual signs are used.

2.4.3.3 OTHER ANIMALS

Similar to the general categories of biocommunication, communication processes within the animal kingdom have been investigated in chimpanzees, elephants, wolves, dogs, rodents, mouse, rats, spiders, ants, termites, crows, parrots, birds, salamanders, chelonians, cetaceae, fish, cephalopods such as octopus, corals, nematodes (Witzany 2014a), and many others not listed here. Although the detailed investigations according to the conceptual categories listed previously are missing, they can be expected to be undertaken within next decades.

Natural signs in nearly all animals are generated to coordinate reproduction cycles and social membership roles, as well as in mating, kinship welfare, attack, defense, etc., by semiochemicals, that is, hormones, in combination with auditory, visual, and tactile signs that are rather species-specific.

2.4.4 BIOCOMMUNICATION OF PLANTS

Plants have traditionally been viewed as growth automata. Now, we recognize that the coordination of growth and development in plants is possible only by using signs rather than pure mechanics. Understanding the use of signs in communication processes requires a differentiated perspective (Baluška et al. 2006). Chemical molecules are used as signs. They function as signals, messenger substances, information carriers, and memory medium in solid, liquid, or gaseous form (Witzany and Baluška 2012a).

Plants are sessile organisms that actively compete for environmental resources, both above and below the ground (Bais et al. 2004). They assess their surroundings, estimate how much energy they need for particular goals, and then realize the optimum variant. They take measures to control certain environmental resources. They perceive themselves and can distinguish between self and non-self. This capability allows them to protect their territory. They process and evaluate information and then modify their behavior accordingly.

To understand these competences, we will notice that this is possible due to parallel communication processes within the plant (intraorganismic), between same and different plant species (interorganismic), and between plants and non-plants (transorganismic). Intraorganismic communication involves sign-mediated interactions in cells (intracellular) and between cells (intercellular).

Intercellular communication processes are crucial in coordinating growth and development and shape and dynamics. Such communication must function on both the local level and between widely separated plant parts. This allows plants to react in a differentiated manner to its current developmental status and physiological influences. Chemical communication is either vesicular trafficking or cell-cell communication via the plasmodesmata. Moreover, numerous signal molecules are produced in or controlled by the cell walls. Physical communication takes place through airborne, electrical, hydraulic, and mechanical signs (Blande and Glinwood 2016).

Natural signs that enable the communication processes between tissues and cells in plants are incredibly complex and encompass nucleic acids, oligonucleotides, proteins and peptides, minerals, oxidative signals, gases, mechanical signals, electrical signals, fatty acids, oligosaccharides, growth factors, several amino acids, various secondary metabolite products (up until now, 100,000 different metabolites are identified), and simple sugars (Witzany and Baluška 2012a).

2.4.5 BIOCOMMUNICATION OF FUNGI

The evolutionary forerunners to animals and plants are fungi, which are represented by single as well as multicellular species. Currently, it is estimated that there are at least 1.5 million fungal species, out of which about 300,000 are described in the scientific literature. It is estimated that fungi account for at least one-fourth of the global biomass. As with plants, fungi are sessile organisms that can live for extremely long periods or extend over large areas: one example (*Armillaria gallica*)

has been found, which covers as much as 15 ha and has an age of approximately 1500 years (Casselman 2007). Another example (*Armillaria ostoyae*) covers 900 ha and has an estimated age of 2400 years (Casselman 2007). Higher fungi are modular hyphal organisms in that they reproduce by clonation or are parasexual. They establish interlocking networks. The symbiotic relation to plants, especially in the rhizosphere, is indispensable, because without fungal degradants, plants cannot uptake soluble nutrients (Witzany and Baluška 2012a).

Natural signs in fungi are restricted to semiochemicals that are generated and interpreted to coordinate further reactions. To exemplify such signaling process, we can look at the following examples: (i) Mitogen-activated protein kinase (MAPK) signaling is involved in cell integrity, cell wall construction, pheromones/mating, and osmoregulation (Dohlman and Slessareva 2006; Yu et al. 2008). (ii) Cyclic adenosine monophosphate/protein kinase A (cAMP/PKA) system is involved in fungal development and virulence. (iii) RAS protein is involved in cross-talk between signaling cascades. (iv) Calcium-calmodulin-calcineurin are involved in cell survival under oxidative stress, high temperature, and membrane/cell wall perturbation. (v) Rapamycin is involved in the control of cell growth and proliferation (Fernandes et al. 2005). (vi) Aromatic alcohols such as tryptophol and phenethyl alcohol are used as quorum-sensing molecules. (vii) A variety of volatiles (alcohols, esters, ketones, acids, and lipids) and non-volatile inhibitory compounds (Farnesol and H₂O₂) (Leeder et al. 2011). To date, 400 different secondary metabolites have been documented. These are known to contain mycotoxins and are used both for defensive and aggressive behaviors.

2.4.6 BIOCOMMUNICATION OF SINGLE-CELLED EUKARYOTES

Unicellular eukaryotes represent an own kingdom of life. The crucial difference to their evolutionary forerunners, that is, akaryotes, is their rather complex cellular structure, which includes several parts being absent in akaryotes, such as the nucleus, which contains the genome. The Serial Endosymbiotic Theory successfully explained this evolutionary event (Margulis 2004; Witzany 2006). They evolved signaling to modulate fundamental activities such as acquisition of nutrients and reproduction. They can be found in abundance in aqueous and soil environments; they assess their surroundings, estimate how much energy they need for particular goals, and then realize the optimum variant. They take measures to control certain environmental resources (Witzany and Nowacki 2016). They perceive themselves and can distinguish between self and non-self. They process and evaluate information and then modify their behavior accordingly. In order to generate an appropriate response behavior, protozoa must be able to not only sense but also interpret and memorize important indices from the abiotic environment and adapt to them accordingly. This is decisive in coordinating growth and development, mating, shape, and dynamics.

Parasitic protozoa cause some of the most severe infectious human diseases worldwide.

Natural signs in unicellular eukaryotes are semiochemicals, such as hormones and secondary metabolites that serve as signs within interactions of various motifs, such as reproduction, mating, feeding, attack, and defense. In this respect, it is important to interconnect semiochemicals with the concrete interactional motif (Luporini et al. 1995, 2006). Identical signals may be used in several interaction motifs with quite different meanings, and this indicates the context dependence of signals. Quite common are hormone receptors. Signaling also includes cAMP in different life-cycle stages, calcium-mediated adenylyl cyclase (AC) regulation, as well as cyclic nucleotide (guanylyl cyclase) signaling involvement in exflagellation, phosphodiesterases (PDEs), and cyclic-nucleotide-activated protein kinases are essentially conserved in protozoa. Ca²⁺-signaling pathways and intracellular Ca²⁺ channels are present in nearly all unicellular eukaryotes.

2.4.7 BIOCOMMUNICATION OF AKARYOTES (BACTERIA AND ARCHAEA)

Bacteria and non-related akaryotic archaea have been assumed to be the most primitive organisms and consequently have been investigated as single-cell individuals, determined by mechanistic input-output reactions. Now, this picture has changed. Today, we know that bacteria and archaea are part of a community that interacts in a highly sophisticated manner (Crespi 2001). The production and the exchange of messenger molecules enable unicellular organisms to coordinate their behavior like a multicellular organism (Shapiro 1998; Bassler 1999; Schauder and Bassler 2001; Ben Jacob et al. 2004).

The coordinated community, for example, of oral bacteria in humans, relies on intra- and interspecies communication. This community encompasses ca. 500 different species, some of which co-operate while others compete (Kolenbrander et al. 2002). The complexity of potential interactions in the oral cavity and the number of possibilities reach unimaginable proportions if we assume that each of the 500 bacteria species can regulate its genes in response to host-produced molecules and interact with all other bacteria species (Kolenbrander et al. 2002).

The medium of every bacterial and archaeal coordination is communication, that is, sign-mediated interaction (Dunn and Handelsmann 2002). A wide range of chemical molecules serves as signs through which bacterial and archaeal communities coordinate to reach a “quorum,” which is the starting point for decision-making: one of many different behavioral patterns will thereby be organized, such as biofilm organization, bioluminescence, virulence, and sporulation (Sharma et al. 2003). Quorum sensing includes not only chemotaxis but also interpretation, which means that the incoming signs are measured against the background memory of the species colony in their real-life world (Kaiser and Losick 1993; Losick and Kaiser 1997). Interpretation before decision-making, coordination, and organization, such

as fruiting body formation and co-operative hierarchical organization, is context-dependent (Witzany 2017a).

Natural signs in bacterial and archaea communications are semiochemicals involved in producing, releasing, detecting, and responding to small hormone-like molecules termed autoinducers. Acylated homoserine lactone (AHL) and peptides represent the two major classes of known bacterial cell-cell signaling molecules. AHLs are the products of LuxI-type autoinducer synthases, short peptides that often contain chemical modifications, phosphorylation cascades that ultimately impinge on DNA-binding transcription factors responsible for regulation of target genes (Fuqua et al. 1996). In general, bacteria keep their AHL and peptide quorum-sensing conversations private, by each species of bacteria producing and detecting a unique AHL (AHLs differ in their acyl side-chain moieties), peptide, or combination thereof. Archaea share some molecular biological features with Eukarya that are not found in any bacteria, such as ATP production, protein secretion, cell division and vesicles formation, and protein modification pathways (Woese and Fox 1977; Woese et al. 1990; Forterre 1997). Archaea therefore seem to share a strong evolutionary relationship with the Eukarya (Garrett and Klenk 2007; Garrett et al. 2011).

2.4.8 BIOCOMMUNICATION OF VIRUSES

With drawing our attention now to viruses and their relatives, we seem to move from cellular life to sub-cellular elements. Current knowledge about the virosphere and their roles in evolution (“virolution”) indicates interactions of RNA viruses, DNA viruses, viral swarms, and viral and RNA-based sub-viral networks that co-operate and coordinate (regulate) within cellular genomes either as replication-relevant co-players or suppression-relevant silencers (Ryan 2009; Stedman 2013, 2015; Seligmann and Raoult 2016). Some represent infection-derived modular tools of non-coding RNAs, which have built consortia of complementary agents that function together (Tycowski et al. 2015; Heaton and Cullen 2017; Inuoue et al. 2017).

Viruses have long been accepted only as disease-causing, epidemic phenomena, with lytic and therefore extremely dangerous consequences for infected organisms. However, new research has corrected this picture (Villarreal 2009; Witzany 2012b, Berliner et al. 2018). Viruses are part of the living world, in most cases integrated in the cytoplasm or the nucleoplasm of cells, without harming the host. Viruses are on their way to representing the best examples of symbiotic relationships, because there is no living being since the start of life that has not been colonized by them, in most often cases in the form of multiple colonizations (Villarreal and Witzany 2010, 2015, 2018).

Today, we can identify several key players that coordinate and organize the genetic content compositions of host organisms (Koonin 2016). They include endogenous viruses and defectives, transposons, retrotransposons, long terminal repeats, non-long terminal repeats, long interspersed nuclear elements, short interspersed nuclear elements, group I introns, group II introns, phages, and plasmids (Weiner 2006; Jurka et al. 2007; Slotkin and Martienssen 2007; Lambowitz and Zimmerly 2011; McNeil et al. 2016; Belfort 2017). These are

just some examples that use genomic DNA as their preferred living habitat. This means that DNA is not a solely stable genetic storage medium that serves as an evolutionary protocol but is also a species-specific ecological niche for viral RNAs.

Persistent viral lifestyle is the most dominant biological lifestyle on this planet (Villarreal 2005). From this perspective, the total number of cellular organisms looks like small islands in an ocean of the global virosphere. Viruses and virus-derived parts represent the most abundant genetic information on the planet, overrepresenting cellular genetic information 10 times. If we only consider prokaryotic life, we have a number of prokaryote viruses (phages) of 10^{31} , which means if we line up the length of their virions, we get 40 million light-years (Rohwer et al. 2014). Importantly, a key feature of this viral lifestyle is that only few need to remain as functional agents, such as mammalian endogenous retroviruses needed for the syncytia, which regulate mammalian pregnancy (Perot et al. 2012), not to forget the role of persistent viruses in any kind of host immunity functions.

In most cases parts of infectious agents remain as defectives such as LTRs, non-LTRs, SINEs, LINEs, and Alu's. As defectives they are exapted for cellular needs such as regulation tools in all steps and fine-tuned substeps of cellular functions, such as transcription, translation, epigenetics, repair, and immunity (Slotkin and Martienssen 2007; Lambowitz and Zimmerly 2011; Witzany 2011b; Chalopin et al. 2012; Conley and Jordan 2012; Roossinck 2015).

The abundance of such genetic agents has been identified during the last 40 years as obligate inhabitants of all genomes, whether prokaryotic or eukaryotic. They infect, insert, and delete; some cut and paste; others copy and paste; and both spread within the genome. They change host genetic identities by insertion, recombination, or epigenetic regulation or re-regulation of genetic content, and co-evolve with the host to interact in a modular manner (Geuking et al. 2009; Shapiro 2011). Together with non-coding RNAs, they shape both genome architecture and regulation. In this respect, they are the agents of change, not only over evolutionary time but also in real time as domesticated agents.

Viruses can co-operate, that is, they interact to build groups that invade host genomes and even compete as a group for limited resources such as host genomes (Villarreal and Witzany 2013a, 2013b). This leads to an extraordinary effective result and a key behavioral motif that is able to integrate a persistent lifestyle into cellular host organisms, the “addiction” modules: former competing viral groups are counterbalancing each other, together with the host immune system (Villarreal 2012a). Although rather stable under certain circumstances, this addiction balance can also get out of balance, which means the competing viral features may become virulent again. But when stable, we can find such counter-regulating paired genes of the addiction modules, as in the restriction/modulation (RM) systems as well as in the toxin/antitoxin (TA) systems (Harms et al. 2018). Insertion/deletion functions represent similar modules as do the RM systems. This “infectious” colonization by new addiction modules is a main process in generating new

sequence space without error replication and therefore in the evolution, conservation, and plasticity of host genetic identities. In this perspective, the genetic identities of cellular life throughout all domains of life are edited by their genetic parasites.

More recently, it has been found that phages communicate to decide whether to initiate lysogeny or not. Some phages produce communication peptides that are released. In subsequent infections, progeny phages measure the concentration of this peptide and lysogenize if the concentration is high. Interestingly, different phages encode different versions of the communication peptide, representing a phage-specific peptide communication code for lysogeny decisions (Erez et al. 2017). Virus-to-virus interactional motifs generally range from conflict to co-operation in various forms dependent on situational context (Díaz-Muñoz et al. 2017).

Consequently, the biocommunication approach has to integrate coherent natural genome editing of the genetic code by viruses (Witzany 2009). In this perspective, the genetic code of living organisms did not result out of chance mutations (error-replication events) that are biologically selected. The error-replication narrative has problems to explain the sudden emergence of new species, new phenotypic traits, and genome innovations as a sudden single event.

2.4.9 BIOCOMMUNICATION OF RNA STEM-LOOP GROUPS

To go one step deeper to the roots of life, we meet the viroids, short strands of circular, single-stranded RNA virus without a protein coat (Flores et al. 2012, 2014; Diener 2016). Here, we are only at the RNA strand level, which clearly shows infective and host-manipulating properties. This fits into the RNA world of RNA stem-loop groups, RNA group identities, and selection relevant biotic behavior (Robertson and Joyce 2012; Lehman 2015).

Recently, it has been found that single stem loops interact in a purely physical-chemical mode, without selective forces (Hayden and Lehman 2006; Smit et al. 2006). But if these single RNA stem loops build groups, they transcend the purely physical-chemical interaction pattern and emerge biological selection, biological identities of self/non-self identification and preclusion, and immune functions, dynamically varying (adapting) their membership roles (Marraffini and Sontheimer 2010; Vaidya et al. 2013; Krupovic and Koonin 2016).

A single alteration in a base-pairing RNA stem that leads to a new bulge may dynamically alter not just this single stem-loop but also the whole group identity of which this stem loop is part (Villarreal and Witzany 2013a, 2013b). Simple self-ligating RNA stem loops can build much larger groups of RNA stem loops that serve to increase complexity (Briones et al. 2009; Gwiazda et al. 2012). This may lead to ribozymatic consortia, which later on build success stories, such as (1) the merger of the two subunits of transfer RNAs, (2) RNA-dependent RNA polymerases for replication of RNA through RNA, and (3) the subunits of ribosomal RNAs originally evolved for different reasons than the later exapted and conserved modes (Dick and Schamel 1995; Sun

and Caetano-Anolles 2008; Fujishima and Kanai 2014; Kanai 2015).

The RNA stem-loop groups not only generate and constitute nucleotide sequences that serve as information storage media but also primarily interact (Nicholson and White 2014). The generation of RNA stem-loop consortia results in real entities, not just genetic syntax, and they are active in contributing to the identity of such groups and rejecting agents that do not fit in this identity. In several motifs, the interactions depend on the context in which an interaction takes place (Doudna et al. 1989; Przybilski and Hammann 2007; Popovic et al. 2015). This may be evolutionary conserved in DNA, as demonstrated in the co-operative behavior of the two ribosomal subunits. The activity is crucial for the result of co-operation (Doudna and Rath 2002).

Significantly, mixtures of RNA fragments that self-ligate into self-replicating ribozymes spontaneously form co-operative networks (Robertson and Joyce 2014). For example, three-member networks show highly co-operative growth dynamics. When such co-operative networks compete directly against selfish autocatalytic cycles, the former grow faster, indicating the ability of RNA populations to evolve greater complexity through co-operation (Vaidya 2012; Vaidya et al. 2012). In this respect, co-operation clearly outcompetes selfishness. Therefore, the primacy of selfish gene hypothesis is outdated on the RNA level.

RNA groups are able to act as de novo producers of nucleic acid sequences, identify sequence-specific target sites, coherently integrate such sequences into pre-existing ones (without destruction of former content arrangements), recombine according to adaptational needs, and mark sequence sites to vary meaning epigenetically or identify sequences to be marked for excision or deletion (Bushman 2003; Martinez et al. 2017). In all these processes, the genetic identity of the genetic parasite and/or the host genome may vary, with far-reaching consequences in terms of the function, co-operation, and coordination of various regulatory networks. Natural genome editing is therefore far from being a random-like process as a result of error replication (mutations).

Non-coding RNAs interact with DNA, RNA, and proteins and play important roles in nuclear organization, transcription, posttranscriptional, and epigenetic processes (Zuckerkandl and Cavalli 2007; Mattick 2009; Mercer and Mattick 2013). Non-coding RNAs are transcribed in both the sense and anti-sense directions and may be expressed in a cell type, subcellular compartment, developmental stage, or an environmental stimuli-specific, that is, context-dependent, manner (Zinad et al. 2017). Specific RNA polymerases overlap in transcriptional contents, which means that each nucleotide can participate in varying transcriptional content arrangements according to varying contexts (Mattick 2010, 2011).

Non-coding RNAs can be regulated in a varying manner, coordinated or independently, autonomously or functionally interrelated, and can regulate individual genes as well as large genetic networks; they can precisely control the spatiotemporal deployment of genes that are executing neuronal processes

with extreme cell specificity (Bartel 2004; Matera et al. 2007). Various classes of non-coding RNAs target each other for post-transcriptional regulation via alternative splicing, polyadenylation, 5' capping, non-templated modifications, and RNA editing. RNA editing especially can transmit environmental information to the epigenome and therefore enable neuronal plasticity with learning and memory (Kandel 2001; Qureshi and Mehler, 2012). Additionally, non-coding RNAs (ncRNAs) can undergo nuclear-cytoplasmic, nuclear-mitochondrial, and axodendritic trafficking via ribonucleoprotein complexes that promote the spatiotemporal distribution and function of various combinations of ncRNAs, messenger RNAs (mRNAs), and RNA-binding proteins (Clark et al. 2013; Mercer and Mattick 2013).

If we think of biocommunication as sign-mediated interaction, the question arises what are the signs used in RNA stem-loop interactions? RNAs themselves represent signs as their four bases of the RNA alphabet. In these interacting agents the binding sites are the bases themselves that serve as identity indices. As identity indices they are relevant for interactional motifs such as integration or preclusion (self and non-self differentiation).

2.4.10 COMMUNICATION AT THE ORIGIN OF LIFE

How did prebiotic chemistry start life? From the biocommunication approach, there is a variety of RNA agents that share the competence to act on nucleic acid sequences (genetic code) by several techniques, such as de novo generation, ligation/degradation, insertion/deletion, silencing, amplification, epigenetic markings, editing, splicing, and kissing. This is in tune with the general assumption that no natural code codes itself but needs a consortium of competent agents that act on this code (Witzany 2011b, 2012, 2014b; Witzany and Baluška 2012b). Now, we can ask how these agent consortia evolve and how they interact, co-operate, or compete, or even both, at different times, depending on the varying real-life contexts.

2.4.10.1 FROM “DEAD” TO “LIVING” BY SOCIAL INTERACTING RNAs

It has been suggested that a “dead” state controlled by prebiotic chemistry and a “living” state controlled by autocatalytic replication should be differentiated (Higgs and Lehman 2014).

Recent empirical data and experiments demonstrated that single RNA stem loops react only in a physical-chemical way according to natural laws, without any biotic feature assembling a “dead” state clearly. If we have a group of RNA-set loops that interact and initiate group building, biological selection emerges, which resembles a “living” state (Vaidya 2012).

As demonstrated experimentally co-operative RNA stem loops are more successful in biological selection processes than selfish agents.

From the biocommunication approach, the autocatalytic set narrative of Stuart Kauffman looks rather coherent, because it

represents a kind of social interaction. Unfortunately, the autocatalytic set concept reduces behavioral motifs to an explanatory model of systems theory, that is, the interacting RNA stem loops as a “system” that functions according to mathematical (formalizable) features. As we have seen in the introduction, behavioral motifs of interacting living agents are not within the expertise of mathematical theories or their derivatives, for several serious reasons (Witzany 1995, 2011a).

Also, the in-between definition of abiotic and biotic features such as “molecular co-operation” does not function as an appropriate explanatory tool, because if we look at biotic co-operation, we deal with living agents that co-operate. RNA “entities” consist of molecules, but molecules in a prebiotic world cannot co-operate like agents representing living organisms that co-operate based on communicative interactions, which is absent in abiotic matter. Molecules in a prebiotic world only react strictly according to physical/chemical laws. No biological selection is present here.

The reaction between single-stranded RNAs and their fold-back capability to form double strands (stems), including single-stranded regions (loops), that are free to interact in *cis* (kissing loop to increase complex functional motifs) and *trans* (integration or warding off infectious non-self agents) are based on a physical/chemical feature (complementary base pairing). Although their biotic interactions depend on complementary base pairing, they overrule physical/chemical laws by their biotic behavior such as biological selection, group building, group identity, and self/non-self differentiation, all of which are absent in abiotic planets.

In RNA groups that interact on identity motifs such as integration or warding off and self and/or non-self RNAs, the RNAs represent living agents underlying biological selection. This phenomenon is clearly absent in abiotic planets. The primary goal is the interaction becoming part of co-operative networks that may also be competing and restricting (Popovic et al. 2015), as documented in the predominant ligase function, in contrast to the nuclease function (Hayden and Lehman 2006; Díaz Arenas and Lehman 2010). This means the turn to life is also a behavioral pattern between becoming part of an identity of RNA groups that reject those that do not fit into this identity. The unique aspect of such RNA stem loops is that they may act both as templates for replication and as catalysts, if they are spatially separated.

2.4.10.2 THE ORIGIN OF RNA GROUP IDENTITY AND THE ORIGIN AS A GENETIC CODE

Humans consist of molecules. Yes, we need an abundance of oxygen atoms (that we call air) to transport vocal sound and talk to each other to organize everyday life. But this does not help us understand human language and communication. Detailed investigations and measurements of the molecular movements of oxygen atoms when humans talk to each other do not tell us anything about intentions being expressed by several different behavioral motifs.

If the interactions of individual RNA stem loops lead to groups of RNA consortia, we can look at the crucial event

of them becoming more than physics and chemistry, which determine abiotic planets exclusively. The group interactions of RNA stem loops make the genotype evolve into semiotic biology, which means the emergence of natural code rules (syntax, pragmatics, and semantics). The characters get their natural language-like feature *only through the social interactions* of RNAs. Their emergence as semiotic signs and as characters for a language/code-like property, which represents information about RNA-group identities, crucially depends on the social interactions. Although statistically measurable, this semiotic feature cannot be substantiated by quantifiable analyses, because it is a socially interacting feature (Witzany 2016).

All such interactions depend on the ability to identify appropriate interaction partners and therefore differentiate between self and non-self, which means differentiating identity-sharing agents against proponents, which represent non-identity and must be fought, precluded, and warded off (Marraffini and Sontheimer 2010). Others may represent co-operation partners; some are actually interaction partners. Others remain as silenced enemies, which could destroy identity. Importantly, later on, in another context, they may be useful tools for co-opting or ex-apted processes. At different times, formerly fought non-identity proponents may be useful tools for generating new partnership (Villarreal 2011, 2012a, 2012b, 2015, 2016).

Several DNA- and RNA-degrading processes are not investigated under the assumption that they serve as useful resources for re-use and identity-building modules (Vaidya et al. 2013; Villarreal 2015, 2016). Additionally, important and key features of this agent-based co-operativity are the fast-changing identities, which lead to the question of how a former enemy becomes a new co-operation partner. What does this mean for former co-operative partners, which may turn into enemies, in fast-changing functional partnerships and the concurrent changes in organization and syntax order? These interaction processes start from the beginning of RNA life (Hayden and Lehman 2006; Mattick 2011; Yarus 2011; Higgs and Wu 2012; Higgs and Lehman 2015), that is, life without unicellular organism. But group identity and co-operativity

of an RNA collective also require opposite functions for the genesis of life (social behavior of agents). This is an essential part of the “gangen hypothesis,” which describes RNA groups emerging and acting like gangs (Villarreal 2015) in the context of the virosphere and the world of cell-based organisms.

The genetic code with its typical language-like features, that is, characters assembled according to syntactic, pragmatic, and semantic (combinatorial, context-dependent, and content-coherent) rules, takes the stage of a real, natural language, with the interactional group building of various RNA stem loops. The interactional and group-building co-operativity of the RNA stem loops constitutes the genetic code as a real natural code, not its physico-chemical key characters alone.

The crucial difference of the biocommunication perspective to that of molecular biology is that it is not the molecular aspect solely, but the agent-groups’ aspect. The RNA stem loops are part of a group identity, which co-operates or precludes and, by compartmentalization, gets the same first stages of conservation. Until DNA was invented—reverse transcriptase is the most appropriate candidate for this—conservation would have been a rare event, instead of being a constantly evolutionary innovation process of maximum productivity of genetic novelties (Witzany 2008; Moelling et al. 2017). Too much productivity in former concepts has been termed “error catastrophe.” Pure physico-chemical variations based on replication are correctly termed error. In a social RNA perspective as the biocommunication approach, this is not an error but productivity of novelties. The paradigmatic differences between the concepts of molecular biology and the biocommunication approach are shown in Table 2.4.1.

2.4.10.3 REPETITIVE SEQUENCE SYNTAX IS ESSENTIAL IN RNA COMMUNICATION

The repetitive syntax comprises the main characteristics of nucleotide sequences that represent interactions of RNA stem loops (Shapiro and Sternberg 2005). Stem-loop group building is and was based on repeat syntax and the complementary binding rules of the four bases of the RNA alphabet. Also, the

TABLE 2.4.1
Different Paradigms Investigating and Defining Life

Key Terms	Molecular Biology	Biocommunication
“Dead”	Pre-biotic chemical reactions	No sign-mediated interactions
“Living”	Replication/biological selection (molecular reactions)	Sign-mediated interactions (social events)
Determinants	Natural laws	Semiotic rules
RNA-ensembles	Molecular co-operation	Identity-groups integrate or preclude non-self agents
Viruses	Escaped selfish parasites	Essential agents of all life
Biological selection	Fittest type	Fittest consortium
Genetic code	Genetic material	Genetic text (according syntax, pragmatics, semantics)
Communication	Information transfer (via coding/decoding mechanisms)	Social interactions (of agent-groups mediated by signs according semiotic rules)

The molecular biological paradigm explains life by the physical-chemical and information theoretical (mathematical theory of language) properties of living organisms and life processes; the biocommunication approach explains life as a social event of cellular and sub-cellular agents that communicate, that is, based on interactions that are sign-mediated according to three levels of semiotic rules.

modifications on RNA sequences—after being transcribed out of DNA storage medium, such as loop kissing, RNA editing, splicing, and others—depend on repetitive syntax (Witzany 2017b). The non-repetitive syntax—main characteristics of protein-coding sequences—represents another code, an evolutionarily later-derived code for DNA storage of protein blueprints, not relevant for social RNA interactions such as group building, recognition (identifying), attack, and defense against genetic parasites (which rely also on repetitive sequence order). The main reason is that repetitive syntax represents a recognition pattern completely different from non-repetitive ones (Jurka et al. 2007). If an invading RNA species meets a host genome, it will sense and use repetitive sequences, which are much easier for insertion than non-repetitive ones. This is why genetic parasites insert more into non-coding repetitive syntax structures than in protein-coding non-repetitive syntax structures. This means that insertions with relevant evolutionary drive are inserted into regulation-relevant genome space, not in protein coding regions.

2.4.10.4 DNA SEQUENCE SYNTAX WITH VARIABLE MEANINGS

Consequently, the biocommunication approach has to integrate coherent natural genome editing of the genetic code of living organisms. In this perspective, the genetic code of living organisms cannot be the result of chance mutations (error-replication events) that are biologically selected. The error-replication narrative has serious problems to explain the sudden emergence of new species, new phenotypic traits, and genome innovations as a sudden single event.

The genetic syntax, that is, the nucleotide arrangement of genetic information, is not unequivocal. This means that a given genetic sequence does not offer its final meaning. There are several processual steps in which the same sequence syntax may get several different meanings (functions). In natural languages and codes, this is a usual procedure and—additionally—it saves energy costs: A given sign sequence may represent various meanings/functions according its contextual use. It is not necessary to generate a new sequence for every function. This indicates the primacy of pragmatics in determining the sequence structure, not its syntax (Doudna et al. 1989; Cech 2012; Witzany 2014b). Several context-dependent natural modifications of the meaning (function) of a given DNA sequence are currently known and investigated. Let's have a look at the various techniques to modify meaning (function) of given genetic sequences.

The currently known natural processes of generating variable natural meaning functions out of a given DNA sequence are the context-dependent markings in epigenetics, which also play a key role to understand and coherently explain memory and learning as competencies of living organisms in all domains of life (Witzany 2018). Additionally, we may think of complex regulatory control via RNA editing, alternative splicing, the various roles of tRNA-derived fragments, ribosomal frameshifting, the interaction motif of kissing loops, bypassing, translation, the role of competing endogenous

RNAs, and diversity-generating retroelements, not to forget pseudoknotting (Maizels and Weiner 1994; Keam and Hutvagner 2015; Arkhipova 2017; Yablonovitch et al. 2017).

Most interestingly, the base pairing in pseudoknots tends to be strictly context-sensitive, and base pairing overlaps in sequence positions. Additionally, the emergence of single-nucleotide bulge loops can hardly be predicted. This currently places limitations on algorithm-based prediction models, such as dynamic programming, and on stochastic context-free grammars (Lyngsø and Pedersen 2004). It indicates the language/code nature of nucleic acid language, which represents the possibility of coherent de novo generation and context-dependent alterations for a diversity of different meanings (functions) relating to the same syntax structures.

All these natural techniques fulfilled by RNA consortia must be mentioned if we think about artificially manipulating genes of living organisms. Without these historically evolved interwoven interaction networks, the natural competence of gene conservation cannot be understood coherently. Genes and their regulatory networks are not at all molecular bricks that can be combined and divided in a lego-like manner. If synthetic biology tries to generate living organisms artificially, it should be sure to guarantee the whole network coherence. Otherwise, low-level manipulation will be the result and may cause far-reaching ethical problems, which are not within the expertise of natural sciences in general.

2.4.11 CONCLUSIONS

If we look at life in contrast to abiotic matter, we will identify cellular organisms that coordinate and organize their life actively by communicative actions, which means that they use signs in various forms to interact. The use of signs is essential. The sign use is governed by three levels of rules: how to combine signs to sign sequences for more complex information (syntax); the context dependence, which determines meaning of the used sign sequence (pragmatics); and content coherence, in which signs are used to designate something (semantics). All communication processes in the cellular world share these features.

If we go a step deeper, communication forms change dramatically. In the RNA world, the evolutionary produced sign sequences, which we would term a kind of “writing down” what happened (as evolutionary protocol), are a side result of constant interacting RNAs, stabilizing their functional forms by proteins. The communication in the RNA world is a different one to that of the cellular world, another essential level. Communicating RNAs share common motifs to reach their goals, described earlier. The signs in this form of communication are the interacting agents themselves, as they represent a natural code alphabet of four nucleotides, which are combined according to semiotic rules coherent with the physical chemical structures. The interacting RNAs resemble both a syntax like alphabetic order, dominated by repeat sequences, and context-dependent interaction that represent (and are the result of) biological selection, which is absent in abiotic matter. The RNAs serve as editors of RNA sequence only

by their group interactions, which lead to group identities. Competing RNA group identities initiate biological selection. Several smaller RNA groups may be combined to form bigger elements such as tRNA and even ribosome and other ribonucleoproteins (RNPs) with essential functions in all life, as they serve as crucial tools for gene regulation in transcription, translation, repair, immunity, inheritance, etc. in any known cellular organism.

The very vivid and highly active meeting place of these two levels of communication, (1) cellular sign-mediated interactions and (2) RNA stem-loop group interactions, are (3) competent viruses or, better, the virospheres, which use both communication systems, perfectly adapted to the whole life on this planet. They are the driving force of life based on (a) RNA world communication and (b) cellular communication, which can be edited by viruses in an abundance of ways. As masters of the technique of natural genome editing in all the cellular world, they do not need a cell-independent replication. Interestingly, they do not damage cellular life during persistent integration but serve as the key for all forms of immunity for their host organisms constantly adapting to the high productivity of viruses. They serve as key, based on the RNA world communication, which they use actively for their tremendous repertoire of techniques to invade, manipulate, and regulate cellular life forms. Together, these three agent-based lifeworlds, RNA world, virosphere, and cellular organisms, constitute life as we know it. We may come closer to understand the secret of life now, if we do not take life mechanistically again.

3.1.1 INTRODUCTION

The scientific study of the origin of life is based on the philosophical postulate that living systems emerged on the primordial Earth by natural means. This fundamental presupposition is implemented in the search for physical and chemical processes that might have brought about the emergence of life under prebiotic conditions. The naturalistic conception of the origin of life is by now part of the general scientific worldview that developed historically beginning in the 16th and 17th centuries. This worldview was stimulated first by the rise of the physical sciences and was joined during the nineteenth century by the development of modern biology. Specific cultural, social, and political changes constituted the framework within which this worldview grew. One of the major tenets that came to characterize this intellectual and cultural transformation was the rejection of supernatural purposes as causal explanations of natural phenomena. These scientific and philosophical developments reached their culmination when Darwin’s theory of evolution, published in mid-nineteenth century, came into fruition in the first half of the twentieth

century. It was the “neo-Darwinian synthesis,” taking place in the 1940s, that established natural selection as the major evolutionary mechanism and rejected all purposive explanations of evolution previously entertained (Mayr 1991:135, 138; McMullin 1998:704; Provine 1988:58–62).

The scientific field investigating the emergence of life still faces enormous challenges and is plagued by various dividing issues. There is as yet no agreed-upon theory accounting for the origin of life, and no suggested scenario has yet been simulated in full in the laboratory. However, it is due to the robustness of the scientific-evolutionary worldview that the presupposition that life arose by natural means is no longer just one option among others but constitutes the basis for research of the origin of life (see, Searle 1994:85–86, 90–91). At the same time, the epistemological status of the naturalistic philosophical presupposition should be noted. This presupposition makes a general claim about the natural and the supernatural that transcends our possible experience. There is no empirical proof or disproof of the belief in the sufficiency of natural mechanisms to explain the emergence of life. Yet, as an inherent part of the scientific-evolutionary

worldview, it is not a dogmatic belief. Unlike belief in the divine, the naturalistic conception developed in interaction with wide-ranged empirical data, grew stronger historically based on such data, and, furthermore, is continuously giving rise to testable empirical hypotheses that advance research. As part of a general scientific framework that proved itself fruitful in accounting for natural phenomena, the conception that life emerged naturally thus reached the status of a fully justified “given” (Fry 2012).

In fact, the commitment of origin-of-life researchers goes further than the naturalistic postulate. The realization that the emergence of life itself was an evolutionary process is also shared by most researchers in the field (Pascal et al. 2013:1–3). It is well established today that the “end point” of the emergence process, the cells constituting the Last Universal Common Ancestor at the root of the evolutionary tree, were already highly complex, organized systems. Within a naturalistic framework, the only feasible process that could have produced such a complex organization could not have been an all-or-none chance emergence but a gradual succession of increasingly complex stages (see, Peretó 2012:5394). What I suggest to call, *the evolutionary hypothesis of the emergence of life* maintains that physical and chemical prebiotic processes under specific geochemical conditions gave rise to a chemical infrastructure that could have gradually evolved toward primitive living systems. What could have been the nature of such evolutionary processes prior to the establishment of living systems? On the face of it, the very possibility of evolution prior to life is paradoxical. Didn’t natural selection depend on the existence of a population of genetic replicating and mutating systems catalyzed by encoded enzymes?

It was the rise of molecular biology and experiments conducted in the 1970s and 1980s that revealed that natural selection and evolution could have taken place not only in populations of living cells but also in populations of RNA molecules in the test tube (Eigen et al. 1981:82–85; Orgel 1973; Saghil et al. 1970). Though these experiments were carried out under conditions far removed from prebiotic conditions, they drove the search for the most primitive chemical systems compatible with such conditions and with the basic evolutionary requirements of reproduction, division, and selection. Concomitantly, the discovery of the interdependence of genetic material and protein enzymes in extant cells and the specter of the chicken-and-egg problem became principal stimuli for research in the origin-of-life field.

Various prebiotic evolvable systems, some of them very different from the replicating genetic systems familiar to us from extant organisms, are suggested and studied in the field. The nature of these systems, the details of their prebiotic synthesis, and the various factors involved in their evolution are still issues contested among investigators. However, based on data from numerous experiments and on insights gained from theoretical models, study in the field is guided by several shared hypotheses: Notwithstanding the role of random events and randomly changing geochemical conditions, the gradual construction of evolvable structures

was highly constrained and channeled by the characteristics of prebiotic chemistry and the nature of geochemical locals on ancient Earth (see, among many, Copley et al. 2007; de Duve 2005:21–24; Ferris 2006). Inorganic and organic catalysts, physical and chemical selection events, and the interaction between physico-chemical selection and primitive forms of natural selection led to the emergence of Darwinian evolution “in a series of stages, step by step” (Szostak 2012a:600).

The objective of this chapter is to shed light on the philosophical aspects of the origin-of-life problem. This aim will be tackled by examining the two main ideas, opposed to the evolutionary hypothesis of the origin of life, supernatural design, and chance. The position advanced by proponents of intelligent design (ID), among the most vocal current creationists, will be one of my targets. The various aspects of the ID movement, including its strategy and tactics in fighting science in general and biological evolution in particular, have been well documented and explored (Forrest 2007; Forrest and Gross 2004; Pennock 2000). I will concentrate here mainly on the contentions made by IDers on the origin of life. As part of their attack, they repudiate the notion of prebiotic natural selection as “a contradiction in terms” (Meyer 2004:244–248). However, this is just another pretext to deny the very possibility of a natural origin of life (Behe 1996; Bradley and Thaxton 1994; Meyer 2009). I will call attention to the most fundamental anti-scientific tenet of ID creationism—the belief in supernatural purpose and intention as a causal agent in the natural world (Johnson 1993:115).

Remarkably, the denial of the evolutionary conception of the origin of life makes for curious bed fellows: Richard Dawkins, the renowned evolutionary biologist, also rejects the relevance of evolution to the origin of life, contending that natural selection could have proceeded only once life had originated (Dawkins 2006:137, 140). Dawkins, a defender of evolutionary naturalism, obviously rejects the creationist viewpoint. However, instead of divine teleology, he suggests that the origin of life could have been an extremely improbable single-step chance event (Dawkins 1986:140, 2006:135). My discussion will point to the deep division between Dawkins’s position and the conception and practice of origin-of-life investigators. Most significantly, Dawkins’s chance thesis conflicts with the various scenarios that suggest viable gradual alternatives leading to life. Although only two examples of such scenarios will be described briefly in this philosophically oriented chapter, detailed examination of major scenarios in the field that serve as case studies of the evolutionary hypothesis of the origin of life can be found in Chapter 6.5 of this volume.

The philosophical dimension of Dawkins’s position will be examined in juxtaposition to the ideas of ID creationists. The question of chance versus design will be further illuminated by considering the views of Thomas Nagel, an eminent New York University philosopher, who under the influence of ID creationists mounted an attack against the possibility of a natural origin of life. My conclusion will be that despite Dawkins’s intentions, his chance position does not provide

an answer to the challenge of design but rather weakens the scientific case. It is the hypothesis of the evolutionary emergence of life that obviates both the chance and the design solutions.

3.1.2 A HISTORICAL INTERLUDE: WHAT DID DARWIN THINK?

The evolutionary hypothesis of the origin of life, guiding investigations in the field, obviously assumes a continuous transition between the emergence of life and biological evolution. Proponents of ID, from their creationist perspective, attack the origin of life and biological evolution as a unified target, claiming that both could not have happened without divine intervention (see, Johnson 1993:103). One of their major arguments against biological evolution is based on their characterization of complex organized biological systems as un-evolvable “irreducible complex systems.” As will be shown later, this is also their argument against a natural origin of life (Behe 1996:187–205). It is remarkable that several philosophers and historians of biology, as part of their repudiation of creationism, insist on considering the origin of life and biological evolution as two separate categories. This position is often justified by citing Darwin’s views on the origin of life. In his witness testimony against the ideas of “creation science” in the 1981 McLean v. Arkansas trial, philosopher Michael Ruse stated that “The ultimate origins of life and the subsequent evolution of life were separated by Darwin (he never mentions the former in the *Origin*). They have been kept separate ever since” (Ruse 1996:27). Ruse (Ruse 2001:65, see, Ruse 2006:53) changed his view in more recent books, describing the origin of life as an “extension of Darwinism, for scientists are now starting to think in terms of the ways in which selection might have taken over the process.” Robert Pennock, philosopher and historian of the ID movement, criticized prominent IDer Michael Behe for including in the definition of evolution also the emergence of life by natural means and especially for wrongly attributing this perception of evolution also to Darwin (Pennock 2000:160–161). To refute Behe, Pennock referred to Darwin’s quote in the *Origin* that “it hardly concerns us how life itself originated” (Darwin 1988 [1872]:151). So, what did Darwin think on the origin of life? It might seem peculiar that Darwin (1859) hardly discussed the subject of the origin of life in his major opus *The Origin of Species* (1859). As attested especially in Darwin’s post *Origin* letters, there were two major reasons why he avoided the subject in the *Origin*. First, Darwin perceptively realized and repeatedly stated that the origin-of-life question was beyond the powers of the science of his day (see, among many, Darwin 1863, 1959 [1882]). Second, realizing the inflammatory potential of the origin-of-life subject in the theological context of his day, Darwin didn’t wish to alienate his public even more. So much so that at the end of the second edition of the *Origin*, departing from the general tenor of the work, Darwin used the biblical term of the creation of life (Darwin 1860:484). However, in a letter

to his close friend Joseph Hooker, Darwin later expressed his regret that he had given in to public opinion, emphasizing that all he meant to say was that the origin-of-life subject is “some wholly unknown process” (Darwin 1863).

Despite his apparent “silence” in the *Origin*, Darwin was preoccupied with the question of the original appearance of life, and quite a few of his comments on the subject reflected his feeling that the origin of life was a natural process (see, Peretó et al. 2009:404). Darwin’s most famous allusion to the subject appeared in 1871 in another private letter to Hooker, where he raised a hypothesis that he considered extremely daring (“But if – and oh! What a big if!”). He imagined the synthesis in “a warm little pond” on the ancient Earth of “a protein compound...ready to undergo still more complex changes” from inorganic compounds under the influence of various sources of energy (Darwin 1871). Furthermore, in a most revealing letter in 1882, the last year of his life, Darwin explicitly stated that though “no evidence worth anything has as yet, in my opinion, been advanced in favor of a living being, being developed from inorganic matter, yet I cannot avoid believing the possibility of this will be proved some day in accordance with the law of continuity” (Darwin 1882). In light of Darwin’s warm-little-pond musings in his letter to Hooker in 1871, “the law of continuity” of 1882 might have suggested a natural mechanism of emergence.

Clearly, Darwin was not silent on the question of the origin of life. His (mostly private) consideration of a natural origin of life and his realization of the incompetence of the science of his day to face the enormous complexity of the problem should not surprise us. Relying on Darwin’s separation of the origin of life and its evolution is thus not a convincing argument against creationists. Moreover, anachronism in the history of science is a bad policy, or “poor history,” as put by historian of evolution David Kohn (1989:221). Kohn speaks of Darwin’s secularization of biology by changing the biological meaning of teleology (Kohn 1989:220–221, 229), but at the same time, he shows convincingly that Darwin’s context was still theological and that Darwin was “a theologically transitional figure” (Kohn 1989:232). Even Darwin cannot be read out of the cultural and social context of his time.

3.1.3 FROM OPARIN AND HALDANE VIA THE CHICKEN-AND-EGG PUZZLE TO GENETIC AND METABOLIC INFRASTRUCTURES

Based on the far-reaching naturalistic implications of Darwin’s theory, the major Darwinians in the last decades of the nineteenth century believed that a natural origin of life was an essential element of a consistent general evolutionary worldview (Haeckel 1902:256–258; Kamminga 1988). However, by the beginning of the twentieth century, new cytological studies revealed the heterogeneity of the cell content and the role of the nucleus. The rise of biochemistry led to the discovery and isolation of enzymes (Fry 2000:58–59). This new awareness of the complexity of the simplest of cells convinced many scientists of the impassable gap between the living and the inanimate (Oparin 1967:203). In addition, in the beginning of the twentieth

century, the mechanism of natural selection came under heavy attack, especially as a result of the uncertainties surrounding the causes and nature of mutations (Bowler 1989:246; Kellogg 1907:1–7). This also led to an impasse in the scientific perception of the origin of life. Despite these obstacles and the avoidance of the problem by most of the scientific community (Muller 1966:494), several scientists, notably the biochemist Alexander Oparin in the Soviet Union and the geneticist and biochemist J. B. S. Haldane in Britain, independently published in the 1920s pioneering theories based on the evolutionary conception of the origin of life (Haldane 1967 [1929]; Oparin 1967 [1924]).

The empirical aspects of Oparin's and Haldane's scenarios were inspired by the new disciplines of biochemistry and genetics. They also relied on new data from the study of geochemistry and astronomy in their description of the prebiotic environment. Oparin, the biochemist, contended that cell-like structures that engaged in primitive metabolism could have been synthesized on the primordial Earth, whereas Haldane, the geneticist and biochemist, suggested the prebiotic synthesis of gene-like or virus-like molecules. These structures, as they both hypothesized, could have undergone evolutionary processes, leading to “protoorganisms” and later to life (see, Fry 2006). By assuming that such prebiotic structures could have evolved, Oparin and Haldane unknowingly foreshadowed theoretical ideas that were made possible and empirical data that became available only after the rise of molecular biology (Eigen et al. 1981:82–85; Orgel 1973; Safhill et al. 1970). Their theories, especially Oparin's, contributed to a scientific breakthrough in the 1950s. Oparin's hypothesis concerning the prebiotic synthesis of organic compounds was successfully implemented in the laboratory for the first time in the early 1950s by Stanley Miller (1953). Miller's experiments, and others that followed, and the rise of molecular biology in the 1950s and 1960s led to the establishment of a new experimental field devoted to the origin of life (Fry 2006).

One of the crucial discoveries of molecular biology that transformed the thinking on the origin-of-life problem was the functional interdependence of nucleic acids and proteins. It was realized that nucleic acids cannot be synthesized and cannot function without protein enzymes. Proteins, in order to be formed, have to be translated from nucleic acids. How could such a “chicken-and-egg” circle first emerge? Which came first, proteins or nucleic acids? From the early 1960s, origin-of-life scientists explored the two options of nucleic-acid-first (e.g., Orgel 1994) and proteins-first (e.g., Fox and Dose 1977), in order to solve the puzzle and establish a basis for an evolutionary process. The discovery in the early 1980s of RNA molecules in extant cells that function as enzymes, given the name “ribozymes,” seemed to have overcome the conundrum. The idea of RNA as both chicken and egg dramatically changed the scene. It led to the hypothesis, now backed by strong evolutionary data (Benner et al. 2012:4; Cech 2012:2), that an “RNA world,” in which ribozymes functioned both as genetic material and as enzymes, existed at one stage or another during the emergence of life (Gilbert 1986). However, despite numerous experiments throughout the years aimed to reconstruct the emergence of such an RNA world,

enormous challenges still remain, especially associated with the prebiotic synthesis of nucleotides and of a replicating RNA ribozyme (Joyce and Orgel 2006:23–24).

Currently, genetically oriented researchers (proponents of the gene-first notion) are divided into supporters of “RNA-first” and “RNA-later” scenarios. The latter doubt the feasibility of the spontaneous prebiotic synthesis of RNA and examine alternative genetic molecules as more probable candidates (Orgel 2003). Metabolism-first theorists reject gene-first models on the grounds that the prebiotic emergence of a replicating genetic polymer was extremely improbable (de Duve 1991:112–113; Shapiro 2007). Instead, they suggest various scenarios in which metabolic autocatalytic cycles could have emerged spontaneously to function as an evolvable infrastructure. Such metabolic infrastructures are supposed to have engaged in an evolutionary process entirely different from the familiar genetic-based process but still based on reproduction, variation, and selection (Lancet and Shenhav 2009:239, 243; Segré et al. 2001:137–139; Smith et al. 2009:445–446; Vasas et al. 2012; Wächtershäuser 1992:89, 111–112, 2007:594–595). Yet, many practitioners in the field doubt the viability of these scenarios. It is the potential of such metabolic cycles to diversify in order to undergo Darwinian evolution that is mainly questioned (Eigen 1971:498–503; Maynard Smith and Szathmáry 1985:68, 71). Unlike the essentially unlimited diversity of replicating polymers, in terms of base sequence, the ability of metabolic cycles to diversify in order to provide competing metabolic variations is very limited (Eschenmoser 2007:12828; Peretó 2012:5398; Vasas et al. 2010).

Some researchers who consider the RNA world as crucial in the emergence of life promote the hypothesis that nucleotides and their assembled sequences could have emerged only with the help of a previously growing protometabolism (de Duve 1991:133–143, 2005:73–75; Martin and Russell 2007:1893). Preparatory metabolic theories postpone the onset of natural selection to the rise of RNA. The emergence of prebiotic metabolic networks is assumed to have been physically and chemically determined to a large extent by specific geochemical conditions, by inorganic and organic catalysts, and by physical and chemical selection processes (de Duve 2005:23–24; Russell et al. 2014). Another noteworthy scenario suggests that replication and metabolism could have co-evolved in a specific geochemical site and could have interactively led to the emergence of the RNA world (Copley et al. 2007). This mechanism entails a multi-stage process, during which mutual catalysis among small molecules, such as amino acids and nucleotides, led to the gradual synthesis of longer and more efficient catalysts, to the rise of protometabolism, and to the emergence of RNA as the dominant macromolecule because of its unique combination of catalytic and template-replication capabilities (Copley et al. 2007:430–431). This scenario is based on physical and chemical selection processes and the interaction between such processes and emerging forms of natural selection. Significantly, it is emphasized that the proposed processes toward the RNA

world were not chance-like but rather highly channeled. As the mutual catalysis in protometabolic reaction networks led to more effective catalysts, the “emergence of RNA as the dominant macromolecule became inevitable” (Copley et al. 2007:440, 431, 432). Thus, the various theories currently entertained by researchers in the field, including those examined in Chapter 6.5 and not mentioned here for lack of space, presuppose different versions of the evolutionary thesis of the emergence of life.

3.1.4 “A PIECE OF STATISTICAL LUCK” OR AN EVOLUTIONARY PROCESS?

In his seminal book, *The Blind Watchmaker* (1986), Richard Dawkins discussed at length the question of the emergence of life, which he identified with the rise of a “minimal machinery of replication and replicator power” (Dawkins 1986:141). He returned to this question, though in less detail, in his later books, maintaining his original view that the origin of life was “a single-step chance event,” entirely different from the process of biological evolution based on cumulative selection (Dawkins 1986:139–141, 2006:139–140). According to Dawkins (1986:140), his chance-event claim is an inevitable conclusion of “what seems to be a paradox” that lies at the heart of the origin of life. This paradox is no other than a version of the “chicken-and-egg” dilemma, already apparent at this first step: Natural selection, the mechanism responsible for biological evolution, depends on the existence of replicating molecules and a catalytic machinery enabling this replication. However, such a complex system could not have emerged without evolution by natural selection. This paradox led Dawkins (1986:140) to conclude that there is no other way to account for the source of a self-replicating molecule but to postulate “a single-step chance event in the origin of cumulative selection itself.” Dawkins (1986:158) admitted that before he gave the matter a deeper thought, his feeling was that “it would take a miracle to make randomly jostling atoms join together into a self-replicating molecule.” However, he realized that we are allowed to include the whole universe in order to answer the question “how improbable, how miraculous, a single event...we are allowed to postulate” in order to account for the presence of life on Earth (Dawkins 1986:141). In an argument he titled later the “Planetary version of the Anthropic Principle” (Dawkins 2006:134), and based on the estimated number of planets in the universe, Dawkins (1986:145) concluded that we should not be surprised at all by a chance-like origin of life on Earth. Since there are around a billion billion planets in the universe, a model that predicts that “life will arise on *one* planet in a billion billion [will] give us a good and entirely satisfying explanation for the presence of life here” (Dawkins 2006:137–138). Adding to his calculation the estimate that life could have emerged on Earth during about a billion years (based on findings of the first “fossil organisms” from around 3.5 billion years ago), we have about a billion billion billion planet years “to play with.” This amount of time can explain nicely how “random

thermal jostling of atoms and molecules resulted in a self-replicating molecule” (Dawkins 1986:144–145).

Obviously, Dawkins’s conclusion leads the science of the origin of life to a dead-end. No hypothesis aiming to reconstruct a possible emergence process in the laboratory can account in scientific terms for a “random jostling of atoms” of such improbabilities. Several leading researchers in the field have described the lucky-accident claim as “sterile” or as “stifling research” (Cairns-Smith 1986:7; de Duve 2005:74; Orgel 1973:192). The ideas of the eminent molecular biologist Jacques Monod on the origin of life and its probability come to mind. In his book *Chance and Necessity*, published in 1970, when origin-of-life research was taking its first steps, Monod expressed his conviction that the origin of the linked system of nucleic acids and proteins (the chicken-and-egg vicious circle) poses a “veritable enigma.” In his view, it is entirely possible that the origin of life occurred only once, “which would mean that its *a priori* probability was ‘virtually zero’” (Monod 1974:136). Monod was fully aware of the unfortunate bearing of his conclusion on the scientific study of the origin of life (*Ibid.*). Dawkins, unlike Monod, seems strangely to ignore the significance of his one-in-billion-billion probability notion for the possibility of finding a specific mechanism of emergence. His claim is that we should not be afraid of such enormous numbers because an event or events of such staggeringly improbability are still feasible and calculable in a universe in which these numbers are based on astronomical facts (Dawkins 1986:143–144).

It is quite surprising that despite what seems like a consistent position on the origin of life, Dawkins occasionally vacillated between very different estimates of the probability of the event. In his various books, he discussed several theories that attempted to offer plausible explanations for the origin of life such as the primeval soup theory (Dawkins 1978:16) and Cairns-Smith’s clay model (Dawkins 1986:148–157). Describing the subject of the origin of life as “a flourishing, if speculative subject for research,” he astonishingly commented at one point that “I shall not be surprised if, within the next few years, chemists report that they have successfully midwifed a new origin of life in the laboratory” (Dawkins 2006:137). In his examination of the RNA-world theory, Dawkins (2009:421) asserted that he found this theory “plausible, and I think it quite likely that chemists will, within the next few decades, simulate in the laboratory a full reconstruction of the events that launched natural selection on its momentous way four billion years ago.” The picture gets more confusing when Dawkins considers the subject of extraterrestrial life. He takes very seriously the famous question raised by the distinguished physicist Enrico Fermi in 1950, “Where is everybody”? Why haven’t we detected any signs, even by radio signals, of the existence of life elsewhere in the universe? (Dawkins 2009:421). Assuming unequivocally that once life existed, the evolution of intelligence was probable (Dawkins 1986:146), Dawkins saw the failure to detect signs of extraterrestrial intelligence as an indication of the “paucity of life in the universe” (Dawkins 1986:165). Dawkins’s guess was that “life in the universe is very rare” and we should

expect that “no plausible theory of the origin of life exists” (Dawkins 1986:145, 2009:422). His conclusion was, thus, that the various origin-of-life theories that he examined err “on the side of being too plausible” (Dawkins 1986:165).

How can one account for Dawkins’s fluctuating views on the likelihood of origin-of-life theories? Do these fluctuations reflect the still-prevailing uncertainty and controversy over the questions whether the emergence of life on Earth was “easy” or “difficult” and whether life, intelligent or not, is common or rare in the universe? In my view, the problem lies in Dawkins’s focus of interest, which is neither on the scientific questions that occupy researchers in the field, nor on the specifics of the “pet theories” that scientists suggest (Dawkins 1986:147). On his own admittance, the theories that he discussed were chosen “arbitrarily...any one of the modern theories would have served the same purpose” (Dawkins 1986:139). Rather, Dawkins’s main objective is to show that chance on a cosmological scale, replacing the inapplicable alternative of natural selection, is an adequate naturalistic answer (Dawkins 1986:141, 147, 2006:139). This and other philosophical implications of Dawkins’s chance solution will be discussed presently. It is important first to point to the gap separating current research of the origin of life and Dawkins’s perception of the subject.

3.1.5 ORIGIN-OF-LIFE RESEARCH VERSUS DAWKINS’S LUCKY-ACCIDENT SOLUTION

Disregarding the option of an evolutionary hypothesis, Dawkins, as we saw, considers “chance” a valid account for the emergence of life. Based on calculations very different from Dawkins’s, active researchers reject the “statistical luck” solution (see, e.g., de Duve 1991:137; Eigen 1992:10–11, 12–13, 22; Miyakawa and Ferris 2003:8202; Pascal et al. 2013:2). A few examples will suffice to demonstrate why they would find Dawkins’s “jostling of atoms” equivalent to a miracle. Eminent biochemist and origin-of-life theorist, Christian de Duve, calculated that the probability of a small protein enzyme, for example, human cytochrome C (104 amino acids), coming together by chance, assuming that all possible combinations of 104 amino acids have the same probability, is 20^{-104} , or about 10^{-135} . De Duve concluded that “there simply was not enough time, space, and matter on the prebiotic Earth, even in the entire universe, to try more than an infinitesimal fraction of the possible amino acid combinations” (de Duve 1991:137–138, 137, note 4). In another example, considering the probability of the synthesis of a specific RNA sequence made of 100 nucleotides, needed for an active ribozyme, out of all possible sequences, it is concluded that “synthesizing all of the [sequences] in one molecular unit over 1 billion years would lead to the synthesis of a mass of nucleic acid representing several tens that of the Earth per day” (Pascal et al. 2013:2). Another distinguished researcher, physical chemist Manfred Eigen, calculated the number of alternative arrangements of the four nucleotides of a single gene, with only a thousand symbols. He reached the staggering number of 4^{1000} , or about 10^{602} . The volume of the whole universe

(calculated on the basis of astronomical data) and the entire material of the cosmos lag far behind the combined volume and mass of this number of variants (Eigen 1992:10).

In distinction, Dawkins did not refer specifically to what, according to his own view, will be needed chemically in order to overcome the “paradox” of the origin of life. He did not calculate the probabilities of the chance assembly of a genetic polymer and a protein replicating enzyme or of two ribozyme molecules, one acting as an RNA template and the other as a replicase ribozyme. The examples cited earlier, few of the many found in the literature, by referring to such specific requirements, demonstrate why investigators regard the contention that the origin of life was a chance event as a “scientifically respectable version of the special miracle” (Cairns-Smith 1986:7).

In addition to the strong doubts cast upon Dawkins’s position as a result of specific calculations, the rejection of the “statistical luck” option by origin-of-life researchers rests mainly on their suggested scenarios.

3.1.5.1 SINGLE-STEP SELECTION, CUMULATIVE SELECTION, AND EVOLUTIONARY SCENARIOS OF THE ORIGIN OF LIFE

The conflict between the evolutionary hypothesis of the origin of life and Dawkins’s view may be further clarified by Dawkins’s distinction between “single-step selection” and “cumulative selection” (Dawkins 1986:45–49). A non-random arrangement of pebbles on a beach by the action of waves and a sieve separating objects non-randomly according to size are among Dawkins’s examples of single-step selection events. Single-step selection applies to physical and chemical events, in which entities are selected on the basis of physical and chemical features such as size and stability. Most importantly, each single-step selection event starts afresh. In cumulative selection, on the other hand, reproduction or “memory” is involved, and hence, the selected product is retained in the next generation and serves as the starting point for the next selection event. Dawkins asserts that for reasons of probability, the innumerable cases of complex organization manifested by living organisms could not have been the result of a concatenation of chance-like events but only of the gradual process of the accumulation of selected small advantages dependent on the mechanism of natural selection (Dawkins 1986:43–74; see, Cairns-Smith 1986:45–49). As we saw, according to Dawkins, the case of the origin of life is different. Whereas single-step selection events, that is, “lucky chance,” could never have been enough to explain biological evolution, “the origin of life was (or could have been) a unique event which had to happen only once” (Dawkins 1986:163, 2006:139). Given enough time and space, in fact, given the whole universe and its billion billion planets, a complex replicating molecular system at the origin of cumulative selection could have been the result of a single-step highly improbable chance event (Dawkins 1986:140).

Thus, the realms of the emergence of life and of biological evolution are separated by Dawkins and are kept distinct.

Based on this dichotomous view, the origin of Darwinian evolution is presented as an all-or-none transformation. In distinction, scenarios suggested by origin-of-life researchers describe various means by which what might be described by Dawkins as single-step selection events could have contributed to the step-wise growth of complexity and the gradual emergence of Darwinian evolution. Major scenarios in the field are examined in [Chapter 6.5](#) of this volume, and their evolutionary characteristics are pointed out. Two examples out of these scenarios will be concisely presented here in order to demonstrate the difference between Dawkins's position and the scientific study of the origin of life: First, the empirical study in the framework of an RNA-first position, conducted in the laboratory of Jack Szostak, and second, the theoretical protometabolic scenario suggested by Christian de Duve. Another scenario, not discussed here, of the emergence of life in hydrothermal fields, suggested by Deamer, Damer, and colleagues (Damer and Deamer 2015), is a clear example of the role of physico-chemical selection in the evolutionary emergence of life (see [Chapter 6.5](#), Section 6.5.9).

3.1.5.2 THE EVOLUTIONARY EMERGENCE OF RNA-CONTAINING PROTOCELL

Experimental work in progress during more than two decades in the laboratory of leading origin-of-life researcher Jack Szostak was aimed to study the origin of cellular life. It explored models of cellular compartments containing replicating RNAs, supposedly analogous to protocells that emerged during the origin of life. Physico-chemical features and processes that were crucial to the emergence of replicating vesicles, replicating RNAs, and their interaction were studied in these experiments. Among them are the chemical composition of membranes, mineral catalysis of the assembly and growth of vesicles, encapsulation of RNA adsorbed to minerals, chemical conditions affecting the stability of both RNA and vesicles, vesicle growth and division affected by internal osmotic pressure and by other mechanisms, and the impact of internal osmotic pressure on competition among vesicles. All these processes, and many more, are hypothesized to have contributed to the emergence of Darwinian evolution during the origin of life (Chen et al. 2004:1746; Szostak 2012a).

Not able to review here, in detail, Szostak's work in progress, I will consider only two major instances demonstrating how the evolutionary hypothesis shaped Szostak's scenario: First, the change in attitude of Szostak and other RNA-world researchers toward the need for an early protocell, and second, the decision of the Szostak group to consider anew, after years of failed trials, a non-enzymatic alternative to RNA replication by a ribozyme replicase, originally thought to be the basis of the RNA-world hypothesis.

3.1.5.2.1 RNA-World Research and Compartments

The concept of some sort of "primitive cell" engulfing emerging metabolism characterized early metabolism-first theories, notably Oparin's. Continuing the Oparin tradition in later years, the division of protocells, representing reproduction, was

included by "metabolists" in their evolutionary scenarios (e.g., Lancet and Shenhav 2009; Morowitz 1992:153, 1999:44). In distinction, "geneticists" considered proto-cellular membranes as possible barriers, preventing the easy access of organic molecules from the "soup," and preferred to postpone their emergence (see, Eigen et al. 1981:91–92; Orgel 2004:117–118). Reflecting on the development of his own professional interest in protocells, Szostak commented that "geneticists" traditionally "neglected the cellular nature of life," and work within the RNA-world program continued this tradition. For example, most "template copying experiments have been...performed in solution," not within a membrane-engulfed compartment (Service 2013:1034; Szostak 2012b:1, 2). However, the need for spatial localization is now commonly accepted by RNA-world researchers, not only because it allows the concentration of the ingredients of life but especially also because it enables the emergence of Darwinian evolution (Monnard 2007:389). It is realized that a population of RNA replicating molecules free in solution could not have evolved into more efficient or accurate replicators. "By keeping molecules that are closely related together, advantageous mutations can lead to preferential replication" (Szostak et al. 2001:387). Within a compartment, better replicators will be able to replicate each other more efficiently and will have an advantage over other compartments (Service 2013:1034; Szostak et al. 2001:387). Indeed, this change in perception proved itself fruitful. As shown in more detail in [Chapter 6.5](#), the Szostak group demonstrated growth, division, and competition among vesicles containing RNA replicating molecules as a result of various physico-chemical mechanisms (Budin and Szostak 2011:5249; Chen et al. 2004; Hanczyc et al. 2003; Szostak 2011:2897; Zhu and Szostak 2009:5706–5709).

3.1.5.2.2 Alternative Route to RNA Replicase

Following the numerous difficulties encountered by researchers in their attempts to reconstruct a ribozyme replicase in the laboratory, Szostak and colleagues wondered whether RNA-catalyzed RNA replication could have emerged through a series of simpler steps, "driven purely by physical and chemical processes" (Schrum et al. 2010:8; Szostak 2012b:1). They thus decided to try to replicate RNA chemically, that is, without enzymes, in the "simplest form of genetic replication" (Blain and Szostak 2014:11.2). This reaction was studied in the 1970s and early 1980s in the Orgel laboratory (prior to the discovery of ribozymes). However, full cycles of chemical replication of RNA could not be achieved without the participation of a protein enzyme (Orgel 1994:60, 2004:111–112). Among the many obstacles preventing full replication was the fact that the complementary strand produced in the non-enzymatic copying process always contained a random mixture of "non-natural" 2'-5' and "natural" 3'-5' phosphodiester linkages, unlike the homogenous 3'-5' linkages in contemporary RNA. After the discovery of ribozymes, it was commonly assumed that a random mixture of 2'-5' and 3'-5' linkages will prevent the spatial folding of the RNA chain needed for ribozyme activity, thus preventing an origin of life based on RNA catalysis (Engelhart et al. 2013:390). Another major problem encountered by Orgel and others in the studies of

non-enzymatic RNA replication was the difficulty to separate the strands after copying the template, because of the thermal stability of the duplex.

However, the experiments conducted by the Szostak group revealed that the heterogenous chains that were copied non-enzymatically from an RNA template and that contained low to moderate percentage of 2'-5' linkages not only allowed easier thermal separation of the duplex but were also capable of folding into spatial structures that showed catalytic properties (Engelhart et al. 2013). The authors thus suggested that the random incorporation of “wrong,” “non-natural” 2'-5' linkages “far from being problematic” might have, in fact, contributed to the emergence of RNA as the first genetic polymer of life (Engelhart et al. 2013:391). Furthermore, when non-enzymatic RNA replication became the leading hypothesis in studying the origin of cellular life, an alternative model of an evolutionary pathway was suggested (Adamala and Szostak 2013). The early model of a protocell was assumed by Szostak and others to enable Darwinian evolution based on an RNA replicase, self-replicating within a vesicle. Now, chemical replication of RNA implied that the first evolved RNA catalysts, rather than improving replication, might have functioned as metabolic ribozymes (Szostak 2012b:1, 12). Experiments conducted by the Szostak group focused on a metabolic function that “conferred an advantage on its host cell” (Szostak 2012b:12). More specifically, a model was constructed, in which a metabolic ribozyme catalyzed the synthesis of a possible membrane component that led to an accelerated vesicle growth and division (Adamala and Szostak 2013:500).

To recapitulate, the system under study in Szostak’s genetic scenario consists of an RNA polymer engulfed by a vesicle. As hypothesized and tested experimentally, both elements could not have been synthesized prebiotically without what Dawkins might have called “single-step selection events.” These were part and parcel of the processes carried out by inorganic and organic catalysts, affected by physico-chemical selection under specific geochemical conditions. Such was the case also with the processes of vesicle growth and division and the processes of competition among vesicles. Even in the non-enzymatic chemical replication of RNA, the random distribution of 2'-5' linkages results from pure physico-chemical factors. None of these events and processes is endowed with “memory” and in itself cannot guarantee an accumulation effect. However, all these “single-step selection” events resulted in the development of a coordinated genetic system, which began to undergo primitive forms of natural selection. Remarkably, Szostak’s experiments attempt to follow not just the preparation for but also the step-wise development of Darwinian evolution.

3.1.5.3 DE DUVE’S THEORY OF PROTOMETABOLISM AND THE RISE OF THE RNA WORLD

3.1.5.3.1 The Multimer Hypothesis

The eminent biochemist, Christian de Duve, regarded the RNA world as a crucial, though not the earliest, stage in the way to life. De Duve contended that the synthesis of

nucleotides, their assembled RNA sequences, and the RNA world could have emerged only with the help of a previously growing protometabolism, whose function depended on various kinds of prebiotic catalysts (de Duve 1991:133–143, 2003:562, 567–569, 2005:75). In most origin-of-life scenarios, the focus was usually on the role of minerals, especially metal ions and clays, as prebiotic catalysts. Inspired by the work of Sidney Fox on “proteinoids” (Fox and Dose 1977), de Duve raised the hypothesis that heterogenous, peptide-like molecules that he called “multimers,” made of amino acids and occasionally also hydroxy acids, were the major catalysts sustaining primordial metabolism (de Duve 2003:567–568, 2005:22). It should be noted that experiments attesting to the catalytic capabilities of small organic molecules, especially short peptides, even single amino acids, in carrying out prebiotic syntheses are increasingly being conducted in various laboratories (Adamala et al. 2014; Wieczorek et al. 2013). According to de Duve, a “thioester world” was a critical chemical stage enabling the synthesis of multimers and the emergence of a primordial metabolism. In de Duve’s scenario, sulfur compounds called thioesters could have been formed from the condensation of amino acids (and hydroxy acids) with thiols (alcohol-type compounds containing sulfur) that were all prebiotically available. This condensation required energy and was favored under acidic and hot conditions (de Duve 1991:116). De Duve (2005:64) indeed supported a volcanic setting at hydrothermal vents for the origin of life. Once formed, thioesters could have assembled to form multimers with the help of the energy derived from the thioester bond. De Duve (1991:113–116) hypothesized that among the multimers were probably a number of crude catalysts that could have catalyzed the synthesis of various organic compounds, including additional thioesters and multimers. Thus, like other metabolic theories, de Duve’s theory is based on an autocatalytic process that drove the growth of protometabolism. In addition to catalyzing their own formation, multimers could have also catalyzed the formation of other protoenzymes. The increasing catalytic capabilities of the growing protometabolic network could have eventually led to the synthesis of nucleotides and oligonucleotides and to the rise of the RNA world (de Duve 1991:115).

3.1.5.3.2 What Kind of Evolutionary Hypothesis?

What are the evolutionary aspects of de Duve’s theory? De Duve’s protometabolic theory postpones the onset of natural selection to the rise of RNA replication. In this, it differs from scenarios that propose a metabolic evolvable infrastructure such as an autocatalytic metabolic cycle engaged in reproduction, variation, and selection (Lancet and Shenhav 2009:239, 243; Smith et al. 2009:445–446; Vasas et al. 2012; Wächtershäuser 1992:89, 111–112, Wächtershäuser 2007:594–595). In not suggesting the step-wise emergence of the process of natural selection itself, de Duve’s theory also differs from gene-first theories, for example, Szostak’s theory, that portray the emergence of a replicating RNA, within a membrane-engulfed compartment, as part of the gradual emergence of Darwinian evolution (Szostak 2012a). Indeed, de Duve

acknowledged that his multimer hypothesis was criticized for not including a mechanism of replication and selection. This is true, he believed, of all processes that preceded the emergence of the first replicative machinery (de Duve 2005:23).

Thus, how did de Duve envisage the emergence and growth of protometabolism up to the emergence of replicating RNA? How did he account for the selection of active catalysts without a mechanism such as natural selection? (de Duve 2003:568, 2005:23)? First, it should be noted that he was utterly opposed to the chance thesis (1991:212–213). He did not refer specifically to Dawkins but argued with and rejected Jacques Monod's similar notion of the “fantastic luck hypothesis,” which he viewed as implausible and as stifling research, just like the ID idea (de Duve 2005:73–74). De Duve contended that without natural selection, his suggested scenario depended on two elements, chemistry and environment: First, deterministic, reproducible chemical events resulted in an active set of catalysts as part of the multimer mixture, arising spontaneously under the prevailing conditions. Second, these conditions remained stable long enough to ensure an uninterrupted supply of catalysts, until they could be dispensed with (de Duve 2005:23–24). De Duve's “chemical determinism,” his alternative to natural selection prior to the emergence of RNA, will be made clear by pointing to his concept of randomness and the way it was implemented in his multimer hypothesis (de Duve 1991:140–143). De Duve insisted that “randomness” in the context of the origin of life was not the commonly assumed “statistical randomness.” “Random events or processes” involved in the synthesis of multimers were not statistically random or chance-like. Owing to stringent physical and chemical constraints, not all possible multimer sequences were equally probable. De Duve pointed to the “significant differences in bond energies and, especially in activation energies...between different associations...[that affected] the probabilities of their formation” (de Duve 1991:141). Also, differences among the multimers in solubility, stability, and ability to fold affected their survival and catalytic potential. Owing to physico-chemical selection channeling the synthesis and function of the catalytic multimers, de Duve claimed that only very rare peptides out of the theoretically possible ones could have been synthesized and only very rare peptides out of those produced could have survived. Thus, in this process, the end products were fully determined by the initial conditions (de Duve 1991:137–145, 213).

De Duve also sought to deal with the general problem of the multistage growth of complex biological molecules during the emergence of life (de Duve 1991:141). Without a “continuous renewal mechanism,” such as replication, to counter spontaneous decay phenomena (see, Luisi 2015:915), how could intermediates survive and reach effective concentrations (de Duve 1991:141)? De Duve's proposed mechanism to overcome this problem was the selection and stabilization of multimeric crude catalysts by binding to substrates (de Duve 1991:143–145). He noted that this mechanism, unlike “regular” physico-chemical selection, “does not just rely on favorable coincidence. It is truly selective, in that it contains a built-in

feedback loop that actually makes it save what is useful” (de Duve 1991:143). At the same time, unlike natural selection, this mechanism “can operate with random chemistry of production,” selecting by differential survival, in distinction to the complex machinery of replication, selecting by differential replication (*Ibid.*).

We have noticed, when discussing Szostak's scenario, how “single-step-selection events,” to use Dawkins's parlance were important in the emergence of an evolvable genetic infrastructure. It is also demonstrated in de Duve's theory that Dawkins's clear-cut distinction between single-step selection and cumulative selection does not apply to the origin of life. The synthesis and selection of multimers serve as another example of the involvement of “single-step-selection events” in the construction of a metabolic infrastructure leading to the rise of RNA. De Duve's proposed mechanism for the protection of physically and chemically selected multimers by the binding to substrates is a clear rebuttal of Dawkins's distinction (de Duve 1991:140–144).

3.1.6 CHANCE OR DESIGN?

3.1.6.1 THE PHILOSOPHICAL IMPLICATIONS OF DAWKINS'S CHANCE HYPOTHESIS

A clarifying comment is called for from the very beginning of this discussion. In the following examination, I suggest that Dawkins's views on the origin of life involve a philosophical element that contributed to his improbable-chance conclusion. However, there is no doubt that Dawkins would deny any philosophical interpretation of his views, which he considers purely scientific (Dawkins 2006:48, 50–51,109; see Fry 2012:670–671). It could be added in passing that Dawkins is not the only scientist to adopt a similar negative attitude, either explicitly or implicitly, toward the involvement of philosophy in science (see, Fry 2012). Thus, the attribution of a philosophical dimension to Dawkins's ideas is all mine.

Dawkins's blind-watchmaker thesis, presented forcefully in his 1986 book and since then in numerous books and public appearances throughout his career, was aimed to reject the “myth that Darwinism is a theory of ‘chance’” and to assert that biological evolution through natural selection is the antithesis of chance (Dawkins 1986:xv, 49). Biological complexity could have come about only through cumulative selection of small advantageous changes. However, Dawkins pointed out that the same also seems to be true for the machinery of replication needed at the origin of life, the very beginning of the evolutionary process (Dawkins 1986:141). This realization, according to Dawkins, leads either to an infinite regress or to a scientific conundrum. His solution to overcome this dilemma was the one-in-a-billion-billion chance hypothesis. As we saw, his suggestion that, given enough space and time, “random thermal jostling of atoms and molecules resulted in a self-replicating molecule” (Dawkins 1986:144–145) is commonly rejected by origin-of-life researchers, notwithstanding their various specific commitments. During the first decades of the twentieth century, before the molecular intricacies of the

living cell were known and when the notion that life emerged during vast geological times was still popular, scientists were much more cavalier about attributing various stages of the emergence process to chance (Fry 2000:71, 74–76, 102, 193). This was still occasionally the case during the “optimistic years” of the 1960s and 1970s, especially in gene-first theories (Fry 2000:193–194), and the “lucky accident” notion was still considered, for example, by Monod in 1970 and by Francis Crick and several other scientists in the 1980s (Fry 1995). A minority position at its outset, it is now considered completely obsolete on both theoretical and empirical grounds (Fry 2000:102, 2009).

How can Dawkins’s unique position be explained? I have noted earlier that Dawkins’s focus of interest in his discussion of the origin of life is not on actual scientific questions that preoccupy investigators in their efforts toward a solution (Dawkins 1986:147). Rather, when describing the “paradox at the heart of the origin of life” (Dawkins 1986:140–141), Dawkins expressed his worry that this obstacle might be conceived as a threat to the understanding of life without a designer, that is, to his “blind watchmaker” thesis (Dawkins 1986:141, 147). The “gap theologians,” he pointed out, indeed insist on the need for a designer to cross the huge gap of the origin of life (Dawkins 2006:134–135). I believe that this challenge to the blind-watchmaker thesis and Dawkins’s wish to fend off this threat are at the heart of Dawkins’s position on the origin of life. Presenting his argument, he insists that chance on a cosmological scale is an adequate naturalistic answer and that “this statistical argument completely demolishes any suggestion that we should postulate design to fill the gap” (Dawkins 2006:139). The philosophical question to be considered is whether Dawkins’s chance thesis indeed constitutes a convincing rebuttal of the design challenge. In order to comment on the question of chance versus design, the views expressed by IDers on the origin of life and the highly relevant ideas of philosopher Thomas Nagel will be examined.

3.1.6.2 INTELLIGENT DESIGN PROPONENTS AND THOMAS NAGEL ON THE ORIGIN OF LIFE

3.1.6.2.1 “Irreducibly Complex Systems”

In *Darwin’s Black Box* (1996), Michael Behe, a professor of biochemistry and a leading promoter of ID views, offered to the ID movement an invaluable gift—an argument for design in molecular language. Behe’s terms of discussion have been in use by proponents of the movement ever since, upheld as representing a “scientific” argument for ID (Dembski 1999:147–148; see, Nagel 2012a:10). Behe (1996:3–6) argued that the discoveries of biochemistry, by opening the black box of the cell and revealing the existence of complex molecular machines, created an unsurmountable challenge for the Darwinian theory. Each cell, according to Behe, contains intricate systems, whose function depends on the interaction of their various components. If a single component in such a system is missing, the system ceases to function. Obviously,

he claimed, such systems could not have evolved gradually. Any earlier system that is missing a part is, by definition, non-functional and thus could not have been favored by natural selection (Behe 1996:39). Such systems also could not have emerged by chance. The probability that “irreducibly complex systems” could have arisen “as an integrated unit in one fell swoop” is nil. Denying the possibility of an alternative natural mechanism that could have accomplished such a feat and relying on an analogy with the power of intelligent agents, that is, humans, to design such intricate machines, Behe (1996:187–205, 219) concluded that these systems had to result from the action of an intelligent designer. Space will not allow me to dwell on the various mechanisms that could have led to the natural evolution of functional systems of interdependent parts, brought forth in the literature by evolutionary biologists and cell biologists (see, among many, Coyne 2006; Gishlick 2004; Miller 1999:129–161; Musgrave 2004).

The same “irreducible-complexity” logic guided Behe in his account of the origin of life. In his “simplest possible design scenario,” he suggested that “nearly four billion years ago the designer made the first cell already containing all of the irreducible complex biochemical systems... (One can postulate that the designs for systems that were to be used later, such as blood clotting, were present but not ‘turned on’)” (Behe 1996:227–228, 231). Behe indicated that the defining feature of intelligent design is its purposeful nature. Biochemical systems, either turned on or off, “were designed not by the laws of nature...rather, they were planned. The designer knew what the systems would look like when they were completed, then took steps to bring the systems about” (Behe 1996:193). In the same vein, ID proponents, the scientists Walter Bradley and Charles Thaxton, suggested that the information for the first nucleic acids on Earth came from some intelligence and that life originated from “a who rather than from a what” (Bradley and Thaxton 1994:209). The opposition between Dawkins and IDers is clear. The contention that integrated biochemical systems could not have arisen naturally by a “one-fell-swoop” event is IDers’ justification for an intervention of a purposeful intelligent designer. A naturalistic origin of life via a “single-step chance event” is Dawkins’s anti-designer argument. Significantly, however, both deny the possibility of a gradual, evolutionary emergence of life.

3.1.6.2.2 Thomas Nagel on the Origin of Life

Thomas Nagel, the esteemed New York University professor, has developed, since the 1970s, his criticism of science for its materialist reductionism and its in-principle failure to solve the mind-body problem. In recent years and especially in his book, *Mind and Cosmos: Why the Materialist Neo-Darwinian Conception on Nature is Almost Certainly False* (2012), Nagel extended his criticism, claiming that science has also failed in accounting for the origin of life and its evolution. He found it “highly implausible that life is a result of a sequence of physical accidents combined with natural selection” (Nagel 2012a:6). Nagel (2012a:10) mentioned that his expanded criticism of science has been stimulated by “the attack on Darwinism mounted...from a religious perspective

by the defenders of intelligent design.” He pointed out that though he is not “drawn to the explanation by the actions of a designer” on the grounds of his own atheistic position (Nagel 2012a:12n, 2012b:63), he favors the critical “negative part of intelligent design position” (Nagel 2012a:10–11). Nagel was particularly impressed with a book published by Stephen Meyer, *Signature in the Cell: DNA and the Evidence for Intelligent Design* (2009). Nagel (2009) even suggested to nominate Meyer’s book to the Times Literary Supplement list of top books of the year. In his recommendation, Nagel (2009) called upon atheists and anti-ID theists to be “instructed by [Meyer’s] careful presentation” of the origin-of-life problem and of the present state of research on “non-purposive chemical explanations of the origin of life.” Following IDers, Nagel (2012a:5, 6–9) came to find the materialistic explanation of biological evolution “hard to believe.” As for the scientific accounts of the emergence of life from “dead matter,” he felt positive that it is a complete failure, because the only possible mechanism of natural selection is ruled out in this case (Nagel 2012a:9–10).

3.1.6.2.2.1 Stephen Meyer’s “Thorough Search”

In his *Signature* book and other publications, Stephen Meyer, a senior fellow at the Discovery Institute, the major organization behind the ID movement, defined the “mystery of the origin of life as the DNA enigma,” that is, the origin of biological information “needed to build the first living organisms” (Meyer 2009:13). In order to show that ID is the best and “only causally adequate explanation” of the origin of biological information (Meyer 2009:171), Meyer conducted a “thorough search” of theories and scenarios suggested by origin-of-life investigators. It will be impossible to indicate all the distortions in Meyer’s review. I believe the following example will suffice. Meyer shared with his readers a moment of discovery, when “the day of the breakthrough came” in the mid-1990s while he was looking at slides of the double helix. There and then Meyer discovered that “there are no [direct] chemical bonds *between the bases* along the longitudinal axis in the center of the helix. Yet, it is precisely along this axis of the DNA molecule that the genetic information is stored” (Meyer 2009:241, emphasis in the text). Meyer then indicated the “devastating implications for self-organization models” that attempt to explain the DNA enigma on the basis of “bonding affinities” (Meyer 2009:244), while regrettably no direct bonding exists between the bases in DNA. This is all figment of Meyer’s imagination. No origin-of-life scientist claimed or could have made such a claim. In fact, it is embarrassing to discover that while Meyer completed a Ph.D. dissertation on origin-of-life studies in 1990 and while he was devoting himself from the late 1980s to “developing the case for intelligent design upon the discovery of the ...digital code stored in the DNA molecule” (Meyer 2009:4–5), he was all along ignorant of the basic structure of DNA, with which every undergraduate student of biology must be familiar. It also might be of interest to readers of this chapter that following Meyer’s critique of the improbability involved in any claim for prebiotic natural selection, he added that “nevertheless,

during the 1980s, Richard Dawkins...[in 1986] attempted to resuscitate prebiotic natural selection as an explanation for the origin of biological information” (Meyer 2004:246–247)!

Yet, despite Meyer’s unreliable account of the current state of origin-of-life research, Nagel was fully convinced by his demonstration that “nonpurposive chemical explanations” cannot provide an answer to the origin of life. Nagel noted that another source shaping his views on the origin of life was “an important paper” by Roger White, an MIT philosopher and linguist, claiming that attempts by scientists to account for the origin of life in terms of “nonpurposive principles of physics and chemistry” are “based on a confusion” (Nagel 2012a:ix; 89).

3.1.6.2.2.2 White: “Biased Toward the Marvelous”

In his paper, “Does origins of life research rest on a mistake?” (2007), White states his conviction that the insistence of origin-of-life researchers on finding a natural explanation for the origin of life reveals no less than a confused psyche. According to White, researchers try as hard as they can to find convincing mechanisms based on “non-intentional biasing” (White 2007:462). However, the crucial stage in the origin of life, the appearance of self-replicating molecules, is not more likely to happen as a result of non-intentional bias compared to chance. “Translating” his abstract text into prebiotic chemical terms, White contends that physical and chemical constraints that could have enabled physico-chemical selection (e.g., differential chemical affinities between diverse building blocks; differential thermodynamic stability of molecular structures; and catalysis by, e.g., metal ions, specific minerals, and short peptides) could not have made the outcome of self-replicating molecules more probable. The reason, as stated by White is that “what makes certain molecular configurations stand out from the multitude of possibilities seems to be that they are capable of developing into something which strikes us as *rather marvelous*, namely a world of living creatures. But there is no conceivable reason that blind forces of nature or physical attributes should be *biased toward the marvelous*” (White 2007:467, emphasis added). White’s reasoning is clearly teleological and anti-evolutionary. Indeed, “blind forces of nature” are not “biased toward the marvelous,” nor are they preordained to produce life. Yet, it just so happened because of “physical attributes” that certain configurations of molecules in specific geophysical conditions on the primordial Earth about four billion years ago interacted in certain ways, obeying the “blind forces of nature,” and resulted in specific chemical outcomes that could have evolved into living systems. It certainly could have been otherwise, here on Earth. It probably was otherwise on myriad of other planets.

Rejecting “non-intentional biasing” as contributing to an explanation of the origin of life, we are left, according to White, with the alternatives of chance and “intentional biasing,” that is, “an agent.” White’s psychological diagnosis as to why most origin-of-life scientists will not embrace chance, despite the fact that a natural non-intentional biasing does not work, suggests that scientists cannot resist the “intuition that people really have” upon contemplating the

molecular mechanisms from which life developed (White 2007:475). It is a “gut reaction to the data” that such molecular mechanisms “were designed by an agent” (White 2007:474). White goes as far as claiming that “it is just the reaction that everyone has” [!]. However, acting upon such an intuition is considered illegitimate scientifically. According to White, this explains the insistence on looking for a physico-chemical non-purposive mechanism that promises no advantage over chance (White 2007:475). White’s anti-naturalistic and anti-evolutionary perspective strengthened Nagel’s conviction that physical and chemical means were insufficient to guarantee the choice of the desired “marvelous” molecules out of all the possible ones (Nagel 2012a:89–91).

3.1.6.3 DAWKINS’S CHANCE POSITION: SCIENTIFICALLY UNNECESSARY AND PHILOSOPHICALLY DAMAGING

Convinced by the arguments of White and IDers, Nagel came to deny the possibility of a naturalistic origin of life. However, denying also explanations based on chance and on intelligent design (Nagel 2012a:91), he raised the alternative of a “natural teleology,” assuring that “the universe is rationally governed...also through principles that imply that things happen because they are on a path that leads toward certain outcomes – notably the existence of living, and ultimately of conscious, organisms” (Nagel 2012a:67). The question how natural could such a “natural teleology” be and the possibility of an internal contradiction in a cosmic teleology, without a “rational agent” or a God that makes the choices of specific physical parameters (Plantinga 2012:6; White 2007:466), though relevant to our discussion, cannot be elaborated upon here. Yet, coming back to Dawkins’s position on the origin of life, I suggest that by assuming to raise a solution distinct from a natural solution but also from design, Nagel might contribute another perspective from which to evaluate Dawkins’s chance-versus-design contention.

Interestingly, unlike Stephen Meyer and Roger White, who erroneously attributed to Dawkins, respectively, the “resuscitation of prebiotic natural selection” and the rejection of a chance account of the origin of life (Meyer 2004:246–247; White 2007:459, 474), Nagel (2010a:19–26) confronted Dawkins on his actual chance attitude to the origin of life. First, Nagel noted that Dawkins acknowledged the problem, or “paradox,” inherent in the attempt to provide a natural explanation for the origin of life, that is, the need for and, at the same time, the impossibility of applying evolution prior to life (Nagel 2010a:23, 24). Nagel and Dawkins thus agree in rejecting any involvement of an evolutionary process in the origin of life. However, Nagel saw Dawkins’s chance solution as no more than “pure hand waving” and “a desperate device to avoid the demand for a real explanation” (Nagel 2010a:24, 25). As to Dawkins’s one-in-a-billion-billion statistics, Nagel criticized his calculation for being too probable: The genetic material is so staggeringly complex that “no one has a theory that would support anything remotely near such a high probability as one in a billion billion” (Nagel 2010a:24).

Referring to the argument from design, Nagel commented that it was prompted by the “overwhelming improbability” of life coming into existence by chance, “simply by the purposeless laws of physics” (Nagel 2010a:24). Claiming that science has no alternative to chance, Nagel asserted that *the problem of the origin of life is the reason “why the argument from design is still alive”* (Nagel 2010a:25, emphasis added). Though Nagel is mistaken and science does have an evolutionary alternative to chance, his evaluation of Dawkins’s attempt to account for the origin of life by a single chance event accurately addresses Dawkins’s problem. Here, in a nutshell, in Nagel’s words, is the reason why Dawkins’s position fails in confronting the argument from design.

Dawkins’s contention that chance on a cosmological scale is a valid explanation of the origin of life is not based on a serious examination of scenarios offered by researchers in the field. His position thus draws attention away from such evolutionary scenarios and strengthens the IDers’ cause of bringing back the argument from design, this time based on “the DNA enigma.” By implying that chance and design are the only explanatory options of the emergence of life, Dawkins unwillingly encourages both religious and “natural” teleological views.

3.1.7 CONCLUSION

This chapter called attention to the active role of philosophical presuppositions in the scientific study of the origin of life. This is generally true of science but most notable when science tackles a problem whose philosophical dimension challenges deep-seated traditional beliefs. As pointed out here, the scientific worldview that grew historically in the last few hundred years became strongly established when the theory of evolution and the rejection of “big teleology” were fully accepted by the scientific community in the first half of the twentieth century. It is this scientific-evolutionary worldview, based on the interaction between the theoretical and empirical achievements of science and the philosophical tenets of naturalism, that underlies the scientific study of the emergence of life. The attack by proponents of ID on this study, under the guise of theoretical and empirical critique (see Behe 1996; Meyer 2009), is in fact a philosophical-theological rejection of the naturalistic tenets, a continuation in molecular garb of William Paley’s argument from design.

Though the pioneering theories of Oparin and Haldane raised the possibility of an evolutionary origin of life, only following the discoveries of molecular biology; the demonstration of *in vitro* molecular evolution and, more recently, the study of ribozymes, of various organic and inorganic compartments, and of inorganic and organic catalytic molecules involved in metabolism; and the discoveries of geochemical sites that might have been conducive to the emergence of life could the evolutionary hypothesis of the emergence of life become a fruitful research tool. Maintaining that constrained prebiotic processes could have given rise

to an evolvable infrastructure and that Darwinian evolution itself emerged gradually through physical and chemical processes, the evolutionary hypothesis is also not neutral philosophically. By guiding the various scenarios suggested in the field, it implements the philosophical postulate of the natural emergence of life in active research.

Dawkins's contention that the origin of life was the result of a highly improbable single chance event is a principled denial of this implementation. Though a most prominent defender of evolutionary naturalism, Dawkins's clear-cut separation between the origin of life and biological evolution conflicts with the continuity of the physical, chemical, and biological underlying origin-of-life research. As commented previously, Dawkins seems to regard the "event" of the origin of life as a problem that luckily had to happen only once, opening the way to the working of the blind watchmaker. Interestingly, Dawkins suggested that "Darwin probably (and in my view rightly) saw the origin of primitive life as a relatively easy problem compared with the one he solved" (Dawkins 2004:574). This interpretation of Darwin's attitude to the origin of life seems to fit Dawkins's inclination to put the origin-of-life "event" in parentheses.

Another case of, so to speak, "marginalizing" the origin-of-life problem, but from a different perspective, is encountered in the position of various scientists and philosophers of science. It is a reaction to the fact that researchers have not yet reached an agreement as to the path by which life emerged on Earth, nor have they managed so far to simulate this process in the laboratory. Consequently, the scientific status of origin-of-life research, compared with biological evolution, is often perceived as too weak to stand a chance against creationists' attacks (de Duve 2002:288; Miller 1999:276–277; Ruse 2001:65; Scott 1996:515–516). In my view, judging the science investigating the origin of life exclusively on the basis of its current empirical achievements misses the point. Clearly, there are huge objective hurdles hindering the solution of the origin-of-life problem. Most significantly, traces of early-Earth's geochemistry were eradicated by geological and biological processes of over 4 billion years (Pizzarello and Shock 2010:1). The uncertainty about the specific site where life could have emerged, and its physical and chemical conditions will be difficult to dispel (Eschenmoser 2007:12822). There are enormous difficulties in searching for remnants of analogous processes on other planets (Benner et al. 2012), and the interdisciplinary nature of the problem requires active engagement of diverse scientists (Eschenmoser 2007:12821). However, disregarding the interaction between the theoretical, empirical, and philosophical aspects, demonstrated, in particular, in the evolutionary hypothesis of the origin of life, ignores the major basis for the most promising hypotheses raised in the field.

Regretting that researchers still have not provided facts "to demonstrate an entirely material origin of life" (Easterbrook 1997:893) wrongly assumes that there are "facts" to demonstrate or refute an entirely natural emergence of life. The philosophical naturalistic postulate cannot be proved or disproved empirically. However, it is robustly established by now as a result of its historically developed interdependence

with empirical data. It is neither doubted by researchers nor put to the test afresh in their experiments, despite the fact that the problem of the origin of life was not yet solved. Moreover, despite the lack of solution, the scientific investigation of the origin of life, far from being a "problem" or the "soft underbelly of evolutionary biology" (Scott 1996:515–516), is central to the evolutionary worldview. It is not by chance that Nagel, from his philosophical anti-evolutionary perspective, contended that "the profoundly nonteleological character" of the failed evolutionary naturalism of our day is especially expressed in its attempt to provide a natural explanation to the origin of life (Nagel 2010b:15).

Indeed, it will be appropriate to conclude this chapter by reiterating the "nonteleological" or rather anti-teleological character of the evolutionary hypothesis of the origin of life. This hypothesis is incompatible not only with the idea that life was created by a designer for a purpose but also with Nagel's "natural-teleology" that postulates the existence of teleological principles, ensuring the bound-to-happen emergence and evolution of living and eventually conscious organisms (Nagel 2012a:67). Assuming such teleological principles, the emergence of life is claimed to have resulted from a "path toward a certain outcome," which is predetermined and guaranteed (Nagel 2012a:93). In distinction, the scenarios raised by investigators in the field, referred to shortly in this chapter and in more detail in [Chapter 6.5](#), though evaluating prebiotic physical and chemical constraining factors as "preparatory" for the emergence of life, do not imply purpose, plan, or, in general, teleological tendencies. As put by Christian de Duve, "chemistry has no prescience." It did not produce nucleotides "for the purpose" of synthesizing RNA. RNA itself was not "destined to be the first bearer of information in nascent life" (de Duve 2005:74–75; see, Luisi 2015:908, 909). Only in retrospect can we judge these outcomes as relevant biologically. Only from the perspective of extant life, and assuming the continuity between prebiotic chemistry and biochemistry, can we try to discern by theoretical considerations and simulation experiments what were the relevant constraints and what were the various catalyzed reactions "preparatory" for the emergence of life. Under different physical and chemical circumstances, other results, less "marvelous" (White 2007:467), could have been produced, as might have been the case on other planets in the solar system and beyond.

The major objective of this chapter was to analyze the philosophical aspects of the origin-of-life problem in light of the challenges faced by the evolutionary hypothesis, the chance thesis, and supernatural and natural teleology. As part of this analysis, Dawkins's contention that his highly-improbable-chance thesis provides an answer to the notion of design and IDers' and Nagel's claims to counter chance by divine or "natural" telos were also examined. We can conclude that there is no real dichotomy between chance and telos. Chance and telos are the two horns of a faulty dilemma. The true conflict is between chance and purpose on the one hand and an evolutionary emergence of life on the other hand.

No sooner had Mr. Darwin peered through the microscope on one of the finest specimens when he started up from his seat and exclaimed:

“Almighty God! what a wonderful discovery! Wonderful!”

And after a pause of silent reflection he added:

“Now reaches life down!” (Rachel 1881)

3.2.1 THE PLURALITY OF WORLDS

Charles Darwin's *On the Origin of Species by Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* was published in 1859. It came at the end of a decade when the possibility of extraterrestrials – beings on other planets, especially intelligent beings – had been discussed very extensively, in both Britain and America. In 1853, publishing anonymously, William Whewell – tidologist, textbook writer, historian, and philosopher of science and moral theorist – had produced *On the Plurality of Worlds*, a work in which he argued that our world alone – Planet Earth – has sentient beings. The rest of space is empty and lifeless (Whewell [1853] 2001).

Everyone knew the identity of the author, but Whewell then was Master of Trinity College, Cambridge, and was shortly to become the tutor of the Prince of Wales, the future Edward the Seventh (Todhunter 1876). He thought it would be unseemly to be too publicly identified with a controversy on this topic, and in assuming that there would be a controversy, he was right, although whether many thought the less of him for it is a moot point. He certainly stirred up a lively debate, and those who

did think the less of him undoubtedly did so already. These included Sir David Brewster, general Scottish man of science and biographer of Isaac Newton. He had already taken umbrage at what he considered Whewell's rather cavalier attitude to Scottish culture, a topic on which he tended to take umbrage. His response to Whewell (under his own name!) had the glorious title *More Worlds than One, the Creed of the Philosopher and the Hope of the Christian*. “Philosopher” here meant scientist, as in “natural philosopher” rather than “moral philosopher,” which was more Whewell's field (Brewster 1854).

What Brewster's title tells us is that this controversy was as much theological as it was scientific or (what we would call) philosophical. Whewell had not put pen to paper because he was worried about origin of life questions or that sort of thing. Did all life forms have the same pattern kind of question? Whewell was no evolutionist and – for all that, when a young man, Darwin had been mentored by Whewell and so naturally later was to send his old teacher a copy of the *Origin* – remained a non-believer on this subject. So, particularly, Whewell was not asking whether in development organisms always took the same path. What worried him was revealed theology – religion through faith – and the possibility that there might be intelligent organisms other than those down here on Earth. If there were, did they too have their Adams and Eves? Did their first people succumb to temptation and fall? Are these beings tainted therefore by original sin? And, worst of all, did this mean that Jesus had to come down on their planets and die over and over again on the Cross? Even as we are now, is Jesus somewhere in the universe being nailed up?

The problem Whewell faced was that if the universe other than our planet is empty, then why on earth did God create it.

We need the Sun and perhaps the Moon, but not much else. This goes flatly against the main premise of natural theology – religion through reason – that the world shows such evidence of design that it points unhesitatingly to a Designer, namely God (Ruse 2017b). It is true that usually the big evidence of design is to be found in organisms – teeth for chewing, eyes for seeing, flowers for pollination – but Whewell, of all people, 20 years earlier had contributed to a series on natural theology, the *Bridgewater Treatises*, and his contribution had been about astronomy. He had become a public figure based on his lively arguments about the ubiquity of design, in all things! Now, he had to backtrack or at least find some way of wriggling out of the dilemma (Whewell 1833).

This Whewell did, and it really took some gall, by arguing that straightforward design is not so ubiquitous anyway. He drew on work by anatomists, particularly his good friend at the Royal College of Surgeons, Richard Owen (Owen 1848, 1849), who was showing that isomorphisms – what Owen was to call “homologies” – are widespread in the animal kingdom but have no obvious functional value. Particularly popular were the analogies between the bone structures of the forelimb of the human, the horse, the bat, the bird, the mole, and the porpoise – different functions, often very different functions, but the same bones in the same order. Of course, the paradox is that Whewell was jumping from the teleological fat and into the evolutionary fire. Homologies are the best of all possible evidence for evolution. The aged Immanuel Kant worried about them in the *Third Critique* (Kant [1790] 1928), and Darwin was to make much of them in the *Origin*. Probably, Owen had already been converted to evolution on the basis of them. He sensibly kept quiet, because he did not want to upset his non-evolutionary sponsors like Whewell.

To defend his revealed theology, Whewell was turning his natural theology – he claimed that homologies are evidence of a Creator, who likes symmetry and order (Shades of Plato’s *Phaedo*) – into good support for evolution. Brewster spotted this and, in response, peopled the whole universe. He even had intelligent beings living on the Sun, which is ridiculous, but which points, as does Whewell’s thinking, to an important point about science. In his *The Structure of Scientific Revolutions* (1962), Thomas Kuhn argues that one of the major reasons for a change of paradigms, a revolution, is that the old paradigm starts to break down (Kuhn 1962). It reveals inner contradictions and the like. Whewell and Brewster illustrate this perfectly. In their entanglements, caused by their desire to maintain the old, anti-evolutionary harmony between revealed and natural theology, they put the whole system under great strain. Let no one deny the honors to Darwin, but the ground for the new was being prepared by the crumbling of the old.

3.2.2 DARWINIAN THEORY

The *Origin of Species* is deceptive. For a work of science, it is written in a highly user-friendly fashion. This is not Newton’s *Principia*. But it is a very carefully constructed

piece of work, one that shows a sophisticated appreciation of the dicta of the leading methodologists of the day, the physicist John F. W. Herschel and the polymath William Whewell (Ruse 1975, 1979). Darwin’s problem, obviously, was to convince the reader of events that happened in the past, as hidden from us today as are the waves that supposedly lie behind visible light, as it bends its way through prisms and splits into many colors when coaxed in the right way. A pertinent analogy, because just when Darwin was becoming an evolutionist and seeking a cause, in the 1830s, the wave theory of light (of the Dutchman Christian Huygens) was just then conquering the particle theory, due to Newton and popular for over a hundred years.

The quest was for what Newton had called a “true cause,” a *vera causa*. Herschel (1830), somewhat of an empiricist, said that what you need is an analogy, from what you know to what you don’t know but presume to exist or to be true. In the case of light, we have physical waves as in water – the waves you make in the bathtub – and most obviously sound, and Herschel argued that this prepares the way to accept light waves. Whewell (1840), somewhat of a rationalist, said that no direct evidence was needed for a true cause. We work rather as a detective looking for clues that point to the culprit. If all the clues point the same way, then we can be pretty sure that we know who did it. Whewell called this a “consilience of inductions.”

Darwin covered his options, offering evidence in both modes that his cause, natural selection, was a *vera causa*. He opened the *Origin* by arguing that the work of animal and plant breeders in making new forms is analogous to what goes on in nature.

That most skilful breeder habitually speak of an animal’s organization as something quite plastic, which they can model almost as they please. If I had space, I could quote numerous passages to this effect from highly competent authorities. Youatt, who was probably better acquainted with the works of agriculturalists than almost any other individual and who was himself a very good judge of an animal, speaks of the principle of selection as “that which enables the agriculturist, not only to modify the character of his flock, but to change it altogether. It is the magician’s wand, by means of which he may summon into life whatever form and mould he pleases.” Lord Somerville, speaking of what breeders have done for sheep, says “It would seem as if they had chalked out upon a wall a form perfect in itself, and then had given it existence.” Most skillful breeder, Sir John Sebright, used to say, with respect to pigeons, that “he would produce any given feather in three years, but it would take him six years to obtain head and beak.” In Saxony, the importance of the principle of selection in regard to merino sheep is so fully recognized that men follow it as a trade: the sheep are placed on a table and are studied, like a picture by a connoisseur; this is done three times at intervals of months, and each time, the sheep are marked and classed, so that the very best may ultimately be selected for breeding (Darwin 1859, p. 31).

Darwin made much of the fact that pigeons have such variety, yet clearly, all come from common stock.

Then, having postulated that new variations are constantly appearing in populations – not uncaused but undirected – he was ready for his key inferences. These were put in (quasi- or proto-) deductive form. As Herschel and Whewell pointed out non-stop, this was the form of the gravitational theory of Newton. First was the Malthusian element to a struggle for existence.

A struggle for existence inevitably follows from the high rate at which all organic beings tend to increase. Every being, which, during its natural lifetime, produces several eggs or seeds, must suffer destruction during some period of its life and during some season or occasional year; otherwise, on the principle of geometrical increase, its numbers would quickly become so inordinately great that no country could support the product. Hence, as more individuals are produced than can possibly survive, there must, in every case, be a struggle for existence, either one individual with another of the same species or with the individuals of distinct species or with the physical conditions of life (Darwin 1859, pp. 63–64).

Then, second, to natural selection.

Let it be borne in mind how infinitely complex and close-fitting are the mutual relations of all organic beings to each other and to their physical conditions of life. Can it, then, be thought improbable, seeing that variations useful to man have undoubtedly occurred, that other variations useful in some way to each being in the great and complex battle of life should sometimes occur in the course of thousands of generations? If such do occur, can we doubt (remembering that many more individuals are born than can possibly survive) that individuals having any advantage, however slight, over others would have the best chance of surviving and of procreating their kind? On the other hand, we may feel sure that any variation in the least degree injurious would be rigidly destroyed. I call this preservation of favorable variations and the rejection of injurious variations as Natural Selection (pp. 80–81).

All-important is the fact that this cause – natural selection – points to adaptation, to design-like features. The eye is created as it is in order to see, the flower to attract pollinators, the fangs of the snake to kill, and the instincts of the nest-building bird to promote and continue life. It is not just change, but change of a particular cause.

Under nature, the slightest difference of structure or constitution may well turn the nicely balanced scale in the struggle for life and so be preserved. How fleeting are the wishes and efforts of man! how short his time! And, consequently, how poor will his products be, compared with those accumulated by nature during whole geological periods? Can we wonder, then, that nature's productions should be far "truer" in character than man's productions and that they should be infinitely better adapted to the most complex conditions of life and should plainly bear the stamp of far higher workmanship? (pp. 83–84).

Having shown that this should all lead to the venerable tree of life, Darwin was ready for the third and final part of the *Origin*, although in length well over half. Darwin showed the

causal power of natural selection by going in a Whewellian consilience right through the life sciences: social behavior, the fossil record (paleontology), geographical distributions (biogeography), anatomy and morphology, systematics, and embryology. Why is there a progressive fossil record? Evolution through natural selection. Why do organisms fit the Linnaean system? Because it reflects the tree of life. Picking up on homology, why are there isomorphisms between the bones of different species? Evolution through natural selection. *Déjà vu*, all over again. Why are there such similarities between the organisms of very different adult forms? Because selection only works on the adults. This all done, Darwin was ready for his final famous passage.

It is interesting to contemplate an entangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth, and to reflect that these elaborately constructed forms, so different from each other and dependent on each other in so complex a manner, have all been produced by laws acting around us... Thus, from the war of nature, from famine and death, the most exalted object that we are capable of conceiving, namely, the production of the higher animals, directly follows. There is grandeur in this view of life, with its several powers, having been originally breathed into a few forms or into one, and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved (pp. 489–490).

3.2.3 RECEPTION

For completeness, I will talk about the reception of Darwin's ideas, even though I don't intend to spend much time on the topic. The received position is that, despite some well-known opposition – notoriously the Bishop of Oxford, Soapy Sam Wilberforce (son of William Wilberforce of slave trade abolition fame) – evolution as such was accepted quickly in both Britain and North America, the evangelicals of the American South – using the bible read literally as consolation for the defeat in the Civil War – being the notable exception. (Anything to separate them from the Yankees.) However, natural selection was far less successful and only came into its own in the 1930s, when Mendelian genetics had been developed and could be shown to be the complement of natural selection, not its rival.

This story is only partly true (Richards and Ruse 2016; Ruse 2017a). In the world of fast-breeding organisms, insects, there was much profitable theorizing and empirical study using selection. Particularly successful was the work showing how selection was behind industrial melanism, where insects (predated on by birds) develop adaptive coloring that tracks the coloring of the trees on which they perch – as the trees get darker, thanks to industrial soot, the insects (butterflies and moths) get darker too. One enthusiast even wrote to Darwin about this.

My dear Sir,

The belief that I am about to relate something which may be of interest to you, must be my excuse for troubling you with a letter.

Perhaps among the whole of the British Lepidoptera, no species varies more, according to the locality in which it is found, than does that Geometer, *Gnophos obscurata*. They are almost black on the New Forest peat; grey on limestone; almost white on the chalk near Lewes; and brown on clay, and on the red soil of Herefordshire.

Do these variations point to the “survival of the fittest”? I think so. It was, therefore, with some surprise that I took specimens as dark as any of those in the New Forest on a chalk slope; and I have pondered for a solution. Can this be it?

It is a curious fact, in connexion with these dark specimens, that for the last quarter of a century the chalk slope, on which they occur, has been swept by volumes of black smoke from some lime-kilns situated at the bottom: the herbage, although growing luxuriantly, is blackened by it.

I am told, too, that the very light specimens are now much less common at Lewes than formerly, and that, for some few years, lime-kilns have been in use there.

These are the facts I desire to bring to your notice.

I am, Dear Sir, Yours very faithfully,
A. B. Farn

Letter from Albert Brydges Farn on November 18, 1878
(Darwin Correspondence Project, 11747).

The other place fascinatingly where natural selection made a splash – and a secondary mechanism that Darwin introduced of competition for mates, sexual selection, even more – was in the realm of poetry and fiction (Ruse 2017a). After all, what is this most often but stories of elaborate mating dances, which may or may not be successful? This poem is by a young woman, in the 1880s. It is entitled “Natural Selection” although truly, it is more about sexual selection.

I HAD found out a gift for my fair,
I had found where the cave men were laid:
Skulls, femur and pelvis were there,
And spears that of silex they made.
But he ne'er could be true, she averred,
Who would dig up an ancestor's grave—
And I loved her the more when I heard
Such foolish regard for the cave.
My shelves they are furnished with stones,
All sorted and labelled with care;
And a splendid collection of bones,
Each one of them ancient and rare;
One would think she might like to retire

To my study—she calls it a “hole”!
Not a fossil I heard her admire
But I begged it, or borrowed, or stole.
But there comes an idealess lad,
With a strut and a stare and a smirk;
And I watch, scientific, though sad,
The Law of Selection at work.
Of Science he had not a trace,
He seeks not the How and the Why,
But he sings with an amateur's grace,
And he dances much better than I.
And we know the more dandified males
By dance and by song win their wives—
'Tis a law that with *avis* prevails,
And ever in *Homo* survives.
Shall I rage as they whirl in the valse?
Shall I sneer as they carol and coo?
Ah no! for since Chloe is false
I'm certain that Darwin is true.
(Naden 1999, pp. 207–208)

All a good joke, but serious for all that. (I note that this is by a woman. In the first hundred years of professional evolutionary biology after Darwin, I do not think I have ever encountered a female author. In the realm of creative writing, at least half of the authors writing on evolution and using ideas of selection are females – George Eliot, Emily Dickinson, Mrs. Humphrey Ward, Edith Wharton, Edna St. Vincent Millay – the list is nigh endless.)

3.2.4 WHAT DARWIN LEFT OUT AND WHY

So, go back to Darwin and the *Origin* and focus on our interests. Two things are to be noted, again not by chance but by very careful design. They are both related to the fact that Darwin was a very skilled methodologist and equally to the fact that Darwin appreciated that sometimes saying nothing is a better strategy than plunging in half-baked, as it were. First, humans. Darwin knew that, as soon as he published, his theory would be considered in the light of possible human evolution. And so, it proved. At once, it was known as the monkey theory or the gorilla theory, and people started writing on this. In 1863, Darwin's “bulldog,” Thomas Henry Huxley, published *Man's Place in Nature*, locating us firmly in the animal world (Huxley 1863). Darwin himself was essentially silent, but he never had any doubts that we are part of the animal world. The first evidence, in late 1838, that Darwin had hit on natural selection is a comment in a private notebook applying natural selection to humans, and not just to our bodies but also to our mental abilities. In his *Autobiography*, written toward the end of his life, Darwin reaffirmed this belief. “I am inclined to agree with Francis Galton [Darwin's half cousin] in believing that education and environment produce only a small effect on the mind of any one, and that most of our qualities are innate” (Darwin 1958, p. 43). From the first to the last, Darwin was (in today's terms) a human sociobiologist or evolutionary psychologist. In the *Origin*, however, Darwin wanted to get his main theory into the public domain. So, not

to appear cowardly, he simply said “light will be thrown on man and his history” (p. 488).

If he had been left to his own devices, Darwin may never have written on humans – it was not to be. Darwin was spurred into publishing the *Origin* by the arrival in 1858 of an essay by a young naturalist, Alfred Russel Wallace – an essay that contained just about the same ideas that Darwin had been hugging privately for 20 years (Wallace 1858). In the 1860s, Wallace turned to spiritualism, arguing that only supernatural forces could explain human evolution (Wallace 1870). Horrified, Darwin again put pen to paper, and in 1871, he published *The Descent of Man and Selection in Relation to Sex*. Much of the early part of the book is predictable, as Darwin argued that his theory applies to us. What makes the *Descent* rather odd is that most of it is not about humans at all! It is a very detailed and lengthy discussion of the second mechanism of “sexual selection,” where the competition is within a species for mates – as the peacock having a ludicrously large and flamboyant tail to attract the peahen. The reason for the imbalance is simple. Wallace argued that certain human features, such as hairlessness, could not have been produced by natural selection and hence demanded spirit forces. Darwin agreed that natural selection could not do the job but argued that sexual selection could! Hairlessness was all a matter of people choosing those mates they found most attractive, all of which led to some very Victorian sentiments.

Man is more courageous, pugnacious, and energetic than woman and has a more inventive genius. His brain is absolutely larger, but whether relatively to the larger size of his body, in comparison with that of woman, has not, I believe, been fully ascertained.

Continuing:

Male and female children resemble each other closely, like the young of so many other animals in which the adult sexes differ; they likewise resemble the mature female much more closely than the mature male. The female, however, ultimately assumes certain distinctive characters and, in the formation of her skull, is said to be intermediate between the child and the man (Darwin 1871, pp. 2, 317).

Darwin was a great revolutionary. He was no rebel against the mores and norms of Victorian society!

The second topic that Darwin eschewed in the *Origin* was the origin of life problem. It was not customary to avoid the topic in evolutionary discussions. Darwin’s grandfather Erasmus Darwin (1801) had been an evolutionist at the end of the eighteenth century, and he had talked of it, and so too did the great French evolutionist Jean Baptiste de Lamarck. In his *Philosophie Zoologique* of 1809, the year of Charles Darwin’s birth, he speculated that electricity (lightening) on ponds of chemically saturated water would start off life. Then, in 1844, the publisher Robert Chambers, writing anonymously, penned *The Vestiges of the Natural History of Creation* (Chambers, 1844). He argued for evolution, thus incurring the wrath of the respectable scientific community, including Whewell (1845). This, no doubt, confirmed to Darwin the wisdom of keeping quiet about his speculations. There was much on the origin of life, spontaneous generation, involving mites on electrical

batteries, and such things. Bringing the scorn of the professional scientists, who knew only too well how dirty fingers can contaminate things. If this were not enough, by the end of the 1850s, in France, Louis Pasteur was showing how most, if not all, claims about natural origins of life were unsubstantiated. (Contrary to popular opinion, Pasteur believed in natural origins – just that they had not yet been proven.)

Darwin wisely stayed away from the topic, speaking only of “this view of life, with its several powers, having been originally breathed into a few forms or into one.” Take that as you will. He made a smart move, because it was not a big charge brought against his theory. This didn’t mean that Darwin had no ideas on the topic. Later, to his friend Joseph Hooker, he speculated in a very Lamarckian fashion.

It is often said that all the conditions for the first production of a living organism are now present, which could ever have been present.—But if (& oh what a big if) we could conceive in some warm little pond with all sorts of ammonia & phosphoric salts,—light, heat, electricity &c present, that a protein compound was chemically formed, ready to undergo still more complex changes, at the present day such matter w^d be instantly devoured, or absorbed, which would not have been the case before living creatures were formed.—(Letter from Darwin to Hooker, February 1, 1871, Darwin Correspondence, DCP-LETT-7471)

I don’t think Darwin had any objections to life elsewhere in the universe. After all, why would he? It would be grist for his mill. But judging from his writings, public and private, not to mention his correspondence, he seems to have stayed away from the subject. This makes sense. We know from a private reading list that, in 1854, Darwin read Whewell’s *Plurality of Worlds*. But, apart from the natural desire to get distance from Whewell, given the latter’s strident anti-evolutionism, Darwin would have seen how greatly the whole topic is plunged into theological controversy, natural and revealed religion. Apart from his lack of personal interest in such topics – he protested truly that although circumstances forced him to think much about religion, it was not really a topic that excited him (unlike, say, Thomas Henry Huxley) – he would see how fatal it would be to the presentation of his theory if it were draped in sheets of religious controversy. A better metaphor would be strangulated by the coils of the aggressive religious anaconda. As a kind of epilogue to Darwin’s life’s work, the quotation in the story at the beginning of this essay shows that almost at the end of his life (Darwin died in the spring of 1882), he was shown evidence that convinced him that probably this Earth of ours was seeded by life from elsewhere. He reacted strongly and favorably to this information, although to be honest, Darwin was rather given to reacting strongly and favorably to ideas from people whom he liked.

3.2.5 ALIENS OF OUTER SPACE

Turn now from Darwin and broaden the discussion. Even if Darwin didn’t have a lot to say, others did and embraced with enthusiasm aspects of Darwin’s thinking, using them in fact and fiction – almost always fiction, even when presented as fact – to speculate on life elsewhere. One thinks, for instance,

of the most famous case of all, H. G. Wells' story *The War of the Worlds*, with those pesky Martians coming in to do a job on us – at least, until they got wiped out by our diseases. I discern something of a common pattern in fiction about extraterrestrials. There will be evolution or development of mobile, talking animals. Take the *Star Wars* movies. You get all kinds of non-humans, such as the Wookie Chewbacca, Jabba the Hutt, and my all-time favorite, the truly dreadful little Kowakian monkey-lizard, Salacious B. Crumb. Anyone who has had Cairn Terriers knows the type and the reason why, for all that they are absolutely appalling in behavior, there is something about them that makes them deeply loved. Often, alien beings are really intelligent, like Chewbacca and Jabba. They can be much brighter than us. Yoda, the teacher of the Jedi, is an example.

In such fiction, humans also have a way of making an appearance. Sometimes, there is no real question about their authenticity. Are they real humans? The humans in *Planet of the Apes* are all in or descendants from our species today. Technically, whether all such human-like beings are truly in our species is a happily discussed question. With respect to *Star Wars*, some say sternly that, given that *Star Wars* takes place “a long, long time ago” in a “galaxy far, far away,” they can’t be human. However, common sense and the droids think otherwise. In *The Empire Strikes Back*, C-3PO says that Luke is “quite clever, you know ... for a human being.” Since C-3PO is fluent in 7 million languages, one presumes that he knows.

The question at issue is whether, in the world of Charles Darwin, these various life forms are even scientifically possible. First up, obviously, is whether on all and any planets or planet substitutes, natural selection is going to be operating and the main cause of any kind of change. Richard Dawkins (1983) has discussed this very problem. He starts with the ubiquitous design-like nature of organisms and argues that any cause must be able to produce such a nature. The only two competitors here are Darwinian selection – the blacksmith’s arms are strong because, in early times, strong laborers had more kids than weak laborers – and Lamarckian inheritance of acquired characteristics – the blacksmith’s arms are strong because his dad worked hard at the forge and built up strong muscles, which he then passed on. We know that Lamarckism is false, so that just leaves selection. All other competitors for the job simply leave the design problem unsolved. To suppose saltations – jumps from one form to another – is to drop design. Jumps, what we today would call macromutations, almost always mess things up. Being albino, for instance, can be a terrible life choice, because you then have absolutely no adaptive camouflage. You stand out, and the predators can spot you at once. Dawkins concludes that where you get life, you get selection. The ancestors of Salacious Crumb really did outreproduce their (no doubt, warm and friendly, and boring) rivals.

Would selection produce consciousness and eventually intelligence? Could selection produce humans? This seems to imply that some kind of force is operative for progress, driving organisms up from (as was said) the monad to the man. Practically, all evolutionists, at least up to Charles Darwin,

assumed without question that evolution is progressive. Thus, Erasmus Darwin, his grandfather:

Organic Life beneath the shoreless waves
Was born and nurs’d in Ocean’s pearly caves;
First forms minute, unseen by spheric glass,
Move on the mud, or pierce the watery mass;
These, as successive generations bloom,
New powers acquire, and larger limbs assume;
Whence countless groups of vegetation spring,
And breathing realms of fin, and feet, and wing.
Thus the tall Oak, the giant of the wood,
Which bears Britannia’s thunders on the flood;
The Whale, unmeasured monster of the main,
The lordly Lion, monarch of the plain,
The Eagle soaring in the realms of air,
Whose eye undazzled drinks the solar glare,
Imperious man, who rules the bestial crowd,
Of language, reason, and reflection proud,
With brow erect who scorns this earthy sod,
And styles himself the image of his God;
Arose from rudiments of form and sense,
An embryon point, or microscopic ens!

(Darwin 1803, pp. 1, 11, 295–314)

Notions of biological progress, running up from the blob to the human, make the very backbone (to use an apt metaphor) of this vision, shown as Darwin explicitly tied his biology into his philosophy. The idea of organic progressive evolution “is analogous to the improving excellence observable in every part of the creation; such as the progressive increase of the wisdom and happiness of its inhabitants” (Darwin 1794–1796, pp. 2, 247–242).

At the time of the *Origin*, the man who in respects was an even-better-known English evolutionist than Charles Darwin was the wildly enthusiastic Herbert Spencer.

Now, we propose in the first place to show that this law of organic progress is the law of all progress. Whether it be in the development of the Earth, in the development of Life upon its surface, in the development of Society, of Government, of Manufactures, of Commerce, of Language, of Literature, of Science, or of Art, this same evolution of the simple into the complex, through successive differentiations, holds throughout. From the earliest traceable cosmical changes down to the latest results of civilization, we shall find that the transformation of the homogeneous into the heterogeneous is that in which Progress essentially consists (Spencer 1857, pp. 2–3).

Always a bit iffy about selection – for all that he discovered a decade before the *Origin* was published – Spencer simply assumed that evolution progresses upward. In this, he was like Lamarck and Erasmus Darwin. One suspects that in Spencer’s case, he was strongly influenced by the German Romantics – especially Friedrich Schelling – who saw history progressively, for Hegel particularly to the German state (Ruse 2013).

Of course, the English knew that it could not be so, but they were receptive to ideas of world spirits or forces acting for the good. Thus, William Wordsworth in *Tintern Abbey*:

And I have felt
A presence that disturbs me with the joy
Of elevated thoughts; a sense sublime
Of something far more deeply interfused,
Whose dwelling is the light of setting suns,
And the round ocean, and the living air,
And the blue sky, and in the mind of man,
A motion and a spirit, that impels
All thinking things, all objects of all thought,
And rolls through all things.
(Wordsworth, "Tintern Abbey," 1798)

3.2.6 CAN NATURAL SELECTION BE A FORCE FOR PROGRESS?

Now for the sixty-four-thousand-dollar question, or questions: Is natural selection a force that promotes progress – monad to man – or, at least, is it a force that can, in the right circumstances, make for progress? The answer is “not obviously.” On the one hand, the new variations coming into populations, the building blocks of evolution – what today we would call “mutations” – are random. Not random in the sense of uncaused – no one from Darwin on thought that, and most put it down to things like disturbances in reproduction and such things – but random in the sense of not occurring according to need. The climate turns dark, as in industrial pollution. There is no guarantee that the next variation will make you dark. As like as not, it might make you pink. (Today’s evolutionists speak to this issue, arguing, in the tradition of eminent twentieth-century evolutionist Theodosius Dobzhansky (1951), that selection can maintain variation in a population. If a new selective need occurs, you are not waiting on new variations. Already, you have a library at your disposal – with luck, a mutation for darkness or perhaps for making yourself very unpleasant to taste, so birds will avoid young.) On the other hand, natural selection is opportunistic. It doesn’t care about advance. It cares about surviving and reproducing. Paleontologist Jack Sepkoski puts the point colorfully. “I see intelligence as just one of a variety of adaptations among tetrapods for survival. Running fast in a herd while being as dumb as shit, I think, is a very good adaptation for survival” (Ruse 1996, p. 486). Cow power rules supreme!

This said, straight off after the *Origin* appeared, Darwinians (starting with Darwin) went with the tide. No self-respecting Victorian was going to take seriously the idea that we humans – we Europeans – are still down at the warthog level or below. Darwinians built in the thoroughly value-impregnated belief that evolution – evolution through natural selection – leads progressively up to humankind. This was Darwin himself, 20 years before the *Origin*, just before he discovered natural selection.

We see gradation to mans mind in Vertebrate Kindgdom in more instincts in rodents than in other animals &

again in mans mind, in different races. being unequally developed. ? is not Elephant intellectually developed amongst Pachydermata like man amongst Monkeys or dogs in Carnivora.—Man in his arrogance thinks himself a great work worthy the interposition of a deity, more humble & I believe truer to consider him created from animals (Barrett et al., 1987, C 196).

There is progress to humans, if not quite as specially as many presume. Notice how Darwin put things in an evolutionary context and described his position not as superior to another evolutionary position, Lamarck, for instance, but to the Christian position. This is a man who thought in a theological mode. After the discovery of selection, there is still progress albeit with an increasing recognition that selection changes the rules of the game. You could not now get a teleological upward direction à la Spencer, even if you wanted it.

The enormous number of animals in the world depends of their varied structure & complexity. —hence as the forms became complicated, they opened fresh means of adding to their complexity. —but yet there is no necessary tendency in the simple animals to become complicated although all perhaps will have done so from the new relations caused by the advancing complexity of others. —It may be said, why should there not be at any time as many species tending to dis-developement (some probably always have done so, as the simplest fish), my answer is because, if we begin with the simplest forms & suppose them to have changed, their very changes ton tend to give rise to others (E 95-7).

The *Origin* does not discuss humans in detail, but it still makes clear Darwin’s belief in progress: “The inhabitants of each successive period in the world’s history have beaten their predecessors in the race for life, and are, in so far, higher in the scale of nature; and this may account for that vague yet ill-defined sentiment, felt by many palaeontologists, that organisation on the whole has progressed” (Darwin 1859, p. 345). The closing passage to the book repeats that sentiment. The question is how selection brings this about. Through competition, obviously, but precisely how? By the third edition of the *Origin*, 1861, Darwin was confident that he had the answer. He invoked what today’s Darwinians call “arms races” – lines compete against each other, and one line gets better and better. Eventually, this comparative improvement is translated into some form of absolute improvement, *Homo sapiens*.

If we look at the differentiation and specialization of the several organs of each being, when adult (and this will include the advancement of the brain for intellectual purposes), as the best standard of highness of organization, natural selection clearly leads toward highness, for all physiologists admit that the specialization of organs, inasmuch as they perform in this state their functions better, is an advantage to each being, and hence, the accumulation of variations tending toward specialization is within the scope of natural selection (Darwin 1861, p. 134).

Natural selection cannot guarantee anything, but everything is probably going to be just fine. The great success of capitalism and British industry leads the way.

3.2.7 BUT CAN SELECTION PRODUCE ALIEN HUMANS? NO!

It seems that natural selection can and does produce intelligent beings all the way up to humans. I confess that even if this can happen, I would think selection would more likely produce humanoids – beings like humans but not necessarily identical to us. There might be at least as many Wookies in the universe as there are humans (or human-identical beings). Perhaps, Jabba the Hutt and his conspecifics outnumber humans ten to one! There is incidentally an interesting point of theology here. Humans are made in the image of God. Whatever else in the Judeo-Christian story, humans are special. We are not warthogs. It seems to me that humans are necessary to the story (Ruse 2001, 2015). They had to appear. But would a Wookie be adequate? Could Jesus come to Earth as a Wookie? One rather doubts he could come as a conspecific of Jabba the Hutt, although we would certainly satisfy the qualification of original sin. I suppose that if you insist that humans must be humans – perhaps you would allow a greenish tint to the skin – then if you are into multiverses, given enough time anything will happen, and so you will eventually get humans. Perhaps, an infinite number of times, although this then does give rise to the worry of Whewell that perhaps Jesus will be overworked. It does also give rise to the thought of billions and billions of organisms that didn't quite make it. Multiverses filled with human-like failures. Brave New Worlds without the alphas. Is this truly possible given an all-powerful, all-loving God? I guess, since He let the Holocaust occur, it might well be.

Darwin thought that selection could produce humans. How often this would occur is unanswered and perhaps unanswerable, but once it could and did occur. Not all Darwinians in the next hundred years or so shared this optimism. Alfred Russel Wallace is perhaps an atypical exception, because he thought that humans are produced by spirit forces. He wrote about the possibility of life elsewhere, arguing adamantly that selection could not do the job.

Now, the numerous conditions and sub-conditions essential to the development of the higher organic life, which must all exist simultaneously and which must all have continued to exist for enormous periods of time, are improbable in various degrees, as clearly shown by the fact that the great majority of them are not present in the degree required in any other planet of the solar system. The actual degree of improbability of each of these conditions cannot be determined except vaguely, but anyone who will carefully consider and weigh my very imperfect exposition of them will, I think, admit that they are usually very considerable, the chances against each of them being in some cases, perhaps, ten to one and in others being ten thousand to one or even more. But if we take the whole of the simultaneous conditions requisite as only fifty in number, and the chances against each occurring simultaneously with the rest to be only ten to one, an estimate that seems to me absurdly low because many of them are quantitative within narrow limits, then the chances against the simultaneous occurrence of the whole fifty would be a million raised to the eighth power ($1,000,000^8$) or a

million multiplied by a million eight times successively to 10^{24} . These figures are suggested merely to give some indication to the general reader of the way in which the chances against any event happening more than once mount up to unimaginable numbers when the event is a highly complex one (Wallace 1903, p. 336).

This set a pattern. Darwinian evolutionists for the next century were not at all opposed to life elsewhere in the universe – as for Darwin, the origin of life was not their thing – but they didn't want it evolving into humans or even often intelligent beings. The paleontologist George Gaylord Simpson, writing in 1964 (5 years after the centenary of the *Origin*), spoke for many.

The assumption, so freely made by astronomers, physicists, and some bio-chemists, that once life gets started anywhere, humanoids will eventually and inevitably appear is plainly false. The chance of duplicating man on any other planet is the same as the chance that the planet and its organisms have had a history identical in all essentials with that of the Earth through some billions of years. Let us grant the unsubstantiated claim of millions or billions of possible planetary abodes of life; the chances of such historical duplication are still vanishingly small.

Continuing:

I cannot share the euphoria current among so many, even among certain biologists (some of them now ex-biologists converted to exobiologists). The reasons for my pessimism are given here only in barest suggestion. They will not, I know, convince all or indeed many. There are too many emotional factors and, to put it bluntly, selfish interests opposed to these conclusions. In fact, I myself would like to be proved wrong, but a rational view of the evidence seems now to make the following conclusions logically inescapable:

1. There are certainly no humanoids elsewhere in our solar system.
2. There is probably no extraterrestrial life in our solar system, but the possibility is not wholly excluded as regards Mars.
3. There probably are forms of life on other planetary systems somewhere in the universe, but if so, it is unlikely that we can learn anything, whatever about them, even as to the bare fact of their real existence.
4. It is extremely improbable that such forms of life include humanoids and apparently as near impossible as does not matter that we could ever communicate with them in a meaningful and useful way if they did exist (Simpson 1964, p. 774).

Others felt the same way. Stephen Jay Gould (1981), notoriously, was against biological progress. He hated the idea, because he felt that it implied some peoples are better than others, and as a Jew, he was very mindful of how that particular belief had played out earlier in the twentieth century. In his bestseller, *Wonderful Life* (Gould 1989), he wrote of the "... staggeringly improbable series of events, sensible enough in retrospect and subject to rigorous explanation, but utterly unpredictable and quite unrepeatable... Wind back the tape of life to the early days of the Burgess Shale;

starting point, and the chance becomes vanishingly small that anything like human intelligence would grace the replay" (p. 14).

3.2.8 BUT CAN SELECTION PRODUCE ALIEN HUMANS? YES!

Yet, there are those who have endorsed thoughts of progress, including progress up to humans. Paradoxically, elsewhere, Gould (1985) counts himself in this number. "When we use 'evolutionary theory' to deny categorically the possibility of extraterrestrial intelligence, we commit the classic fallacy of substituting specifics (individual repeatability of humanoids) for classes (the probability that evolution elsewhere might produce a creature in the general class of intelligent beings.) I can present a good argument from "evolutionary theory" against the repetition of anything like a human body elsewhere; I cannot extend it to the general proposition that intelligence in some form might pervade the universe."

More generally, we find a range. Very much in the Spencerian tradition of being ardent for progress and simply unbothered by the causes is today's most distinguished evolutionary biologist, the eminent ant specialist, and sociobiologist, Edward O. Wilson. "The overall average across the history of life has moved from the simple and few to the more complex and numerous. During the past billion years, animals as a whole evolved upward in body size, feeding and defensive techniques, brain and behavioral complexity, social organization, and precision of environmental control — in each case farther from the nonliving state than their simpler antecedents did" (Wilson 1992, p. 187). The enthusiasm is for absolute progress, leading to humankind. In his great book, *Sociobiology: The New Synthesis*, Wilson offers a tale of social evolution from colonial invertebrates, through the Hymenoptera, onto the vertebrates and primates, and now humans. "Man has intensified these vertebrate traits while adding unique qualities of his own. In so doing he has achieved an extraordinary degree of cooperation with little or no sacrifice of personal survival and reproduction." The big question is not whether progress occurred, but why it occurred. "Exactly how he alone has been able to cross to this fourth pinnacle, reversing the downward trend of social evolution in general, is the culminating mystery of all biology" (Wilson 1975, p. 382). Parenthetically, one might add that Wilson is an ardent Spencerian. His intellectual grandfather at Harvard, the supervisor of his supervisor, was W. H. Wheeler, a fellow ant specialists and Spencer groupie. In Wilson's lab, there was a picture of Spencer on the wall, hung more prominently than that of Darwin, but neither as prominent as the picture of Wilson receiving the National Medal of Science from then-president Jimmy Carter!

Most, however, try to offer Darwinian reasons for the upward progress. Thomas Henry Huxley (Huxley [1893] 2009), although a keen supporter of Darwin, as a morphologist and paleontologist was never that keen on selection and, as one living toward the end of the nineteenth century, when things were going wrong (like overcrowded cities and

tensions between the great powers), was also a bit dubious about progress. His grandson, Julian Huxley, felt no such doubts. If humans are the end point, the apotheosis of evolution, how did Huxley think we progressed up to us? Arms races! In the spirit of Darwin, it was Julian Huxley who developed the idea, before the Great War, making the case in a little book, *The Individual in the Animal Kingdom* (Huxley 1912). Then, after the War, restating the case in *Animal Biology*, a textbook published jointly with Haldane Deeply influenced by the progressionist thinking of the French philosopher Henri Bergson, stressing the competition between evolving lines leading to improvement, obviously inspired by the pre-War competition between the British and German navies, Huxley gave a graphic description of an arms race couched in terms of naval, military technology (Huxley and Haldane 1927). "The leaden plum-puddings were not unfairly matched against the wooden walls of Nelson's day." Now, however, obviously having in mind, the then-huge competition between Britain and Germany, "though our guns can hurl a third of a ton of sharp-nosed steel with dynamite entrails for a dozen miles, yet they are confronted with twelve-inch armor of backed and hardened steel, water-tight compartments, and targets moving thirty miles an hour. Each advance in attack has brought forth, as if by magic, a corresponding advance in defence." Likewise, in nature, "If one species happens to vary in the direction of greater independence, the inter-related equilibrium is upset, and cannot be restored until a number of competing species have either given way to the increased pressure and become extinct, or else have answered pressure with pressure, and kept the first species in its place by themselves too discovering means of adding to their independence" (Huxley 1912, pp. 115–116). Eventually, "it comes to pass that the continuous change which is passing that through the organic world appears as a succession of phases of equilibrium, each one on a higher average plane of independence than the one before, and each inevitably calling up and giving place to one still higher."

Today, Richard Dawkins stands in this tradition. "Directionalist common sense surely wins on the very long time scale: once there was only blue-green slime and now there are sharp-eyed metazoa" (Dawkins and Krebs 1979, p. 508). He too finds the key in arms races. Perhaps, expectedly, as one who embraced computer technology early and enthusiastically, Dawkins notes that, more and more, today's arms races rely on computer technology rather than brute power, and – in the animal world – he finds this translated into ever-bigger and more efficient brains. No need to hold your breath about who has won. Dawkins invokes a notion known as an animal's EQ, standing for "encephalization quotient" (Jerison 1973). This is a kind of cross-species measure of intelligence quotient (IQ) that takes into account the amount of brain power needed simply to get an organism to function (whales require much bigger brains than shrews, because they need more computing power to get their bigger bodies to function) and that then scales according to the surplus left over. Dawkins (1986) writes, "The fact that humans have an EQ of 7 and hippos an EQ of 0.3 may not literally mean that

humans are 23 times as clever as hippos! But the EQ as measured is probably telling us *something* about how much ‘computing power’ an animal probably has in its head, over and above the irreducible amount of computing power needed for the routine running of its large or small body” (p. 189).

As always, it is the analogy with human Progress that is the key.

Computer evolution in human technology is enormously rapid and unmistakably progressive. It comes about through at least partly a kind of hardware/software coevolution. Advances in hardware are in step with advances in software. There is also software/software coevolution. Not only did the advances in software made possible improvements in short-term computational efficiency – although they certainly do that – they also make possible further advances in the evolution of the software. So, the first point is just the sheer adaptedness of the advances of software for efficient computing. The second point is the progressive thing. The advances of software, open the door – again, I wouldn’t mind using the word “floodgates” in some instances – or open the floodgates, to further advances in software (Conference talk, Melbu, Norway, 1989; printed in Ruse 1996, p. 469).

A rather different but still supposedly Darwinian approach to the question involves the notion of channeling or external direction. Using an argument that seems to have swayed Gould, the paleontologist Simon Conway Morris, as a Christian, is very keen to argue for the inevitability of the appearance of humans. He argues that only certain areas of what we might call “morphological space” are welcoming to life forms (the center of the Sun would not be, for instance) and that this constrains the course of evolution (Conway Morris 2003). Again and again, organisms take the same route into a pre-existing niche. The saber-toothed, tiger-like organisms are a nice example, where the North American placental mammals (real cats) were matched right down the line by South American marsupials (thylacosmilids). There existed a niche for organisms that were predators, with cat-like abilities and shearing/stabbing-like weapons. Darwinian selection found more than one way to enter it – from the placental side and from the marsupial side. It was not a question of beating out others but of finding pathways that others had not found.

Conway Morris argues that, given the ubiquity of convergence, we must allow that the historical course of nature is not random but strongly selection-constrained along certain pathways and to certain destinations. Most particularly, some kind of intelligent being was bound to emerge. After all, our own very existence shows that a kind of cultural adaptive niche exists – a niche that prizes intelligence and social abilities. “If brains can get big independently and provide a neural machine capable of handling a highly complex environment, then perhaps there are other parallels, other convergences that drive some groups towards complexity.” Continuing: “We may be unique, but paradoxically those properties that define our uniqueness can still be inherent in the evolutionary process. In other words, if we humans had not evolved then something more-or-less identical would have emerged sooner or later” (Conway Morris 2003, p. 196).

Finally, let us mention a non-Darwinian solution to the problem, one acknowledged to be more in a Spencerian vein. Duke University colleagues, paleontologist Daniel McShea and philosopher Robert Brandon (2010), promote what they proudly call “Biology’s First Law.” Named the “zero-force evolutionary law” or ZFEL, its general formulation runs: “In any evolutionary system in which there is variation and heredity, there is a tendency for diversity and complexity to increase, one that is always present but that may be opposed or augmented by natural selection, other forces, or constraints acting on diversity or complexity” (p. 4). It is something apparently with the status in evolutionary biology of Newton’s First Law of Motion – a kind of background condition of stability, even though somewhat paradoxically, their law suggests perpetual motion.

Although the authors are fairly (let us say) generic on their understandings of complexity and diversity – number of parts and number of kinds – the claims made are grandiose if familiar. Given the natural tendency of life to complexity – parts tend to be added on – this generates new organic variations and hence types, and so, one gets a version of (what the theoretical biologist Stuart Kauffman (1993) has called) “order for free.” As is usual in these discussions, it is not always obvious whether the claim is that adaptation is created in this way or if adaptation is now irrelevant. Probably, more the former: “we raise the possibility that complex adaptive structures arise spontaneously in organisms with excess part types. One could call this self-organization. But it is more accurately described as the consequence of the explosion of combinatorial possibilities that naturally accompanies the interaction of a large diversity of arbitrary part types” (p. 124).

Expectedly, all of these approaches have attracted criticism. Not every Darwinian biologist is that enthused by arms races. The fossil evidence, for instance, does not show unambiguously that prey and predators have become ever faster. And even if arms races are ubiquitous, it does not follow that intelligence will always emerge. Having high intelligence means having large brains and having large brains means having ready access to large chunks of protein, the bodies of other animals. There were no clever vegans in the Pleistocene. Being clever, however, isn’t everything. Sometimes – as cows and horses demonstrate – it is just easier to get your food in other ways, especially if you are living on grassy savannahs. Remember the cautionary words of Jack Sepkoski.

Even if it exists, why should we or anyone else necessarily or even probably enter the culture niche? Life is full of missed opportunities. Maybe Gould is right, and most times, evolution would have gone other ways and avoided culture entirely. Warthogs rule supreme. Julian Huxley always argued that now that humans occupy the culture niche, no other animal is going to be able to enter (Huxley 1942). Perhaps, other animals – dinosaurs – would have prevented our animals – mammals and then primates – from making their way to the door. In any case, many wonder if it is right to think that niches are just waiting out there, ready to be conquered and entered. Do organisms not create niches as much as find them? There was hardly a niche for head lice, for instance, until vertebrates like

us humans came along. Should we expect that there was a niche for culture, just waiting there, such as dry land or the open air? Perhaps, there are other niches not yet invented. We cannot imagine something other than consciousness, but remember the wise warning of J. B. S. Haldane (1927). "Now my own suspicion is that the Universe is not only queerer than we suppose, but queerer than we *can* suppose" (p. 286). For all their talk about analogy, Christians tend to think that their God can get up to some clever tricks, way beyond their ken. Perhaps, these are not all supernatural abilities but simply abilities that were omitted from our evolution. Perhaps, far from being the best, we are a short sidepath and very limited in the true scheme of things. No more than in the case of arms races do we get much guarantee of either human emergence or a sense that we are in some way superior and, for this reason, we won.

Zero-force evolutionary law (ZFEL)? One can only say that if you believe in this, then you are ready for the tooth fairy. Ideas like this seem to appeal to and only to those who spend their times in front of computers. If they spent less time running simulated scenarios and more time looking at the real world, they would think otherwise. Blind law leads to blind results, and supposing that laws are not really blind is to suppose like Wallace that there is some kind of intelligence behind it all. These days, popular among philosophers is an Aristotelian force, an Unmoved Mover, to which everything strives teleologically. I just don't see the evidence for it, I just don't. In my world, Murphy's Law rules supreme. If it can go wrong, it will go wrong. I am not sure that either arms races or niches did do the job, but I can see how they could and how natural selection was vital.

3.2.9 CONCLUSION

That brings us to the end of the discussion. As one looks at it – the relevance of Darwinism to problems of astrobiology – one might at first wonder if there is much to say on the topic, especially given that for Darwin (except perhaps at the very end), it seems to have been such a non-issue. A non-issue not through ignorance – he had read Whewell – but through non-importance or relevance. However, as I hope I have shown, if one persists, there are both some interesting findings historically, especially about Darwin's strategy of getting his ideas presented and accepted and why alien beings were excluded, and some interesting findings philosophically, about Darwinian evolution and the concept of progress and how it impinges on the question of extraterrestrials generally and humanoids specifically. In a sense, it is the best of all topics, because it is clear that there is a lot more work to be done. That is for another place and another time. Perhaps – *pace* Simpson – our intelligent friends across the galaxy can lend a hand.

3.3.1 INTRODUCTION

The issue of the origin of life as a scientific matter dates back to the eighteenth century. For a very long period, the beginning of life on Earth was only a part of cosmogonies and religious creationist dogmas. With the first scientific revolution, the place of Earth in the universe, and therefore the place of humans in the universe, was completely reconsidered in scientific terms. The Copernican Revolution, which placed the Sun at the center of the solar system, was the first such reconsideration. Moreover, theories, such as Descartes', provoked a new thought on the history of the formation of Earth. However, the issue of the origin of life was neglected for a long time because of the fixist conceptions of the living beings. Since the eighteenth century, the primordial beginnings of life on Earth became a central issue in life sciences. This chapter focuses on this emergence, from the Enlightenment, notably represented by Buffon, to the inter-war period, focusing on Oparin and Haldane. It shows how it became intrinsic to the general issue of the theories of the evolution of living beings.

3.3.2 THE FIRST DEBATES ON SPONTANEOUS GENERATION

Spontaneous generation was a conception of the emergence of life in current nature. According to these early views, living organisms occurred from inert matter and particularly from decayed matter. Spontaneous generation originated in

Antiquity, its history being marked by three main experimental phases between the seventeenth and nineteenth centuries.

In 1668, Francesco Redi (1626–1697), a naturalist and a physician from Pisa (Italy), published *Esperienze intorno all'generazione degli insetti*, a book about his experiments on the spontaneous generation of flies. First, the Italian naturalist exposed samples of meat in two groups of jars. The jars from the first group were left open, in order for the meat to come in direct contact with the air from the room. Those from the second group were covered with caps. Redi observed that fly larvae appeared in the first group of jars, while nothing appeared in the second group. Based on this finding, he concluded that the maggots came from the exterior, from the eggs laid by flies. Some critics argued against this conclusion, according to which the cap prevented air from entering the jars and, in the absence of air, the phenomenon of spontaneous generation could not occur. He thus repeated his experiments and replaced the caps with gauze. The result was the same. The jars closed with gauze never contained maggots, while the others did. Therefore, Redi was able to claim that the spontaneous generation of flies did not exist. This was the first experimental approach of spontaneous generation. There were naturalists who continued to claim its existence.

During the eighteenth century, spontaneous generation was the reason for a scientific debate between Joseph Needham (1713–1781) and Lazarro Spallanzani (1729–1799) (Spallanzani 1769). The former argued for the spontaneous generation of animalcules, which the latter rejected. They discussed their respective experiments. Needham, who was

determined to observe spontaneous generation, criticized Spallanzani's method, arguing that heating the mixtures destroyed the vegetative force.

This debate was closely linked to another fierce one regarding generation. Needham was indeed convinced that generation could be explained through the epigenetic phenomenon—namely, the complete formation of the embryo after fecundation from an unorganized egg—while Spallanzani claimed that eggs contained a preformed organism prior to fecundation.

This debate fascinated naturalists. For instance, the French naturalist Buffon, on the one hand, supported spontaneous generation and used it in his theories. On the other hand, Charles Bonnet (1720–1793) supported Spallanzani. Enlightenment philosophers were also interested in this issue. French philosophers also debated on it. Voltaire, for one, strongly criticized spontaneous generation, while Denis Diderot (1713–1784) supported it in *Le rêve de D'Alembert* (*The D'Alembert's Dream*) as well as in his *Elements de physiologie* (*Elements of physiology*), in which he claimed, “Nature has made only a very small number of beings that she has infinitely varied, perhaps from a single one, by combining, mixing and dissolving from which all the others have been formed” (Diderot 1994, p. 1261).

3.3.3 BUFFON: SPONTANEOUS GENERATIONS AND THE HISTORY OF EARTH

Georges Louis Leclerc, Comte de Buffon (1707–1788) was the most important French naturalist of this century. He developed a set of concepts regarding living beings and implied them in his writings on the history of Earth. Spontaneous generation was one such concept.

Buffon occupied an influent position for a long time, as Intendant of the King's garden as well as part of the King's natural history cabinet. Moreover, between 1749 and 1789, he published, together with his collaborators, a huge encyclopedia about nature, *Histoire naturelle*, comprising 22 volumes and 7 supplements.

The volumes focused mainly on living beings, comprising very famous monographs of species as well as important conceptual perspectives. Buffon's central concept regarded the constitution of living matter. He claimed that all the living beings, that is, plants and animals, are constituted with organic molecules, which, according to Buffon, are microscopic, alive and indestructible. Organic molecules circulate from a living being to another by alimentation, when animals eat animals and animals eat plants. Then, when living beings die, the organic molecules return to the soil and can be absorbed by plant roots, thus beginning a new cycle. Buffon also formulated a concept of species. In the chapter dedicated to the donkey (Buffon 1753, vol 4), he claimed that each species is constituted by a set of living beings characterized by the fact that they can reproduce among themselves and have a fertile offspring. Moreover, the organic molecules take the imprint of the “inner mould” characteristic to each individual and ensure the perpetuation of species. According to Buffon, organic

molecules are transmitted in the semen during reproduction, the characteristic of the inner mould thus being transmitted. It is also of great significance that Buffon was a fixist naturalist and all his concepts allowed him to justify that each species, related to its own original prototype, does not evolve into another species, even if it can vary through the ages.

Buffon's theory of Earth evolved continuously throughout his career, and it was particularly revealed in two volumes of his *Histoire naturelle*. The first, in 1749, was dedicated to a *Theorie de la Terre*, in which he presented a cyclic history of Earth. On the other hand, in 1778, in the seventh supplement, entitled *Les époques de la nature* (*The epochs of Nature*), he proposed a non-cyclic history of Earth, claiming a succession of irreversible transformations due to the irreversible cooling of the planet. Buffon calculated that the age of the Earth, in this linear history, was 75,000 years (Roger 1988). Several aspects of *The Epochs* particularly regarded the origin of life. The first epoch was that of the formation of planets. The second epoch regarded the solidification on Earth. After 2936 years of cooling, Earth was solid and its temperature was compatible with the presence of living beings. These emerged during the third epoch. According to Buffon, life is a physical property of matter; therefore, a big quantity of organic molecules was available from this very early period. During the fifth epoch, large species, such as elephants, were produced by spontaneous generations in the northern regions of the planet. Man emerged only during the seventh epoch (Buffon 1778).

To sum up, Buffon claimed that the origin of species depends on spontaneous generation. The first species emerged as soon as Earth was sufficiently cooled. The first species to emerge were the bigger ones and were progressively followed by the smaller ones.

3.3.4 JEAN-BAPTISTE LAMARCK: SPONTANEOUS GENERATIONS AND THE PERPETUAL BEGINNING OF LINEAGES

Jean-Baptiste Monet de Lamarck (1744–1829) presented a developed theory of the transformation of species in 1802. He explained this process through the influence of environment and the habits of living beings. The principles of his theory were operable at all the levels of complexity of the chain of living beings, including the simplest of the animalcules, which, according to him, emerged by spontaneous generation.

Lamarck began his naturalist career as a botanist, and, in 1779, he published his *Flore de France*. At that time, he was deeply interested in chemistry. However, he never carried out any practical work in this field, but developed his theoretical ideas in several books. During the last decades of the eighteenth century, he struggled to impose his ideas that never took into account the results of Lavoisier's chemical revolution. In 1801, Lamarck became professor of zoology of animals without vertebrae at the Museum of Natural History in Paris. Lamarck was the inventor of the word invertebrate. In 1801, Lamarck (1801) published the first book on this topic: *Le système des animaux sans vertèbres* (*System of animals without vertebrae*).

The following year, in his *Hydrogéologie ou recherches sur l'influence qu'ont les eaux sur la surface du globe terrestre...* (*Hydrogeology or research on the influence that water has on the surface of Earth...*), he suggested an analogy between the role of the fluids on Earth's surface and the fluids that would shape the interior of organisms. In *Hydrogéologie*, as in his previous books, he did not hesitate to claim one of his main chemical concepts, namely that living bodies are the “primary cause of the existence of all compounds” (Lamarck 1797, p. 238). He added that “all compounds we observe on our globe, owe their origins, directly or indirectly, to the organic faculties of living beings” (Lamarck 1797, p. 386). The logical consequence of this idea is that the primordial beginning of life and spontaneous generation are impossible.

Later that year, Lamarck (1802) definitively abandoned his fixist conceptions and presented the first complete version of his theory about the transformation of living beings. Surprisingly, and in complete contradiction with his previous point of view, he used the notion of spontaneous generation for the first time. He presented his theory in a book, *Recherches sur l'organisation des corps vivans*, comprising two parts: the first is the lecture that he read at the Museum d'Histoire Naturelle in 1802, and the second, longer part, is an explanation of his new theory. The book begins with the description of the chain of living beings, from the most complex to the simplest. Lamarck said that, in his description, he followed the reverse order of the order followed by the nature. Taking group by group, he finally arrived at the animalcules, the last and simplest group of polyps, claiming that some of them were probably products of nature, by way of spontaneous generations. Therefore, Lamarck described a process of “animalization” of matter and explained how the fluids of the environment transform the inert gelatinous matter. He distinguished between two types of fluids: “subtle fluids,” that is, “fluids which cannot be contained,” heat and electricity, and fluids “which can be contained,” water and gases. The former fluids give the simplest organization to gelatinous matter and are the cause of the vital organism, which is a sort of an excitation of the matter in which molecules are kept apart. The latter, with their permanent movements through matter, also shape it. At this stage, the gelatinous matter acquires contractility, an ability compared by Lamarck to a property of animalcules. Moreover, fluids passing through the gelatinous matter leave some particles, which the naturalist compared to nutrition. The next stage of shaping is the formation of a hole corresponding to the intestine of polyps. Therefore, according to Lamarck, this process initiates the chain of living that he previously described. Lamarck’s process of animalization resumed all the principles of his theory. He explained the transformations of the more complex animals with the effects of habits, the actions of inner fluids, and the interactions with environment.

It is very important to stress upon the fact that Lamarck claimed that spontaneous generation is a permanent process in today’s nature. Consequently, chains of living beings are permanently initiated, and the diversity of the groups that we currently observe in nature correspond to as many stages of the transformation of different chains (Figure 3.3.1).

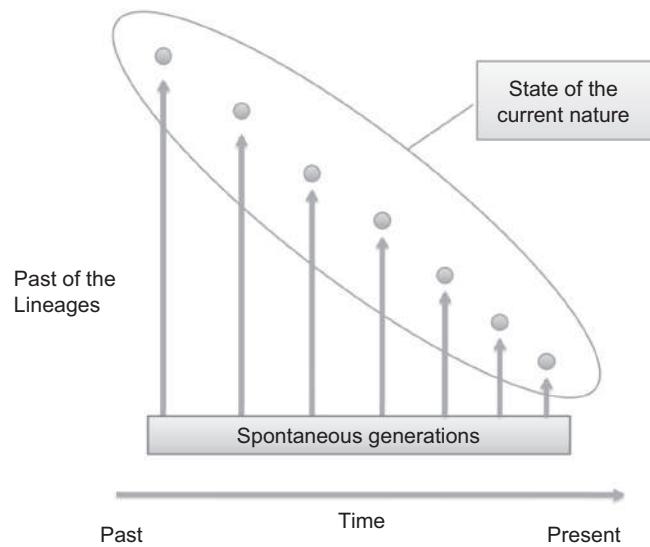

FIGURE 3.3.1 Spontaneous generations and lineages according to Lamarck.

Moreover, there are two crucial questions to be asked regarding the origins of life: did Lamarck believe in the primordial spontaneous generation on the primitive lifeless Earth? In Lamarck’s writings, there are very rare passages about a sort of an absolute beginning of living beings. In *Recherches sur l'organisation des corps vivants*, he said, about the simplest forms of life, that nature began and is still in the process of beginning its production by this extremity. Further, in the same text, he wrote that life has not always been as we see it today. He probably referred to a period in the past, when only very simple living beings were present on Earth. Moreover, it is interesting to notice that he wrote that animal life began in the sea. Therefore, did Lamarck consider a primordial beginning? If so, the permanent spontaneous generation would be the permanent repetition of the primordial one (Tirard 2006).

Nevertheless, Lamarck’s ideas did not dominate the life sciences of the first part of the nineteenth century, and, during the following decades, whenever spontaneous generation was mentioned, his transformist conception was usually not often mentioned.

3.3.5 LOUIS PASTEUR: THE REJECTION OF SPONTANEOUS GENERATION

In the middle of the nineteenth century, a very important debate took place in France between partisans of the spontaneous generation, led by Félix Pouchet (1800–1872), and opponents, led by Louis Pasteur (1822–1895). At the end of the 1850s, Pouchet, a biologist at the museum of Rouen, sent several successive notes to the Académie des sciences de Paris, and in 1859, he published a book: *Hétérogénéité ou Traité de la génération spontanée* (*The Heterogeneity or Spontaneous Generation Treatise*) (Pouchet 1859). In 1862, in light of the discussion provoked by these texts,

the academy decided to award him a prize for the work carried out on the issue of spontaneous generation: “Try, through well done experiments, to throw a new light on the question of spontaneous generations.” His main opponent was Pasteur, a physicist who focused on fundamental issues about life. Before turning to spontaneous generation, Pasteur focused on fermentation and, in his capacity as a crystallographer, discovered the dissymmetry of chemical molecules on living beings, a very interesting characteristic, which would become an important issue in the study of the origins of life.

Therefore, the award launched constituted the beginning of a long opposition between two groups supporting Pouchet and Pasteur, respectively. The two scientists opposed their own experimental results, which were based on heating glass balloons containing organic mixtures. Their results and conclusions were in complete contradiction. Their balloons containing alterable solutions produced opposite results. Pouchet observed spontaneous generation systematically, which was not the case for Pasteur, in whose balloons microorganisms did not occur spontaneously. Pasteur's conclusion was that spontaneous generation could not occur in such conditions. He showed that if the boiling mixture was left unclosed in the balloon, no germs could appear. However, they became present as soon as the balloon was opened. He concluded that the germs that were present in the air also got inside the balloon.

In 1864, in a famous lecture held at the University of Paris, Pasteur presented his conclusions and referred to a drop of water coming from one of his balloons, waiting for spontaneous generation:

“But it’s mute! It has been mute for several years since these experiences began. Ah! It is because I have removed from her, and that I am still removing at this moment, the only thing that man has not been given to produce, I have removed from her the germs that float in the air, I have removed from her life, because life is the germ and the germ is life. The doctrine of spontaneous generation will never rise from the mortal blow that this simple experience brings it.” (Latour 1989, p. 427)

In France, Pasteur's conclusions led to the complete abandonment of spontaneous generation. In other countries, however, the debate continued for a few more years, notably in England with Henry Charlton Bastian (1837–1915). This professor of pathological anatomy at the University College of London argued for the existence of spontaneous generation throughout his career. He notably supported heterogeny, that is, the possibility that every organic matter coming from a living being can produce another living being eventually from another species.

To conclude, spontaneous generation was the subject of experiments or scientific debates several times in history: during the seventeenth century with Redi, during the eighteenth century with Spallanzani and Needham, and during the nineteenth century with notably Pasteur, Pouchet, and Bastian. It appears that despite the relevance of certain pieces of evidence, it was difficult for certain scientists to

abandon this theory. However, the history of spontaneous generation cannot be limited to the history of a progressive denying of an ancient error. Indeed, the issue of spontaneous generation was also present in general thought on life and on its history, as it was demonstrated in Buffon's and Lamarck's works.

3.3.6 DARWIN'S CONCEPTION OF A UNIQUE ORIGIN OF LIFE

The British naturalist Charles Darwin (1809–1882) published his book, *The Origin of Species*, in 1859, after more than 20 years of preparation. He proposed to explain the descent of living beings with modifications, thanks to the concepts of variation and natural selection. Darwin's theory, which explained the history of species on Earth, could logically include the beginning of this history, that is, the first living beings. However, two main remarks can be made regarding Darwin's ideas on the origin of life.

The first regards a very small part of the origins of life in *The Origins of Species*. In this book, or in any of his other books, he did not develop the issue of the beginning of life on Earth, mainly because there was no evidence of this phenomenon (particularly no paleontological evidence). There were only a few lines in the conclusion of his book where he linked his general explanation of the evolution of living beings to the issue of the beginning of life:

“It is interesting to contemplate an entangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth, and to reflect that these elaborately constructed forms, so different from each other in so complex a manner, have all been produced by laws acting around us. These laws, taken in the largest sense, being Growth by Reproduction; inheritance which is almost implied by reproduction; Variability from the indirect and direct action of the external conditions of life, and from use and disuse, a Ratio of Increase so high as to lead to a Struggle for Life, and as a consequence to Natural Selection, entailing Divergence of Character and the Extinction of less-improved forms. Thus, from the war of nature, from famine and death, the most exalted object which we are capable of conceiving, namely, the production of the higher animals, directly follows. There is a grandeur in this view of life, with its several powers, having been originally breathed into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved.” (Darwin 1859, pp. 489–490)

Therefore, it is clear what Darwin thought about the origin of life and about the simple early organisms. He claimed that all the living beings could come from a unique and simple ancestor, an idea that was in accordance with the permanent and divergent modification of species, which characterized the Darwinian evolutionary process. However, he never published anything more about the origin of the first living beings.

It is important to notice that, as a concession to a conservative environment, he introduced a small but important change

in the following editions of his famous book, in the last sentence, with a mention to the creator (we underline):

“There is a grandeur in this view of life, with its several powers, having been originally breathed by the Creator into a few forms or into one; and that, whilst this planet has gone cycling on according to the fixed law of gravity, from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved.” (Darwin 1860, p. 490)

The second remark regards a private letter (1871), in which Darwin explained to his friend, the botanist Joseph Dalton Hooker (1817–1911), his thoughts on the origin of life on Earth. They discussed about spontaneous generations, and Darwin wrote this very interesting paragraph:

“It is often said that all the conditions for the first production of a living organism are now present, which could have been present. But if (and oh what a big if) we could conceive in some warm little pond with all sort of ammonia and phosphoric salts, - light, heat, electricity &c. present, that a protein compound was chemically formed, ready to undergo still more complex changes, at the present day such matter would be instantly devoured, or absorbed, which would not have been the case before living creatures were formed.” (Quoted in Calvin 1969, p. 4)

This quote is important for at least four reasons. First, it is the only time that Darwin has ever claimed a process for the beginning of life. Second, the process of the complexification of matter is clearly described, step by step, from mineral to organic matter. Third, he demonstrated the impossibility of spontaneous generation. This reason has a great significance: it would be life itself that would prevent life to occur again. Fourth, this impossibility of the repetition of the process of the origin of life is characteristic of a historical process, each step depending on the previous steps, without any possibility of reversibility.

Therefore, in this quote, Darwin put the issue of the origin of life in modern terms. Several other biologists would do the same in the following decades.

3.3.7 THE BEGINNING OF EVOLUTIONARY ABIOTGENESIS

During the second part of the nineteenth century, with the emergence of evolutionary theories, some scientists made proposals regarding a progressive evolution from inert matter to living matter (Kamminga 1991). These claims were in accordance with the new concepts that became central in biology and in the issue of the origins of life. The first of them was the cellular theory, which was formulated in two distinct time periods. In 1838, Matthias Schleiden (1804–1881) claimed that plants were composed of cells that have a nucleus. According to him, cells appeared due to the matter of a pre-existing cell. One year later, Theodor Schwann (1810–1882) generalized this claim to include animals and claimed that the matter constituting a new cell could be an intercellular liquid. During the 1850s, Robert Remak (1815–1865) and Virchow (1821–1902), independently of each other, stated that each cell came from the division of a pre-existing cell.

The composition of cells, and particularly of their protoplasm, was also a central issue. In 1868, Thomas Huxley (1825–1895), a British biologist close to Darwin, claimed that albuminous bodies were “The Physical Basis of Life,” as he wrote a lecture on this issue in 1868. Moreover, he was opposed to the idea of spontaneous generations (Huxley 1892).

The importance of the chemical nature of living matter was particularly illustrated in the debate about a substance named *Bathybius haekeli* after its discovery in 1857 on the floor of the North Atlantic Ocean by the Britanic ship Cyclops. For almost 20 years, there had been a discussion on the nature of this substance, that some scientists, such as the German biologist Ernst Haeckel (1834–1919), considered to be a primitive form of life. Finally, in 1876, the chemist John Young Buchanan (1849–1925) subjected it to analysis and determined that it was calcium sulfate and not living matter.

Haeckel, one of the main German zoologists of the second part of the nineteenth century, was always very interested in the issue of the chemical evolution of matter at the origin of life on Earth. He claimed that albuminous protoplasm could be at the origin of *Monera*, which, according to him, could be the most primitive living structure (Haeckel 1879, 1897).

During the same period, the British philosopher Herbert Spencer (1820–1903) developed a huge view of the world by using all sciences, including psychology and sociology, which he published in several books throughout the second part of the nineteenth century. Spencer’s thought on evolution was closer to Lamarck’s than to Darwin’s. He did not agree with natural selection and claimed that transformations of organisms were led by environmental conditions. When it comes to the origin of life, Spencer was strongly against spontaneous generation and, what is more, discussed the notion of the first organism (Tirard 2011). Spencer argued for a very progressive process of evolution and claimed that it was impossible to define the absolute limits between the stages of the evolutionary process. Therefore, according to him, there was no first organism. However, he was interested in this process and, in the 1898 issue of the *Principles of Biology*, presented the steps of the genesis of the characteristics of organic matter. He supported the notion of “protyle” suggested by Crookes, which would be the fundamental compound of organic matter. Its formation, like the formation of all the compounds present in nature, would be a stage of the cosmic evolution. He insisted on the fact that there was a chemical evolution before the evolution of life (Spencer 1898).

Therefore, all these authors, in different ways, were convinced by the possibility of a progressive evolution of matter at the origin of life. Using a word proposed by Huxley, this family of conceptions corresponded to evolutionary abiogenesis.

The turn of the century was also marked by chemical experiments in the field of the organic synthesis. Berthelot’s work was particularly emblematic. Toward the turn of the century, D. Berthelot and H. Gaudechon (1910), O. Baudisch (1913) and E. Baly et al. (1922), for example, obtained amino acids by exposing simple mineral or organic mixtures to various energy sources. Similarly, sugars had been commonly obtained since the second half of the nineteenth century.

The post-war authors interested in the origins of life sometimes cited these results. They reported these results to show that syntheses were possible.

3.3.8 PANSPERMIA

During the second part of the nineteenth century, some scientists supported theories of panspermia regarding the origin of life on Earth. These theories claimed that life on Earth came from germs arriving from space. Indeed, fundamentally, in panspermia theories, the presence of life is eternal in the universe and germs containing life are elsewhere in space. Several propositions had been made in the past, and the scientists who claimed this possibility during this period were notably H.E. Richter in 1865 and William Thomson, Lord Kelvin (1824–1907), in 1871 (Thomson 1872). In an address as president of the British Association for the Advancement of Science, the latter criticized Darwin's theory and argued that the age of Earth, which he calculated himself, was not sufficient for the duration of the life evolution process predicted by the famous naturalist. According to Thomson, the only way to conceive the formation of living beings on Earth was by the importation of germs of life from space. He therefore argued that they were imported on Earth by meteorites. Thomson's view opened a period in which panspermia had some supporters, such as H. von Helmholtz (1821–1894) (Kamminga 1991). At the beginning of the twentieth century, Svante Arrhenius (1859–1927) advanced the most elaborated theory of panspermia, and he described how very tiny germs could travel from a planet to another (Arrhenius 1910).

Finally, panspermia was contradicted in 1910 by the French biologist Paul Becquerel, who tested the resistance of organisms (seeds, bacteria, and so on) experimentally in extreme conditions, simulating those of space (Tirard 2013). He showed that they could not resist being exposed to ultraviolet (UV) rays. Becquerel's work quieted down the last panspermia supporters (Becquerel 1910).

3.3.9 1920s–1940s: THE PERIOD OF THE GREAT HYPOTHESES

During the interwar period, developed hypotheses, constructed as complete scenarios of the origins of life on Earth, were formulated. Two names are particularly noticeable. The first is that of Alexander Ivanovich Oparin (1894–1980), a young Russian scientist specialized in plant physiology. In 1923, in Moscow, he delivered a lecture on the origins of life, and 1 year later, he published a booklet on this issue (Oparin 1924). Published in Russian, this book was only locally diffused; however, it constituted the foundation of his thought on the origins of life, which he developed throughout his life. In this book, Oparin integrated the origins of life into a general presentation of the evolution of Earth. This allowed him to describe the primitive conditions under which the process of the appearance of life could take place. Oparin described how chemical reactions could lead in the primitive atmosphere containing carbon dioxide, and then in the primitive ocean,

from carbon dioxide to organic substances. Finally, according to him, this organic matter could constitute some bits of gel. Therefore, for the first time, a complete scenario of an evolutionary process regarding the origins of life was claimed.

A few years later, in 1929, John Burdon Sanderson Haldane (1892–1964), a biochemist and geneticist, wrote, independently from Oparin, a paper in the Rationalist Annual on the issue of the origin of life (Haldane 1929). Like Oparin's booklet, this text was a broad approach to the process of the origin of life, as well as a general thought on life and its limits. Haldane was mostly interested in the nature of viruses. He stated, especially regarding the origin of life, that the primitive atmosphere contained carbon dioxide and that organic molecules could be synthesized under the effect of the Sun's energy in the "Hot dilute soup" constituted by the primitive sea. He wrote, "when ultraviolet light acts on a mixture of water, carbon dioxide, and ammonia, a vast variety of organic substances are made, including sugars and apparently some of the materials from which proteins are built." According to him, on primitive Earth, "the whole sea was a vast chemical laboratory." The result could be the formation of "half-living molecules," the first step in the process toward life. On several points, Haldane's scenario was pretty close to Oparin's. They both first tried to establish the primitive conditions of the atmosphere and then imagined organic syntheses due to the molecules present in the atmosphere and diluted in the primitive sea (Tirard 2017).

After publishing this paper, Haldane returned to the issue of the origin of life occasionally; however, it was not his specialty. He was best known as a very famous geneticist. In comparison, Oparin focused on this issue throughout his life. In 1936, he published an influent book, translated into English in 1938. It largely developed the ideas of his 1924 booklet (Oparin 1924). Oparin presented the evolution of Earth for the purpose of better understanding the conditions in which the chemical process of the chemical evolution could occur and lead to life. He changed his mind about carbon dioxide in the primitive atmosphere and claimed that it was absent. He then analyzed the chemical reactions that might occur in the environment. This book is based on many references, one of them drawing on (H. G. Bungenberg de Jong 1883–1977), a Belgian biochemist who described microscopic structures in colloidal solutions, which he named coacervates (Bungenberg de Jong 1932). Oparin used them to design models of primitive cellular structures. When it comes to the primitive atmosphere, Oparin's book from 1936 introduced a modification of the atmosphere: from this moment, he claimed that it did not contain carbon dioxide and that it was reducing. This book had an important influence in the middle of the century and was often quoted by specialists in the origins of life (Oparin 1938).

Oparin's and Haldane's proposals marked the interwar period. Their most important and common contribution is represented by the fact that they included the origin of life in the general process of the evolution of Earth and therefore in the primitive conditions in which the evolution of matter occurred.

Just after World War II (WWII), the physician John Desmond Bernal (1901–1971), who was deeply involved in the X-ray diffraction method and interested in biological molecules, held a lecture entitled “The basis of life,” which he published in a paper in 1949 as well as in a book in 1951 (Bernal 1951). He made a synthesis of the issue of the origins of life, mainly referring to Oparin, and conducted a revision of some aspects of the scenario. Bernal added his personal views and made an interesting claim. He noticed that molecules were able to disperse in the liquid environment. Moreover, he argued that chemical reactions had to be catalyzed. Therefore, he claimed that catalysis could be possible if the reactions happened at the clayed bottom of aquatic zones, such as estuaries.

3.3.10 CONCLUSION

During the nineteenth century, the issue of the origins of life on Earth became a part of the issue of the evolution of living beings. From the second half of this century, after spontaneous generation was abandoned and the Darwinian theory of evolution was formulated, many biologists admitted that life resulted from a progressive evolution of matter that could be named evolutionary abiogenesis. A second important period was the interwar one, during which more developed scenarios were constructed, notably by Oparin and Haldane. The third remarkable period in the history of the issue of the origins of life is that of its experimental exploration in the second half of the twentieth century. This is the subject of the next chapters.

4.1.1 INTERSTELLAR MOLECULES: AN OVERVIEW

The past 45 years of the study of interstellar molecules has clearly shown that molecular content of the universe is far more extensive than previously thought. The observation of abundant species in many harsh environments such as around

dying stars, in planetary nebulae (PNe), and in diffuse clouds has demonstrated that molecular material in interstellar gas is remarkably robust. The recent identifications of interesting organics such as CH₃NCO (Halfen et al. 2015), CH₃CONH₂ (Hollis et al. 2006), and CHOCH₂OH (Halfen et al. 2006) suggest that even more complicated prebiotic molecules may be present in interstellar space. Certainly, the discovery of

fullerene species such as C₆₀ and C₇₀ (Cami et al. 2010) is solid evidence that compounds with large numbers of carbons can be formed in astrophysical environments. A picture is emerging of interstellar space as a vast synthetic factory with as-yet unknown limits in complexity, which must, at some unspecified level, affect the origin of prebiotic and possibly biotic compounds.

The chemical richness of interstellar space has only recently been realized, with the development of radioastronomy in the 1960s, which enabled the measurement of gas-phase molecular rotational spectra at high resolution. Prior to that time, a few diatomic molecules such as CH, CH⁺, and CN were known to exist in diffuse gas, identified by their electronic transitions observed at optical wavelengths (e.g., McKellar 1940). The first molecules detected in the radio were at centimeter wavelengths, starting with the OH radical (Weinreb et al. 1963) and followed by H₂O, NH₃, and H₂CO (e.g., Snyder et al. 1969). Perhaps, the most significant discovery, however, was that of carbon monoxide, CO, in 1970 (Wilson et al. 1970), which was identified in the millimeter regime with the fledgling 36-ft telescope on Kitt Peak, AZ.

The observation of CO was in fact a key factor in initiating the field of molecular astrophysics, as this wavelength region is best suited for molecular measurements. Subsequent molecule detections quickly followed, using millimeter telescopes, including that of HCN, HNC, HCO⁺ (known as “Xogen”), H₂S, CS, SiO, CH₃CH, and HNCO (e.g., Snyder and Buhl 1971; Wilson et al. 1971). The field of astrochemistry had begun.

Today, more than 170 individual chemical compounds have been identified in the interstellar medium (ISM) via their gas-phase spectra. The current list of confirmed interstellar molecules is presented in Table 4.1.1, sorted by the number of atoms. As shown in the table, a wide variety of chemical compounds are found in interstellar space, ranging from simple diatomic molecules, such as N₂, CS, and CH, to more complicated organic species, such as methyl formate, HCOOCH₃, and dimethyl ether, (CH₃)₂O, with fullerenes being the most complex. Many of the known interstellar molecules are species commonly found on Earth, such as water, methane, acetylene, and ethanol, but about 50% are free radicals and molecular ions, including CCN, C₄H, H₃O⁺, C₈H⁻, and

^a By number of atoms.

H_2COH^+ . These species are very short-lived under terrestrial conditions and often function as intermediates in chemical reactions.

The gas-phase molecules are usually mixed with dust grains, which typically are 0.5–10 microns in size (e.g., Jones 2001). The composition of the grains is harder to deduce. Some are composed of aliphatic and aromatic carbonaceous materials, while others are silicates. Many grains develop ice mantles typically consisting of water, CO, and methanol. It is also interesting that most interstellar molecules contain carbon, and there is also a significant number with silicon. Carbon comes in the form of long acetylenic chains (HC_3N , HC_5N , C_7H , C_8H , etc.) and simple rings (c-C₃H₂ and CH₂OCH₂). Those containing metals such as magnesium, sodium, and iron are rare, but do exist, and phosphorus-containing compounds currently number six. This rather strange mix of chemical compounds attests to the exotic, but at the same time mundane, nature of interstellar chemistry.

Part of the reason for the presence of unusual compounds in the ISM is that the physical conditions are quite “non-terrestrial.” Typical temperatures in molecular gas fall in the range 10–100 K, while densities are extremely low: 10^2 – 10^7 particles/cc. At 50 K, 10^7 particles/cc (or 10^7 cm^{-3}) corresponds to 10^{-13} atm. Interstellar species therefore mostly exist in a cold vacuum. On the other hand, these conditions can vary. Toward regions of star formation, molecular gas can reach $T > 1000$ K, and densities can increase by orders of magnitude. Bombardment by ultraviolet (UV) radiation or X-rays, both from stars, can substantially alter the physical conditions and energize nearby molecular material, impacting chemical processes (e.g., Gerin et al. 2010).

4.1.1.1 SETTING THE STAGE: THE INTERSTELLAR MOLECULAR LIFE CYCLE

Not all known interstellar species exist in the same regions of space, which complicates our interpretation of the chemistry. Molecular material in interstellar space is cycled through various phases, as shown in Figure 4.1.1, which repeat many times in the lifetime of the galaxy, thought to be ~13.5 billion years.

This “Molecular Life Cycle” can be thought to begin in stars. Most stars, namely those with masses between 1 and 10 M_{\odot} , will deplete hydrogen in their cores, leaving the so-called “Main Sequence,” will begin to burn hydrogen in a shell around a helium core, and then ignite helium in the core, converting it to carbon in the “triple alpha” reaction. These processes, which define the Red Giant phase, have two important consequences for these stars: (1) very convective atmospheres can develop, which mix H-burning intermediates such as ^{13}C to the stellar surface, and (2) substantial mass loss occurs. As the helium in the core becomes depleted, the stars develop a layered structure around a now-carbon core consisting of a H-burning shell and a He-burning shell, entering the Asymptotic Giant Branch (AGB) (e.g., Herwig 2005). The AGB is an important stage in molecule formation and in astrobiology for two reasons. First, mass loss significantly increases to 10^{-6} – $10^{-4} \text{ M}_{\odot}/\text{year}$, creating an outflowing stellar envelope, which quickly cools and allows the formation of both gas-phase molecules and dust (e.g., Glassgold 1996). Second, the very convective envelope can bring the carbon formed in the He-burning shell to the stellar surface, converting material with O > C to that with C > O. Recent calculations suggest that as much as 80% of the carbon arose from

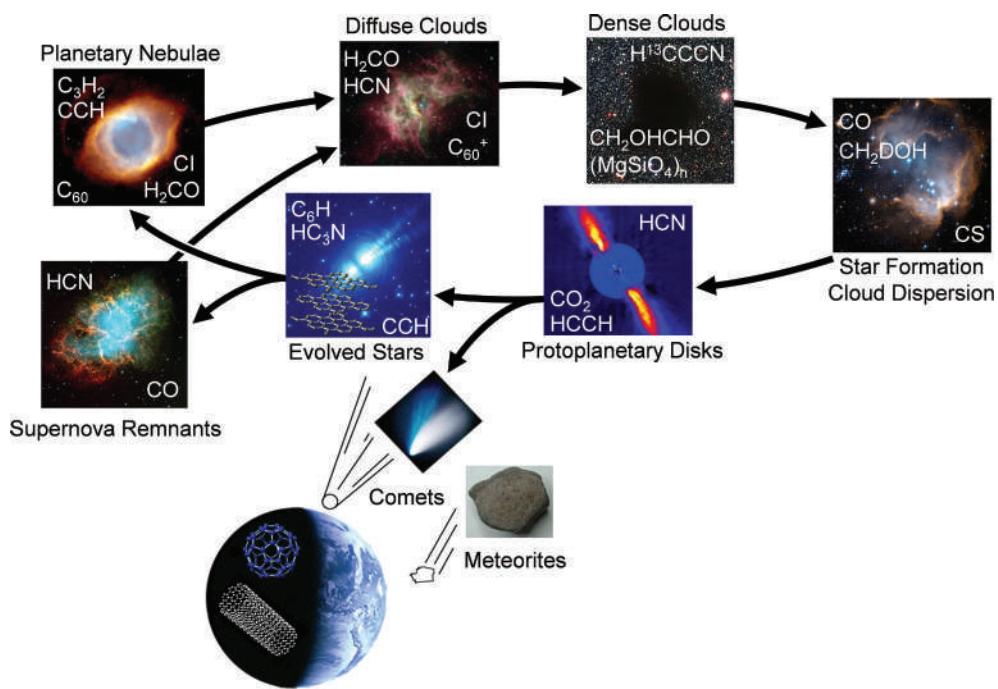

FIGURE 4.1.1 The interstellar life cycle showing how molecular material is passed from one class of objects to another: from stars to diffuse clouds, onto dense clouds, and eventually to protostellar disks and planets.

AGB stars, at least in the solar neighborhood (Mattsson 2010). The basis of organic chemistry may trace its roots back to these unique objects.

Mass loss continues on the AGB until the star has blown off almost all its initial mass and nucleosynthesis ceases, thus entering the PN stage, the next step in the cycle. The core of the progenitor star evolves over the next 10^4 years into a white dwarf (Kwok 2000), which becomes a copious emitter of UV radiation. The remnant circumstellar shell continues to flow away from the star, bringing fresh material into the ISM. In fact, mass loss from these types of stars is responsible for about 85% of interstellar matter (Dorschner and Henning 1995). Recent observations have clearly shown that the gas-phase molecules from the prior evolved star/circumstellar envelope stage survive into the late stages of the PN phase and thus are ejected, along with circumstellar dust grains, into the diffuse ISM. Here, they coalesce into what are called diffuse clouds. These clouds are defined by extremely low densities ($\sim 10\text{--}100 \text{ cm}^{-3}$) and warm temperatures ($T \sim 30\text{--}100 \text{ K}$), with partial attenuation of the ambient stellar radiation field (e.g., Snow and McCall 2006). These objects will collapse or accrete into denser clouds over a period of $10^6\text{--}10^7$ years (e.g., Inoue and Inutsuka 2012), evolving with their molecular material. Dense clouds, defined by gas densities near $10^4\text{--}10^6 \text{ cm}^{-3}$, span a wide range of masses, from $10^3\text{--}10^6 M_{\text{sun}}$ (so-called “giant molecular clouds” [GMCs]) to a few M_{sun} (e.g., Bok globules). They are colder than their diffuse counterparts, with $T \sim 10\text{--}75 \text{ K}$, and are sufficiently self-shielding, so that they are typically rich in molecular material and are referred to as “molecular clouds.” Dense clouds contain a large fraction of the mass in our galaxy (e.g., Ferrière 2001), as much as half of the total gaseous matter in the inner 8–9 kiloparsecs (kpc).

Dense clouds will collapse into stars, incorporating molecular material into protostellar disks. The disks may evolve into solar systems. Some of the primordial molecular matter will be processed and some preserved and condensed into comets, asteroids, and meteorites. Some of this molecular “debris” will continue to survive in a large “bubble” of icy material surrounding a given planetary system; for the solar system, this bubble is the Oort cloud. Other pristine interstellar molecular material will end up on planet surfaces through bombardment by solar system bodies, including comets and meteorites. The central stars of the solar systems will eventually exhaust the supply of hydrogen in their cores, begin to burn helium, and move onto the giant branches, likely engulfing surrounding planets and reinitiating the molecular cycle.

Very massive stars will not pass through the giant branches but rather continue to burn elements beyond helium and then become supernovae (SNe). Supernova explosions also return matter to the diffuse ISM, but only about 10% of the total material. The ejecta for SNe are initially quite hot ($T > 10,000 \text{ K}$). At about 6000 K, the material is all atomic in composition (Clayton and Meyer 2018), but as the gas cools, molecules, perhaps even long carbon chains, likely form, which in turn lead to grain production. It is accepted that certain types of grains originate in SNe, but the contribution of gas-phase molecules by SNe to the diffuse ISM is not known. Supernovae

(Type II) are also thought to be important sources of ^{12}C in the ISM, although, perhaps, not as significant as AGB stars (Mattsson 2010).

Because gas-phase and solid-state molecular materials are passed from one type of object to another, a complete view of interstellar and pre-biotic chemistry must consider the entire cycle. Studies of pre-solar grains have shown that material found in meteorites can be traced back to both AGB stars and SNe (e.g., Lodders and Amari 2005). As will be discussed, the different types of sources harbor distinct physical conditions and therefore spawn varied chemical processes, which influence the next step in the cycle.

4.1.2 IDENTIFICATION OF INTERSTELLAR MOLECULES

4.1.2.1 A BRIEF OVERVIEW OF MOLECULAR SPECTROSCOPY

Molecules are typically identified in interstellar sources by measuring their gas-phase spectra with telescopes. Molecular spectra can be very complicated, because chemical compounds consist of multiple atoms. Therefore, in addition to excitation of electrons within a molecule, which creates electronic transitions, the nuclei can rotate and undergo vibrational motions. Pure rotational spectra occur in the microwave, millimeter, and sub-millimeter regimes ($\sim 10 \text{ GHz}\text{--}1 \text{ THz}$) and involve transitions between the lowest energy levels ($E_{\text{rot}} \leq 100 \text{ cm}^{-1}$). Because interstellar gas is typically cold, population of rotational levels is heavily favored, which readily occurs by collisions with H_2 . As a consequence, about 90% of all known interstellar molecules have been detected via their pure rotational transitions. Rotational spectra can also exhibit additional splittings, known as fine and hyperfine structures, arising from unpaired electrons and nuclei with net spin, which can aid in molecule identification. Vibrational transitions, in contrast, occur in the infrared (IR) region. They are sufficiently high in energy ($E_{\text{vib}} \sim 100\text{--}5000 \text{ cm}^{-1}$) and usually require an external field for excitation, as from a young or old star or in a shock wave (e.g., Goto et al. 2003). Molecules will rotate as they vibrate, and therefore, vibrational transitions consist of rotational structure, typically labeled as P, Q, and R branches, which in some cases may be resolved. Electronic transitions, which involve promotion of an electron to a higher-lying molecular orbital, are the highest-energy transitions ($E_{\text{elec}} > 10,000 \text{ cm}^{-1}$). They occur typically in the optical and UV regions of the electromagnetic spectrum (400–700 nm). In the ISM, they usually require background stellar radiation for the excitation mechanism and are almost always seen only in diatomic molecules. Electronic transitions have both rotational (P, Q, and R branches) and vibrational structures, often resolved in interstellar spectra. (For further detail, see Herzberg 1971; Bernath 2005).

Spectra can also be obtained for molecular material in the solid state (e.g., see Kwok 2000). However, there is no free rotation in solids, and vibrational motion occurs within a crystal lattice or amorphous material. Therefore, solid-state spectra, which are typically measured in the IR, do not have

the specificity found in the gas phase. They are typically used to identify types of bonds rather than discreet molecules (aromatic C–C bends, SiO stretch, etc.).

4.1.2.2 SPECTROSCOPIC LIMITATIONS OF TELESCOPES

Spectroscopic measurements in the radio- and millimeter-wave regions have definite advantages over those in the IR and visible regions. First, there is, for the most part, less obscuration by the Earth's atmosphere at these longer wavelengths. Space-borne telescopes such as the upcoming James Webb Space Telescope (JWST) can ameliorate this problem, but these instruments are very expensive and have short lifetimes. Furthermore, radio- and millimeter-wave telescopes, which are diffraction-limited antennas, typically employ heterodyne mixing techniques to obtain spectral-line data, coupled with a multiplexing spectrometer as the “backend.” This combination of instrumentation results in high spectral resolution capability, typically 1 part in 10^6 – 10^8 . Therefore, the measurement of rotational spectra of interstellar molecules, which are present in cold, quiescent gas, can generate a true “fingerprint” for unambiguous identification, as illustrated in Figure 4.1.2.

Here, a spectrum of the $N = 2 \rightarrow 1$ rotational transition of the CN radical is shown, observed toward the molecular cloud G19.6. This molecule has one unpaired electron, and the nitrogen atom has a nuclear spin, both of which interact to generate a unique fine structure/hyperfine pattern, indicated under the spectrum in blue. The spectrum clearly demonstrates the presence of CN in this source. For molecules without fine and/or hyperfine structure, multiple rotational lines can be observed for unequivocal identification. At radio and millimeter wavelengths, resolution is typically limited by the spectral linewidth generated by the velocity motions within a given astronomical source.

In the case of optical and IR spectroscopy, different instrumentation is used. The telescopes in these cases are essentially “light buckets,” and molecular spectra are created by use of a

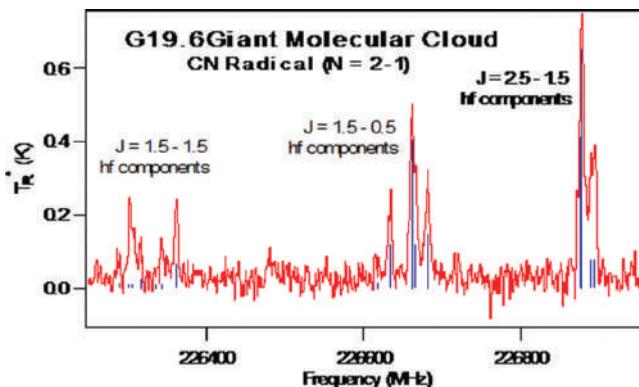

FIGURE 4.1.2 An example of a pure rotational spectrum of the $N = 2 \rightarrow 1$ transition of the CN molecule near 226 GHz, showing all the respective fine and hyperfine components, observed toward the dense cloud G19.6. The red trace is the actual observed spectrum; the blue lines under the data show the predicted laboratory frequencies and relative intensities. The match is virtually exact.

grating or prism. Typical resolution of modern spectrographs is 1 part in 10^3 – 10^4 , with the very best being 1 part in 10^5 . Therefore, for IR and optical spectroscopic measurements, resolution is determined by the instrumentation, not the astronomical source.

4.1.3 BASIC CHEMISTRY OF INTERSTELLAR MOLECULES

Given the cold and highly rarified conditions in the ISM, and the extremely long timescales, it is very difficult to accurately simulate interstellar chemical processes in the laboratory. Formulation of interstellar chemistry has relied heavily on observations and theory. However, identification of interstellar molecules requires precise knowledge of their spectra, and therefore, experimental laboratory spectroscopy has played a major role in our understanding of the chemistry in space.

4.1.3.1 IMPORTANT GAS-PHASE REACTIONS

Because of the very low densities, chemical reactions in molecular gas are typically restricted to two-body processes. There is usually no third body or container wall to stabilize a reaction complex. Furthermore, with temperatures near 10 K, reactions cannot have activation barriers; otherwise, they cannot proceed. A general class of reactions fulfilling these criteria (two-body, no barriers) are ion-molecule processes of the general form (e.g., Herbst and Klempner 1976):

These types of reactions (about 50% have no barriers) proceed very quickly under interstellar conditions, typically at the collisional or Langevin rate of $k \sim 10^{-9} \text{ cm}^3 \text{ s}^{-1}$. They are readily initiated by the cosmic-ray ionization of H_2 , leading to H_2^+ . This species then reacts with another H_2 , producing H_3^+ :

H_3^+ is a key ion in interstellar chemistry and readily donates its proton to other neutral molecules to form a series of ions, HCO^+ , N_2H^+ , H_3O^+ , HCNH^+ , and so forth. Several of these ions are in fact prominent interstellar molecules and have provided good evidence for the ion-molecule scheme. Not all ion-molecule reactions are barrierless, however. An important example involves carbon. The process $\text{C}^+ + \text{H}_2$ is endothermic, and therefore, incorporating carbon into molecular form requires other processes.

Radiative association is another important class of reactions. Here, two smaller gas-phase species collide to form a larger molecule while emitting a photon, that is:

Reactions of this type can also occur between two small neutral molecules, but such processes typically have activation

barriers, except when radicals and atoms are involved (e.g., Gerlich and Horning 1992). Those with ion-neutral reactants are not nearly as fast as classic ion-molecule reactions, typically having rates of $k \sim 10^{-17}\text{--}10^{-12} \text{ cm}^3 \text{ s}^{-1}$. Nonetheless, radiative association can become quite important if faster routes do not exist, such as the case with C⁺. The process $\text{C}^+ + \text{H}_2 \rightarrow \text{CH}_2^+ + h\nu$ is believed, in fact, to be the major route that incorporates carbon into molecules.

Reactions between two neutral molecules can also be significant in interstellar chemistry, particularly if one or both of the reactants are radicals:

Neutral-neutral rates can be as high as $10^{-11}\text{--}10^{-10} \text{ cm}^3 \text{ s}^{-1}$ and thus can compete in certain cases with ion-molecule reactions. The formation of N₂O, for example, is thought to occur from the neutral-neutral route NO + NH → N₂O + H (Halfen et al. 2001).

Another set of reactions imperative to interstellar molecules is dissociative recombination. In this case, a molecular ion combines with an electron, producing neutral fragments:

These types of processes are essential for the production of neutrals after species formation by ion-molecule pathways and proceed relatively quickly, with $k \sim 10^{-7} \text{ s}^{-1}$. A good example of such a reaction is the recombination of HCNH⁺, which then forms HCN and HNC. However, product branching ratios are often unknown and may favor smaller fragments (e.g., Geppert et al. 2006).

These four reaction types form large gas-phase networks that are predicted to lead to the majority of interstellar molecules, creating a chemistry that is kinetically controlled. There are instances, however, where three-body collisions do occur in molecular gas, and thermodynamics is the chemical basis for molecule production. “LTE chemistry” occurs in the inner regions of circumstellar envelopes, for example. It also may take place near imbedded protostars.

4.1.3.2 SURFACE PROCESSES

Dust grains are mixed with gas-phase molecules; therefore, surface chemistry can also occur. There is more uncertainty in the role of reactions on grain surfaces, as solid-state spectroscopy has its limitations. Nonetheless, it is recognized that H₂, the most abundant interstellar molecule, must form on grain surfaces (e.g., Herbst and Millar 2008). All two-body gas-phase processes leading to this species are simply too inefficient, while hydrogen atoms can readily migrate over a surface. Furthermore, energy is released when two H atoms combine to form H₂ on the surface, allowing efficient ejection from the grain.

For molecules larger than H₂, the exact role of surface chemistry is less defined. It is clear that grains can acquire molecular mantles composed of water, methanol, and other species, as deduced from IR astronomical measurements

(e.g., Jones and Nuth 2011). In fact, it is remarkable that more molecular material is not frozen onto grain surfaces, particularly at 10 K. Mantle formation does not imply chemical processing. On the other hand, there are larger “organic”-type molecules, such as CH₃CH₂CN and CH₂CHCN, that, according to chemical modeling, cannot be produced efficiently in the gas phase. It is postulated that hydrogenation of “backbone” species on grain surfaces creates these molecules (e.g., Hickson et al. 2016). The precursor molecules, in this case C₃N or HC₃N, are created in the gas phase; they freeze onto grains and acquire hydrogen atoms, which are labile on the surface. Gas-phase chemistry and surface chemistry are thus closely linked. Defining their relative contributions remains one of the frontiers of interstellar chemistry.

4.1.3.3 INFLUENCE OF STAR FORMATION AND DESTRUCTION

The classic structure of ion-molecule chemistry can be substantially altered by stars. First, when these objects form as protostars, or die as SNe, they can induce shock waves from mass ejection, which can propagate into nearby molecular material. These shocks compress, accelerate, and abruptly heat the affected gas to temperatures as high as a few thousand degrees, often drastically altering its chemical composition, depending on the type of shock (e.g., Bachiller and Gutierrez 1997). The main result is that endothermic reactions can occur, preferentially producing species such as H₂O, SiO, and CH⁺ (e.g., Ziurys et al. 1989; Viti et al. 2011). Very fast shocks ($v > 50 \text{ km/s}$) can also break up dust grains, releasing molecular mantles and/or refractory material and also modifying the local chemical composition.

Young hot stars can also impact the chemistry of adjacent clouds through their strong emission of UV radiation, creating a “photon-dominated region” (PDR). Here, the high UV flux will fragment and ionize molecules, creating a high abundance of ions and radicals, such as CCH and CN (e.g., Cuadrado et al. 2015). Photon-dominated regions host a unique chemical environment, as studies of the Orion Bar has shown (e.g., van der Wiel et al. 2009).

The gravitational collapse of young stars, which are usually imbedded in molecular clouds, can result in the elevation of the density and temperature of the surrounding gas, producing a “hot core” or “corino” (e.g., Cesaroni et al. 2011). Temperatures can typically achieve $T \sim 200\text{--}500 \text{ K}$, with densities increasing to $n \sim 10^7\text{--}10^8 \text{ cm}^{-3}$; under such conditions, reactions with energy barriers can occur, once again altering the molecular composition. Observations suggest that abundances of certain sulfur-bearing molecules are enhanced, along with CH₃CN and HCOOCH₃ (e.g., Xu and Wang 2013). Products of surface chemistry may also be released with elevated temperatures.

4.1.3.4 CHEMICAL MODELING AND REACTION NETWORKS

For comparison with observations, and to test chemical theory, gas-phase molecular abundances are computationally predicted from large reaction networks, using the “rate equation”

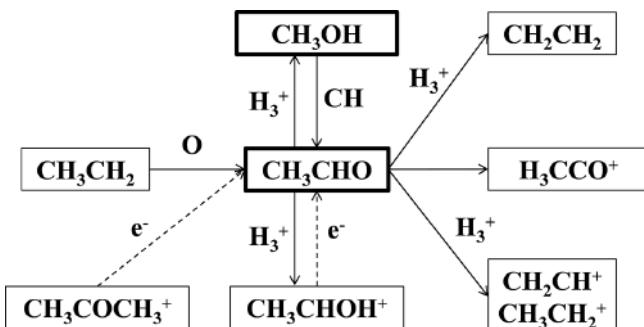

FIGURE 4.1.3 A simplified chemical network showing the reaction pathways leading to the production and destruction of CH_3CHO in dense clouds, including ion-molecule reactions and dissociative electron recombination.

method (e.g., Stantcheva and Herbst 2004). Here, hundreds, often thousands, of chemical reactions are coupled together, and the abundance of a given molecule is balanced between its production and destruction pathways, as a function of time. Often, the calculations are allowed to achieve a steady state. A key factor in this modeling is the accurate assessment of reaction rates and product branching ratios; unfortunately, these quantities are often unknown, perhaps as many as 50% in a given model. Another complication is unusual temperature dependence in many reactions; some rates will actually increase as the temperature drops to ~ 10 K (e.g., see Gerlich and Horning 1992). Large databases have been created to tabulate reaction rates, based on experimental values, theory, or reasonable assumptions, such as the University of Manchester Institute of Science and Technology (UMIST) database (UMIST RATE2012/astrochemistry.net) and KIDA. However, additional experimental data is clearly needed.

Often, insight can be gleamed about a given molecule's abundance by looking at a reaction sub-network, as shown in Figure 4.1.3. In this figure, the major possible formation and destruction routes are shown for CH_3CHO , applicable to molecular clouds. The main pathways leading to this species are the neutral-neutral reactions involving $\text{CH}_3\text{CH}_2 + \text{O}$ and $\text{CH}_3\text{OH} + \text{CH}$, as well as dissociative recombination of $\text{CH}_3\text{COCH}_3^+$ and CH_3CHOH^+ . The molecule is destroyed by reacting with H_3^+ , which leads to various products, including CH_2CH_2 and H_3CCO^+ .

4.1.4 MOLECULES IN CIRCUMSTELLAR ENVIRONMENTS

Circumstellar envelopes are a major site for molecule formation in interstellar space. They are most prominent in AGB stars, as well as supergiants (precursors to SNe), and are created by mass loss, as previously mentioned. Mass loss occurs because of depletion of hydrogen in the stellar core, which causes it to contract and release energy, resulting in expansion of the surrounding hydrogen sphere. This process creates a red giant or supergiant star, depending on the mass; red giants evolve into AGB stars, which have significantly higher

mass loss (see Herwig 2013 and references therein). Once the mass loss begins, dust grains can form in the winds that emerge from the stellar photosphere. Radiation pressure on these grains can further enhance mass loss, along with shocks caused by stellar pulsations.

4.1.4.1 BASIC CHEMICAL SCENARIO OF CIRCUMSTELLAR ENVELOPES

The molecular envelope forms from very hot gas ($T \sim 2000\text{--}4000$ K) that leaves the photosphere and creates a large shell around the star, typically extending out to $r \sim 1000 R_*$ (R_* = stellar radius and r = radial distance from the star). The gas cools as it flows outward, and molecules form, along with dust, as mentioned. There are large temperature and density gradients across the envelope ($n \sim r^{-2}$ and $T \sim r^{-0.5\text{--}0.7}$), which foster varied chemistries. The material adjacent to the photosphere is hot ($T \sim 1000$ K) and sufficiently dense ($n \sim 10^{10} \text{ cm}^{-3}$), such that three body reactions can occur. Chemical processes therefore occur under conditions of Local Thermodynamic Equilibrium (LTE), which means that the most thermodynamically stable species are formed. Molecules such as HCCH, HCN, SiO, H_2O , and CH_4 are in high abundance in this zone and form a group of “parent” compounds (e.g., Glassgold 1996). Dust grains also condense out of the gas under LTE conditions in this region; condensation starts within a few stellar radii and continues until about $15\text{--}20 R_*$. Prominent minerals predicted to form in the shells include fosterite (Mg_2SiO_4), corundum (Al_2O_3), and silicon carbide, depending on the C/O ratio (Lodders and Fegley 1999). As dust forms and radiation pressure comes into play, the gas from the star is accelerated to its terminal velocity by $\sim 20 R_*$. Such velocities are typically $\sim 10\text{--}20$ km/s for AGB stars and somewhat higher for supergiants (e.g., Tenenbaum et al. 2010). The material therefore is transported to the outer envelope sufficiently quickly (~ 1000 years), so that LTE abundances become “frozen” in the intermediate shell, as densities and temperatures drop (e.g., McCabe et al. 1979). In the outer envelope, the temperature and densities have decreased considerably ($T \sim 25$ K and $n \sim 10^4 \text{ cm}^{-3}$), such that UV photons from the diffuse stellar background can penetrate the gas/dust mixture, initiating photochemistry. In this third zone, free radicals, such as CN and CCH, are readily created, which then initiate other radical-neutral or radical-radical reactions (e.g., Anderson and Ziurys 2014). Negative ions are also created through radiative attachment, $A + e^- \rightarrow A^- + h\nu$ (e.g., Thaddeus et al. 2008). A diagram of a cross-section of a circumstellar shell is shown in Figure 4.1.4, displaying the three distinct chemical zones.

4.1.4.2 CHEMICAL CONSEQUENCES OF CARBON ENRICHMENT

The ISM is oxygen-rich, with $\text{O} > \text{C}$ by about a factor of 1.5. Therefore, stars are typically oxygen-rich, which is reflected in the molecular composition of their envelopes (Tenenbaum et al. 2010). However, as AGB stars advance in their evolution, they

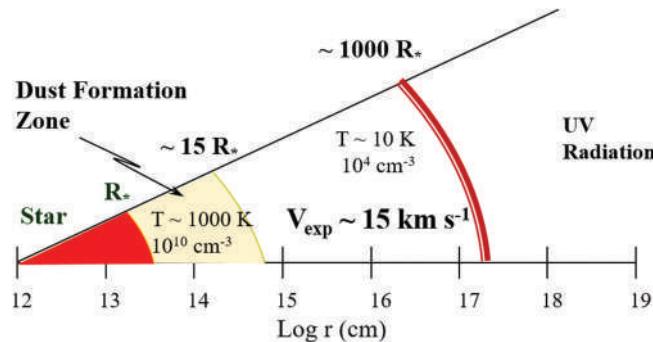

FIGURE 4.1.4 Idealized picture of a cross-section of an AGB circumstellar envelope, plotted as a function of radial distance (log scale, in cm) from the center of the star. The star is shown in red, and the dust acceleration zone is shown in cream. Representative temperatures and densities are shown for the dust zone, in which LTE chemistry occurs, and the outer envelope, where photochemistry is dominant. R_* designates stellar radius.

become thermally unstable, as the H- and He-burning shells thin out and thermal pulses develop. The pulses cause the highly convective hydrogen shell to reach into the helium-burning shell and dredge up the carbon-rich material created there by the triple- α process. This mechanism, so-called “Third Dredge-Up,” converts an initially oxygen-rich star to a carbon-rich one, such that C > O in the stellar envelope, by roughly a factor of 1.5 (Mowlavi 1999). It is not clear that all AGB stars undergo Third Dredge-Up, as the envelopes of many such objects remain oxygen-rich. Those stars that do become carbon-rich, however, develop a very unique chemistry in their envelopes – one of the few sets of objects in the galaxy with C > O.

The C/O ratio has a major influence on molecular composition of a circumstellar envelope. First, carbon-rich shells of AGB stars appear to have a more diverse chemical composition than their oxygen-rich analogs, with more complex molecules, numbering up to 11 atoms. (Note that C₆₀ is observed in ejecta of post-AGB stars). They also contain a larger number of distinct chemical compounds, roughly by a factor of 3–4, with many exotic species. Long, acetylenic chain-type species have been observed in carbon-rich shells, with the formulas HC_nN, C_nH, and C_nN, where n = 1,2,3, ..., as well as more common compounds such as HCCH, CH₃CN, and CH₃CCH. These objects are also sources of rare metal (in the chemist’s sense) and phosphorus-bearing molecules, including FeCN, NaCl, AlNC, CCP, and HCP (e.g., Ziurys et al. 2016). They additionally are the most prominent hosts of silicon-containing compounds (SiS, SiO, SiC₂, SiN, SiC₃, SiC, etc.). In contrast, molecules with up to only four atoms have thus far been observed in oxygen-rich envelopes, and the compounds observed are typically simple, such as HCN, CS, SO₂, and H₂O. However, these sources do contain gas-phase refractory oxides, including AlO, TiO, AlOH, and TiO₂ (e.g., Tenenbaum and Ziurys 2010; Tenenbaum et al. 2010; Kamiński et al. 2013).

An illustration of the chemical differences between carbon- and oxygen-rich envelopes is given in Table 4.1.2. Here, a representative sample of molecules is presented for the carbon-rich envelope of the AGB star IRC+10216 and the

TABLE 4.1.2
Representative Circumstellar Molecules

Carbon-Rich		Oxygen-Rich		
SiO	CO	SiC	H ₂ O	SiO
SiS	AlF	AlCl	SO ₂	SiS
CS	SiN	KCl	H ₂ S	CS
CN	HCP	CH ₃ CN		CN
HCN	SiC ₂	CCP		HCN
HNC	CCH	SiC	NH ₃	HNC
NaCl	NaCN	AlCl	SO	NaCl
PN	1-C ₃ H	KCl	AlO	PN
HCO ⁺	c-C ₃ H	HC ₃ N	AlOH	HCO ⁺
PH ₃	C ₃ N	c-C ₃ H ₂	TiO	NS
CH ₂ NH	H ₂ CO	C ₄ H	TiO ₂	PO
CP	H ₂ CS	CH ₃ CCH	CO	
C ₄ H ⁻	HC ₅ N	CCN		
C ₅ N	HC ₇ N	C ₈ H		

oxygen-rich shell of the supergiant VY Canis Majoris (VY CMa). These objects are chosen because they are the best studied stars in terms of molecular observations.

The dust grain composition also reflects the C/O ratio. As mentioned, grains are thought to form under LTE conditions. Indeed, some grain types are found that are predicted by LTE models (Mg₂SiO₄ and Al₂O₃), but others, such as FeS and FeSi, are not (Lodders and Fegley 1999). In oxygen-rich stars, amorphous silicates are found, as identified by their IR bands at 9.7 and 18 microns (SiO stretching and Si-O-O bending modes). These grains are thought to condense directly out of gaseous SiO, a common circumstellar molecule. Crystalline silicates are also found, but are less abundant, with typical formulas Mg_{2-x}Fe_{2x}SiO₄ (olivine) and Mg_{1-x}Fe_xSiO₃ (pyroxene), as well as refractory oxides such as corundum, Al₂O₃, and spinel, MgAl₂O₄. In contrast, carbon-rich environments favor the formation of silicon carbide (SiC), identified by the 11.3- μ m feature (Si-C stretch), and carbonaceous grains, which might be amorphous, graphitic, and/or organic aromatic/aliphatic compounds (Kwok 2004).

Circumstellar envelopes with C > O are perhaps the richest sources of carbon-carbon bonds. They concentrate this element into gas-phase molecular or solid-state form and prevent it from being locked into CO. For example, in IRC+10216, the carbon chain species alone account for about 10% of the available carbon, based on cosmic abundances. The unusual environment of these envelopes apparently preserves the carbon enrichment that results from Third Dredge-Up and therefore makes them central to astrobiology. They pass this enrichment onto PNe and then subsequently into interstellar clouds. These sources are also unique in that they contain the majority of the known phosphorus- and metal-bearing compounds found in the ISM, with C-P, C-Fe, and C-Mg bonds. It is most interesting from the biological aspect that the most common carrier of metallic elements in the ISM in the gas phase involves bonds to the CN moiety (FeCN, MgCN, KCN,

NaCN, and AlNC). It should also be noted that oxygen-rich envelopes of both supergiant and AGB stars typically contain PO, the only molecule thus far securely identified in interstellar gas with a phosphorus-oxygen bond (Tenenbaum et al. 2007; Ziurys et al. 2018).

4.1.5 THE SURPRISINGLY MOLECULAR CONTENT OF PLANETARY NEBULAE

The AGB stars evolve into PNe. The former circumstellar envelope flows away from the dying star, now a white dwarf, creating a nebula seen in so many optical images. The nebula itself contains most of the original stellar material, as a white dwarf typically has a mass of $\sim 0.5 M_{\text{sun}}$. The amount of matter in the nebula is thus substantial, between approximately $0.5 M_{\text{sun}}$ and $7.5 M_{\text{sun}}$. A major question is the nature of this material, which is the primary source of matter for the general ISM.

4.1.5.1 OBSERVATIONS PROVE THEORY INCORRECT

For many years, it was thought that virtually all of the molecular material from the former AGB shell would be photodissociated and returned to the atomic state in PNe (e.g., Redman et al. 2003; Kimura et al. 2012). White dwarfs are very strong emitters of UV radiation, with fields several orders of magnitude higher than that found in the ambient ISM (Kwok 2000). The bright images of PNe observed in the optical region, resulting from atomic emission lines of [O III], [OII], CII, Ne II, He II, [N II], and H α , support the idea of widespread molecular destruction, as shown in Figure 4.1.5. However,

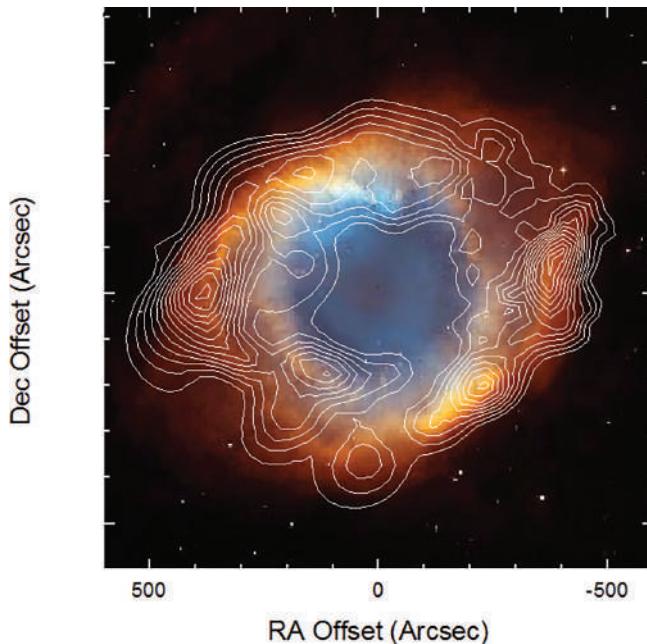

FIGURE 4.1.5 Contour map showing the distribution of HCO $^{+}$ in the Helix nebula, as traced by the J = 1 \rightarrow 0 rotational transition, superimposed over the optical image of the object (reconstructed from Zeigler et al. 2013). The data show that HCO $^{+}$ is widespread throughout the nebula, even where bright, ionized atomic gas also exists.

the ionized, rarified gas in PNe can only account for about $\sim 0.1\text{--}0.5 M_{\text{sun}}$ of the nebular material, creating a “missing mass” problem (Kimura et al. 2012).

Recent observations, however, have shown that many PNe are rich in molecular gas and contain large abundances of polyatomic molecules (e.g., Zack and Ziurys 2013; Edwards et al. 2014; Schmidt and Ziurys 2016, 2017a, 2017b). Both C₆₀ and C₇₀ have been identified in several PNe as well (e.g., Cami et al. 2010; García-Hernández et al. 2012), providing additional evidence for a molecular environment. The list of known molecules in PNe has certainly expanded in the past 5 years, as well as the number of molecule-rich nebulae. The current list of known molecules in PNe, besides fullerenes, includes HCN, HNC, CN, CS, H₂CO, HCO $^{+}$, N₂H $^{+}$, SO, SO₂, SiO, c-C₃H₂, and CCH. Moreover, mapping observations of H₂ and CO show that the molecular material appears to be present in dense, dusty clumps, apparently imbedded in an ionized medium (e.g., O’Dell et al. 2007). The gas-phase molecules, mixed with dust grains and probably macromolecules, are protected in the clumps, which are self-shielding. As a consequence, not only do gas-phase molecules survive throughout the lifetime of the nebulae, but their measured abundances are fairly constant with nebular age (e.g., Edwards et al. 2014; Schmidt and Ziurys 2017a, 2017b). For example, one of the oldest known PN, the “Helix,” has high abundances of CCH, H₂CO, c-C₃H₂, HCN, HCO $^{+}$, and HNC, with values comparable to those in both middle-aged nebulae, such as M2-48 and M3-55, and the youngest ones, such as K4-47, K3-17, and K3-45 (Schmidt and Ziurys 2017b). Furthermore, the widespread molecular distribution in the Helix is coincident with the atomic gas and traces the whole of the nebula, as shown in Figure 4.1.5.

Here, the distribution of HCO $^{+}$ in the Helix nebula is shown, as traced by its fundamental rotational transition. The contours show the integrated intensity of the transition, in units of 0.033 K km/s (see Zeigler et al. 2013 for details), superimposed over the optical image of the nebula. Current chemical models predict that molecular abundances should drop by orders of magnitude as the nebulae evolve and be nonexistent in very old objects such as the Helix (e.g., Redman et al. 2003). Such predictions are simply not correct, and new modeling is needed.

4.1.5.2 ORIGIN OF THE MOLECULAR MATERIAL IN PLANETARY NEBULAE

The molecules in the PNe may, in part, be residual species from the remnant AGB envelope. Abundances of species such as CCH and HCN in PNe are certainly lower than those in AGB envelopes by factors of 5 and 100–1000, respectively (Schmidt and Ziurys 2016, 2017b). Other molecules, such as HCO $^{+}$, on the other hand, are more abundant in PNe. There are obviously chemical processes occurring in the nebulae that are altering AGB abundances, including photo destruction. New synthetic routes, may take place in the early PN or protoplanetary phase (see Schmidt and Ziurys 2106, 2017a). The observations suggest

that molecular abundances are altered in the protoplanetary phase and then are “frozen,” as the nebulae evolve. There is also a possible contribution from the destruction of dust grains or large molecules such as C_{60} , which may be counteracting molecule photodissociation. Independent of the processes, the molecular content in at least some PNe is unexpectedly high. As a consequence, PNe ejecta must contain substantial amounts of molecular material, mixed with dust.

4.1.5.3 FURTHER IMPACT OF CARBON ENRICHMENT IN THE ASYMPTOTIC GIANT BRANCH STAGE

Not all PNe harbor the same molecular species. Like their precursors, circumstellar envelopes, the C/O ratio is reflected in the molecular content of the nebulae. There are also estimates of this ratio from measurements of atomic transitions, but these are rare (see Schmidt and Ziurys 2017a). It is clear that both carbon- and oxygen-rich PNe exist, along with some where $C \sim O$. Carbon-rich nebulae are identified by the presence of CCH, HCN, $c\text{-}C_3H_2$, and, in the most extreme cases, HC_3N , as seen in K4-47, probably the best example of this type (Schmidt et al. in preparation). The Helix nebula also appears to be a carbon-rich type, as it contains widespread CCN and $c\text{-}C_3H_2$. Oxygen-rich PNe, on the other hand, do not contain CCH but harbor oxides such as SiO, SO, and SO_2 , as observed in M2-48 (Edwards and Ziurys 2014). The Red Spider, NGC 6537, contains both CCH and SO, and appears to be an intermediate case. Additional surveys of molecules in PNe are needed to further quantify such classifications, but the distinctions are clearly present.

Carbon enrichment from AGB stars is therefore passed on to PNe and preserved in gas-phase molecules in the form of C–C, C–H, C–N, and C–O bonds, as well as in macromolecules such as fullerenes. This material is then ejected into the diffuse ISM, bringing along the enrichment. Therefore, the expectation is that molecules in diffuse clouds contain more carbon that might be expected in an environment where $O > C$. Observations of species such as C_2 , C_3 , CCH, and $c\text{-}C_3H_2$ toward diffuse clouds support this idea, as well as the recent identification of C_{60}^+ (Liszt et al. 2006; Snow and McCall 2006; Walker et al. 2015).

4.1.6 MOLECULES IN DIFFUSE CLOUDS: ANOTHER SURPRISE

Diffuse clouds are another class of objects with unusual molecular content. These clouds are formed from stellar ejecta (principally AGB stars) and are characterized by low densities ($\sim 10\text{--}100\text{ cm}^{-3}$) and warm temperatures ($T \sim 30\text{--}100\text{ K}$). It is thought that the ambient stellar UV radiation field is somewhat attenuated, such that the H_2 content is >0.1 of the total available hydrogen. Also, the gas-phase carbon is predicted to be predominantly in the form of C^+ (e.g., Snow and McCall 2006).

4.1.6.1 UNEXPECTED POLYATOMIC MOLECULES IN DIFFUSE GAS

It has been universally thought that the chemistry in diffuse clouds would be limited to principally diatomic species, as verified by sophisticated chemical models (e.g., van Dishoeck and Black 1986). First, the densities are so low that it is difficult to build molecules through the usual gas-phase reactions in the ion-molecule scheme. Second, there is not sufficient self-shielding to protect the molecules that are created from the destructive effects of UV photons. It has been therefore very surprising to find that a host of polyatomic molecules exists in diffuse clouds. Many of these species remained “hidden” for decades, because the densities are so low in diffuse clouds that collisional excitation, the principal route to rotational lines and therefore molecule detection, is inefficient. Clever measurements of absorption spectra against background quasars resulted in the identification of numerous polyatomic compounds, including HCN, HNC, CCH, HCO^+ , H_2CO , SO_2 , N_2H^+ , and $c\text{-}C_3H_2$, along with the diatomics CN, CS, SiO, SO, and CO (e.g., Liszt et al. 2006). Interestingly, these molecules are almost an identical set to what has been observed in PNe and strengthen the chemical connection. The species in diffuse clouds also have abundances ($f \sim 10^{-9}\text{--}10^{-8}$, relative to H + H_2) that are about a factor of 10–100 less than that in PNe (e.g., Ziurys et al. 2016), consistent with the gradual dispersion of the dense clumps of gas and dust ejected from the nebulae. Calculations suggest that a clump with $n \sim 3 \times 10^5\text{ cm}^{-3}$ will dissipate into diffuse gas in about 10^7 years (e.g., Tenenbaum et al. 2009).

4.1.6.2 LARGE MACROMOLECULES AND INTERMEDIATE SPECIES

Diffuse clouds also are sources of the Diffuse Interstellar Bands (DIBs), which are observed in absorption in the visible region against background stars. The DIBs have been known for decades but have remained largely unidentified. A few are now attributable to C_{60}^+ (e.g., Walker et al. 2015); the rest remain a mystery but are likely arising from some large complex compounds. A series of IR emission features known as the Unidentified Infrared Bands (UIBs) are also seen in diffuse gas, as well as in PNe and proto-PN (e.g., Snow and McCall 2006, Chapter 4.2 of this book). Based on the wavelengths of the bands (3.3, 6.2, 7.7, 8.6, and 11.3 microns), the UIBs have been attributed to aromatic C–H and C–C stretching and bending modes. The identification of the UIBs is a subject of debate but is likely due to some large organic macromolecules with multiple functional groups (e.g., Kwok and Zhang 2011). More details on the UIBs can be found in Chapter 4.2 of this book.

The UIBs, the DIBs, and C_{60}^+ , as well as other smaller species seen in the millimeter region, all indicate the existence of a far more complex chemistry within diffuse clouds than ever conceived. This chemistry appears to be based on carbon, suggesting that the previous carbon enrichment is, to some degree, preserved. There is also a large jump in chemical

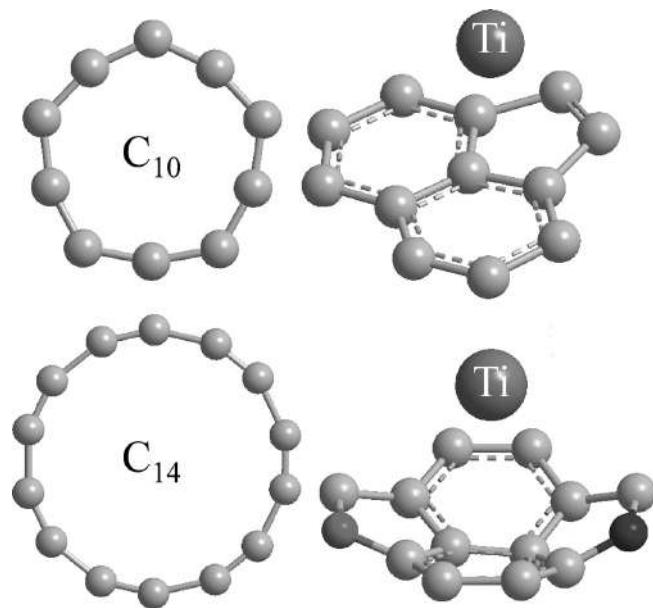

FIGURE 4.1.6 Possible carbon chains and “buckybowls” that might be present in the interstellar medium and represent intermediate complexity between smaller molecules and C_{60} .

complexity from the three- to five-atom molecules to C_{60}^+ and beyond, so intermediate species likely exist. Perhaps, compounds such as “buckybowls” and carbon fragments with a metal or other heteroatom are also present. Examples are shown in Figure 4.1.6. There is clearly more molecular material to be discovered.

4.1.7 COLLAPSE TO DENSE CLOUDS AND THE RISE OF “ORGANIC” CHEMISTRY

Gravitational collapse and/or accretion of diffuse clouds leads to the formation of dense clouds on timescales of about 10 million years (e.g., Inoue and Inutsuka 2012 and references

therein). These clouds are categorized by their high gas densities ($n \sim 10^4\text{--}10^6 \text{ cm}^{-3}$), relative to the general ISM, and by their colder temperatures ($T \sim 10\text{--}75 \text{ K}$). Hydrogen is in the form of H_2 . Their elevated densities enable ion-molecule reactions to proceed efficiently, and “molecular clouds” have rich chemical compositions.

4.1.7.1 GIANT MOLECULAR CLOUDS AND LOWER-MASS OBJECTS

From the chemical viewpoint, molecular clouds can be classified into two types. There are the so-called “giant molecular clouds” (GMCs). These objects contain between 10^3 M_{\odot} and 10^6 M_{\odot} , are $10\text{--}100 \text{ pc}$ in size ($1 \text{ pc} = 3.26 \text{ light-years}$ or $3.086 \times 10^{13} \text{ km}$), and usually have $T \geq 50 \text{ K}$. They are not gravitationally stable and collapse to within $10^6\text{--}10^7 \text{ year}$ to create stars and solar systems (e.g., Lequeux 2013). They often contain protostellar cores, which emit in the IR region and heat the surrounding gas to $T \sim 100\text{--}300 \text{ K}$. Densities are higher in these cores as well, on the order of $10^7\text{--}10^8 \text{ cm}^{-3}$. These clouds usually exhibit spectra rich in molecular lines, partly because of their warmer temperatures, which accelerate the chemistry, evaporate grain mantles, and populate more of the molecular rotational manifolds. An example of such a typical GMC spectrum is displayed in Figure 4.1.7. Here, a portion of the 3-mm region from the Orion Molecular Cloud 1 is shown near 110 GHz, with molecular identifications indicated on the data. The spectral lines are virtually continuous across the spectrum.

There are also less massive, dense clouds, with $M \sim 1\text{--}10^3 \text{ M}_{\odot}$, the most compact of which are Bok globules. These globules, such as Barnard 68, have masses between 1 M_{\odot} and 50 M_{\odot} and are no larger than $\sim 0.3 \text{ pc}$ in size. Typically, lower-mass stars form in these types of clouds, which tend to be more quiescent than GMCs. The very coldest ($T \leq 10 \text{ K}$), dense clouds of this type, such as TMC-1, are sometimes referred to as “dark clouds.”

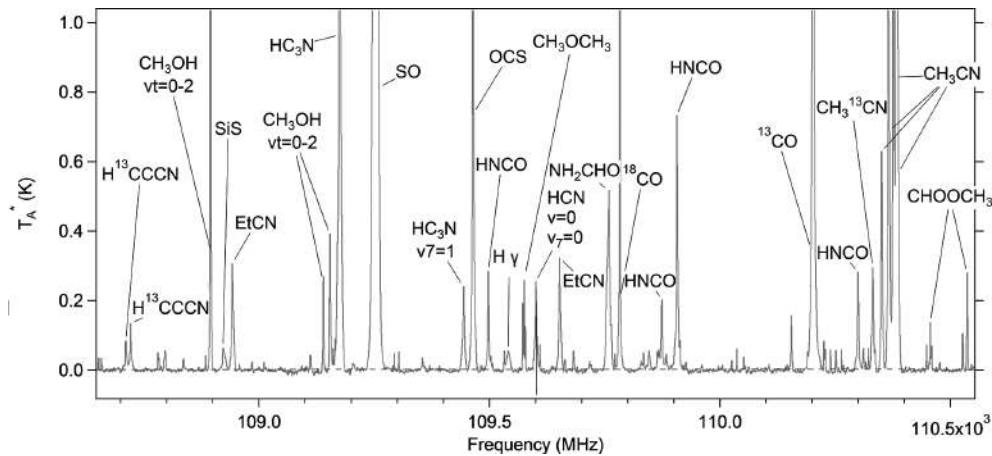

FIGURE 4.1.7 A typical spectrum exhibited by dense molecular clouds with star formation, in this case Orion Molecular Cloud 1, observed at 110 GHz with the Arizona Radio Observatory 12-m telescope. The molecular carriers of many of the spectral features are labeled, but some fractions are unidentified. A variety of organic-type compounds are present in this spectrum, including CH_3OH , EtCN, and HCOOCH_3 . (From Bernal et al., in preparation.)

4.1.7.2 CHEMICAL PROCESSES AND TRENDS TO HIGHER COMPLEXITY

Ion-molecule and associated reactions characterize dense clouds, along with surface processes. The less massive clouds contain the simpler species, such as HCO^+ , N_2H^+ , CS, HCN, HC_3N , CN, CCH, c-C₃H₂, and H_2CO (e.g., Kaifu et al. 2004). Typical abundances, relative to H₂, fall in the range $f \sim 10^{-10}\text{--}10^{-8}$ for common polyatomic species. Also, a few of these clouds, as viewed by their molecular composition, are apparently carbon-rich, with C > O, such as TMC-1. This source contains many of the acetylenic chains and other carbon-bearing molecules observed in carbon-rich AGB envelopes, including HC_3N , HC_5N , HC_7N , and HC_9N , as well as HCCNC, HNCC, C₄H, C₆H, and C₃N (e.g., Kaifu et al. 2004). Clouds like TMC-1 suggest that the chemical environment was inherited from a carbon-rich star.

Giant molecular clouds, in contrast, foster a chemistry that appears to further integrate oxygen. These clouds produce compounds of the more classic “organic” type: alcohols (CH_3OH and $\text{CH}_3\text{CH}_2\text{OH}$), carboxylic acids (HCOOH and CH_3COOH), ketones (CH_3COCH_3), aldehydes (CH_3CHO), ethers (CH_3OCH_3), esters (CH_3OCOOH), pseudo-peptides (CH_3CONH_2), and even sugars (CHOCH_2OH). They also are the only source class besides AGB stars that are currently known to contain phosphorus-bearing species. However, the phosphorus inventory includes only PN and PO (e.g., Ziurys 1987; Rivilla et al. 2016).

Representative examples of GMCs are SgrB2(N), Orion-KL, and W51 (e.g., Belloche et al. 2016; Halfen et al. 2017). Typical abundances of these species are $10^{-10}\text{--}10^{-7}$, an overall increase relative to the less massive clouds. The preponderance of C-O bonds may be a result of the vaporization of icy grain mantles by young protostars or simply because in the general ISM, O > C and material has been mixed. The organic molecules are certainly small by chemists’ standards, but the true extent of the chemical complexity in GMCs is not known. Because the spectra are so complex (c.f. Figure 4.1.7), identification of new molecules becomes increasingly difficult due to line confusion. Furthermore, laboratory spectral studies of larger molecules also face mounting challenges owing to the presence of multiple conformers near the same energy, complications of internal rotation, and floppy molecular structures, as seen in CH_3NCO (e.g., Halfen et al. 2015). Surface processes also play an important role in GMCs, because elevated temperatures from imbedded protostars liberate compounds formed on grain surfaces. Shocks, elevated gas temperatures, and PDRs are also prominent in molecular synthesis in GMCs, as discussed.

Dust grains in these clouds are thought to consist of amorphous silicates, hydrocarbon material, and graphite, some which appear to have mantles of water, CO, CO₂, CH₃OH, and other species (e.g., Jones 2001). Evidence for these grain types arises principally from observations of IR vibrational bands.

4.1.7.3 ISOTOPE ENRICHMENT AND CHEMICAL FRACTIONATION

Molecules in dense clouds are known to be enriched in the heavier isotopes because of chemical fractionation, in particular in deuterium, ¹³C, and ¹⁵N. For the most part, such enhancements occur in very cold gas (T ~ 10 K), where differences in zero-point energies between competing isotopes become significant. Such energy differences are most extreme for deuterium. For example, the reaction of $\text{H}_3^+ + \text{DH} \rightarrow \text{H}_2\text{D}^+ + \text{H}_2$ is exothermic by 230 K (e.g., Millar 2005), effectively funneling the deuterium into the products. Furthermore, the cosmic deuterium and hydrogen (D/H) ratio of ~10⁻⁵ is fixed by the “Big Bang,” unlike ¹²C/¹³C and ¹⁴N/¹⁵N ratios, which are highly influenced by stellar nucleosynthesis. Ratios as high as D/H ~0.001–0.1 have been observed in molecules in dense clouds, with multiply-deuterated species such as CD₃OH and D₂CO, where the enrichment is even higher. These high ratios are often found in cold clouds, particularly in their dense cores, but sometimes also in “hot cores.” The enhancement in the latter case is thought to be a result of previous “fossil” low-temperature chemistry, followed by grain condensation and then subsequent evaporation (e.g., Neill et al. 2013).

There is also some evidence of enrichment of molecules in ¹³C and ¹⁵N, but the zero-point energy differences are not nearly as great. For example, the exchange reaction $^{15}\text{N}^+ + \text{C}^{14}\text{N}$, leading to C^{15}N , is exothermic by only ~23 K (see Adande et al. 2012). Therefore, high enrichments of the heavier isotopes for carbon and nitrogen are not observed. There is some evidence of chemical fractionation in cold clouds (e.g., Taniguchi et al. 2016), but as the gas warms, such fractionation is erased (e.g., Halfen et al. 2017).

4.1.8 THE NEXT STAGE: PROTOPLANETARY DISKS

The gravitational collapse of dense clouds leads to star formation. As motions in the cloud become synchronized, conservation of angular momentum results in the creation of a disk around the young star (e.g., Williams and Cieza 2011). Mass falls from the vertical direction to form the disk and is compressed by the gas pressure. Disks can extend out to 1000 AU and have a flared structure. Over a period of ~3–10 million years, these disks will evolve from having a gas/dust ratio near 100 to <1, as planetesimals and eventually planets form.

4.1.8.1 DISKS: A COMPLEX PHYSICAL AND HENCE CHEMICAL STRUCTURE

Protostellar (or protoplanetary) disks are postulated to contain both vertical and radial temperature and density gradients, with vastly different radiation fields at various disk locations. Disks are therefore quite complicated, and a wide range of chemical processes occur, including photochemistry, ion-molecule reactions, neutral-neutral pathways, and

surface reactions (e.g., Henning and Semenov 2013). In the radial direction, disks consist of a warm inner zone, the site of planet formation, typically <20 AU and a cold outer region. In the inner disk, $T \sim 150\text{--}5000$ K, such that grain mantles are vaporized, and densities approach 10^{12} cm $^{-3}$. Here, the chemical processes are near LTE, and three-body collisions and neutral-neutral reactions play an important role, producing molecules such as H₂O, CO, and HCN. There is a balance between molecule production and thermal dissociation, as well as destruction by radiation from the young star. In the outer zone, the key chemical drivers are radiation and cosmic rays, which promote ion-molecule reactions. “Freeze-out” becomes important as temperatures decrease, pulling molecules from the gas phase and increasing the density of solid particles. At about 150 K, water condenses onto grain surface, defining the so-called “snow line,” the radial distance from the protostar at which ice grains form, typically a few AU. CO and other molecules also have “snow lines,” but much further out (≥ 20 AU). Recently, it has been speculated that a “centrifugal barrier” also exists in the outer disk, namely the radial distance at which the gravitational pull of the central star is balanced by the centrifugal force, such that infall no longer occurs (e.g., Sakai 2015). This barrier is thought to define a change in chemical conditions, possibly indicating the transition from unprocessed to processed material.

In the perpendicular direction, the outer disk can be divided into three regions. There is the dense midplane, typically obscured from observations, where planets/asteroids can form and molecules are frozen out onto grains. Here, it is thought that $T < 20$ K, such that most molecules condense onto grains and surface hydrogenation plays a dominant chemical role. Then, there is the disk surface layer, which is bombarded by UV and, in certain cases, X-ray photons. Photodissociation, ion-molecule reactions, and radical-radical processes are important in this PDR-like material. In between the two layers, protected from UV and X-ray radiations, is the intermediate zone, which is warm ($T \sim 30\text{--}100$ K) and is thought to have the richest molecular content. Common interstellar molecules such as CO, CS, HCO $^+$, and HCN are present there.

4.1.8.2 MOLECULAR CONTENT AND ABUNDANCES IN THE DISKS

Observational work of molecules in protoplanetary disks is in its infancy. Nonetheless, a variety of species have been identified thus far, and more are likely to occur with Atacama Large Millimeter Array (ALMA) and other new facilities. Infrared spectroscopy has revealed the presence of CO₂, H₂O, CO, OH, HCN, and HCCH (e.g., Williams and Cieza 2011), which are observed principally through ro-vibrational transitions. These higher-excitation transitions are thought to trace the hotter gas in the inner disk, within a few AU of the star. Radio- and millimeter-wave molecular measurements typically sample the more extended material, namely the outer disk >30 AU. Detections include H₂CO, CS, C₂H, *c*-C₃H₂, HCN, HNC,

CN, DCN, CCH, HCO $^+$, and DCO $^+$ (e.g., Guilloteau et al. 2016). The deuterated molecules likely arise in regions that are cold and favor ion-molecule reactions (e.g., Bergin 2000). Abundances, relative to H₂, span the range $f \sim 10^{-5}$ for CO to $f \sim 10^{-11}\text{--}10^{-9}$ for other species (see Henning and Semenov 2013). Thus, overall abundances are less than that in dense molecular clouds. Also, the organic content is not nearly as varied as in dense clouds, with the apparent absence of molecules such as CH₃CH₂OH and HCOOCH₃. However, the failure to detect the larger organic species may be a function of telescope sensitivity. It is quite possible that further ALMA studies will reveal that disks have a similar organic complexity to dense clouds. Dust grains appear to be chiefly silicate in composition (amorphous and crystalline), along with carbonaceous types. They have also been found to contain ice and CO₂ mantles.

4.1.9 INTO THE SOLAR SYSTEM: CONNECTING INTERSTELLAR MOLECULAR MATERIAL TO PLANETS

The rich chemistry in protoplanetary disks can significantly influence the composition of planets and their atmospheres, as well as that of asteroids and comets (Aikawa and Herbst 1999; Henning and Semenov 2013). A major uncertainty in the chemistry of protostellar disks is the extent of the processing of molecular material inherited from the primordial dense cloud. Given the physical conditions in disks, with the presence of high temperatures, influx of UV and X-ray photons and turbulent motions, molecular material will be processed, at least in the inner disk; there is also evidence of such processing from meteoritic studies (e.g., Pizzarello and Shock 2010). The degree of processing in the outer disk and the radial distance at which the material remains primordial are not currently known. It can be explored to some extent by studying solar system bodies, namely comets, meteorites, and asteroids.

4.1.9.1 MOLECULAR COMPOSITION OF COMETS

Comets are thought to be among the most primitive bodies in the solar system. They formed from the accretion of icy grains in the outer solar nebula. Many potential comets were incorporated into the giant planets, but others survived, some past the orbit of Neptune, while others were ejected into the Oort cloud (e.g., Cochran et al. 2015). The Oort cloud contains the pristine remains of the original molecular cloud, which spawned the solar system and extends as far out as 100,000 AU.

The chemical composition of comets has been studied by spectroscopic observations, chiefly in the IR and radio/millimeter regions, of gas-phase molecules evaporated from the icy comet nucleus (Biver et al. 2014; Marboeuf and Schmitt 2014). A wide range of chemical compounds have been identified, including simpler compounds such as CO, OH, CS, HCN, CH₄, NH₃, H₂S, and HCCH (e.g., Bockelée-Morvan et al. 2000), as well the more

complex organic species, including H_2CO , CH_3OH , CH_3CN , C_2H_2 , C_2H_6 , CH_3CHO , HC_3N , HCOOH , HNCO , $(\text{CH}_2\text{OH})_2$, and NH_2CHO (e.g., Biver et al. 2014). A few more organic molecules have been identified in mass spectroscopic data of surface dust, vaporized from the nucleus, from the Rosetta mission; these molecules include CH_3CONH_2 , CHOCH_2OH , and CH_3NCO (Goesmann et al. 2015). This work prompted the identification of CH_3NCO in interstellar gas. The solid-state component of comets, derived from spectroscopic and scattering measurements, suggests a mixture of amorphous carbon, carbonates, and aromatic hydrocarbons, as well as ice and silicates (Lisse et al. 2006). Studies by Rosetta indicate the presence of non-volatile organic material similar to the “Insoluble Organic Material” found in meteorites, as well as amorphous and crystalline silicates (e.g., Capaccioni et al. 2015).

The chemical composition of comets thus reflects for the most part that found in dense molecular clouds. With the exception of CO, the abundances of compounds found in comets are remarkably similar to those in dense clouds within an order of magnitude (e.g., Mumma and Charnley 2011). There is also a lack of deuterium, ^{13}C , or ^{15}N enrichment in cometary molecules, suggesting that these compounds formed in warmer gas, likely in the GMC that formed the solar system. The evidence indicates that, for the most part, the gas-phase chemical compounds simply condensed out of the nascent cloud and froze onto grains surfaces, which subsequently aggregated to create larger bodies. Any processing that may have occurred is better described as “recycling,” because the basic organic content of the interstellar cloud has been preserved.

4.1.9.2 A LINK TO METEORITES: ORGANICS IN CARBONACEOUS CHONDRITES

Certain types of meteorites, namely carbonaceous chondrites, are known to contain a wide variety of soluble organic compounds, as well as insoluble, kerogen-like material called “Insoluble Organic Matter” (IOM) (e.g., Pizzarello et al. 2006; Alexander et al. 2007). Many carbonaceous chondrites undergo aqueous processing in the solar system, which is reflected in their organic content, while others appear to be quite pristine. The most primitive, unaltered meteorites contain a wide variety of organic compounds, including α -type amino acids (glycine, isovaline, alanine, and α -aminoisobutyric acid), aldehydes, ketones, hydroxyamino acids, and tertiary amines (e.g., Martins et al. 2007; Elsila et al. 2012). The latter two compound types are very reactive species and likely signify pristine material (Pizzarello and Holmes 2009). Insoluble Organic Matter is macromolecular in nature, with a typical elemental composition $\text{C}^{100}\text{H}^{71}\text{N}^3\text{O}^{12}\text{S}^2$. It represents the bulk of the organic matter in these types of meteorites, as much as 2% by weight. In addition, there has been one report of phosphorus compounds in meteorites; phosphonic acids, R-POOH, have been thought to have been extracted from the Murchison meteorite (Cooper et al. 1992).

The soluble organic compounds found in unaltered meteorites, and processed ones as well, on average contain many

more atoms and are certainly more complex than those found in GMCs. However, simpler species common in dense clouds, such as H_2CO , CH_3CHO , NH_2CH_3 , and even NH_3 , have been extracted from primitive meteoritic material. These compounds are quite volatile at room temperature and so are likely present in some derivative material in the meteorites. Insoluble Organic Matter is composed of both aromatic and aliphatic carbons. The aromatic material appears to consist of one to a few benzene-like rings, while the aliphatic sections have highly branched short chains (Alexander et al. 2007). Oxygen-containing functional groups are also found in the IOM, mostly carbonyl and carboxylic types. All considered, the same types of functional groups ($-\text{COOH}$, C=O , $-\text{NH}_2$, $-\text{CH}_3$, etc.) are found in both interstellar and meteoritic molecules, with an emphasis on carbon in the elemental composition, suggesting a connection.

Analysis of isotopic ratios can provide clues to the origin of the meteoritic organics, in particular D/H, $^{12}\text{C}/^{13}\text{C}$, and $^{14}\text{N}/^{15}\text{N}$. Studies of both the soluble matter and the IOM have shown that they are often heavily enriched in deuterium, often in ^{15}N , and have some minor enhancement in ^{13}C (e.g., Pizzarello 2007). For example, in 2-aminoisobutyric acid from the primitive meteorite GRA 95229, a high deuterium enrichment of $\text{D/H} \sim 0.0012$ (or $\delta\text{D} = +7200\%$) has been found (Pizzarello and Holmes 2009). In certain “hotspots” within IOM samples, values of $\text{D/H} \sim 0.003$ and $^{14}\text{N}/^{15}\text{N} \sim 65$ have been measured, where $^{14}\text{N}/^{15}\text{N}_{\text{standard}} \sim 272$ (e.g., Busemann et al. 2006). These enrichments suggest an origin in a very cold environment, where isotope effects can occur. As discussed, molecules in dense clouds show incredibly high deuterium enrichments, which are subsequently preserved on grains and are therefore found in the much warmer environments of hot cores. Such extreme D enhancements have not yet been found in meteoritic compounds, suggesting that there was partial dilution in the protostellar disk but that some enrichment remained, as dust grains aggregated into meteorites. Not all compounds extracted from meteorites show anomalous D/H ratios, either (e.g., see Pizzarello and Holmes 2009). Enrichments in ^{13}C and ^{15}N are more difficult to interpret, as effects in these isotopes are not as extreme, and these anomalies could also be caused by nucleosynthesis. Nonetheless, the fact that any strong D enrichment is seen in meteoritic organic material is suggestive that this matter had at least in part an interstellar origin.

4.1.9.3 DELIVERY TO PLANETARY SURFACES

It has long been recognized that the Earth and presumably Earth-like planets in other solar systems are bombarded by extraterrestrial bodies, in particular comets, meteorites, and interplanetary dust particles (IDPs) (e.g., Flynn et al. 2003). Furthermore, early Earth was thought to be quite hot and therefore lost most of its volatiles, which contained the bulk of the available carbon. Therefore, a significant fraction of the present surface inventory of organic material was likely brought back to Earth through such bombardment (e.g., Dauphas and Marty 2002; Brack 2014). This matter can be traced back to interstellar molecules, which, despite possible

alteration in the protostellar disk, provided the basic organic material that was deposited on solar system bodies and then delivered to the surface of Earth. The carbon enrichment from AGB stars that was preserved in interstellar matter, including macromolecules such as fullerenes, thus may have provided the basis of terrestrial organic chemistry.

4.1.10 INTERSTELLAR MOLECULES AND LIFE

After decades of observations, it has become evident that organic molecular material is present throughout the galaxy in large quantities and survives under harsh conditions. Furthermore, the molecular material is not formed in isolation but is cycled from one phase in the ISM to another. This cycling enables carbon enrichment from the AGB stars to be preserved at some level and seed the organic chemistry of diffuse and then dense clouds. Although there is processing in the protostellar disk, the basic interstellar organic content remains and is condensed onto surfaces that aggregate to create solar system bodies. Some pristine interstellar organic material is still preserved, as indicated by isotopic enrichment found in meteoritic compounds, which are both discrete molecules and polymers; the latter may be of importance in the formation of cell membranes. In addition to organic molecules, phosphorus-bearing molecules are found in circumstellar and interstellar gas, indicating that this element is still active chemically and not all condensed into inert crystalline forms such as apatite. Mixed into this organic soup are metals. Some relevant metals such as iron, magnesium, and potassium have been found in gas-phase molecules, notably bound to the CN moiety. Metallic grains are also present in carbonaceous chondrites, perhaps providing catalytic sites for more complex chemistry needed to produce larger biological molecules.

Do interstellar molecules play role in prebiotic chemistry? Given their widespread abundance and survival on delivery to planet surfaces, the answer is “very likely.” The necessary ingredients are all present in interstellar material, including phosphorus, metals, and a broad organic content. However, the degree of chemical complexity contributed by interstellar molecules is still unknown, and many pieces of the puzzle remain missing.

4.2.1 INTRODUCTION

Life as we know is based on chemical building blocks of organic molecules. Although organic molecules extracted from living organisms were once believed to possess a special component called “vitality,” we no longer believe “vitality” is a real physical entity, as many organic molecules extracted from living organisms can also be artificially synthesized in the laboratory. Instead, organic molecules are just molecules with the elements carbon (C) and hydrogen (H) as major constituents while also containing other elements such as nitrogen (N), oxygen (O), sulfur (S), and phosphorus (P). From a chemical point of view, there is no intrinsic difference between organic and other molecules.

Since the 1950s, we have learned that all chemical elements (except H and some helium, He) in our bodies originated from nucleosynthesis in the interior of stars (Burbidge et al. 1957). This is the first established link between stars and life on Earth. Advances in infrared and millimeter-wave observing capabilities in the 1960s led to the discovery of molecules in space and to our realization that stars can synthesize molecules and minerals during their late stages of evolution (Ziurys et al. 2016). The most surprising aspect of these discoveries was the detection of complex organics in the circumstellar envelopes of evolved stars. Infrared spectroscopic

observations have shown that common, ordinary stars can synthesize complex organics during their last stage of evolution in the planetary nebulae phase, before their nuclear fuel supplies are exhausted in the following white dwarf phase. This organic synthesis takes place under an extremely low ($<10^6 \text{ cm}^{-3}$) density environment and occurs over very short (10^4 year) timescales. These organics are ejected into the interstellar medium and quite probably have spread across the Milky Way Galaxy (Kwok 2004).

In this chapter, we will summarize the observational evidence of stellar organic synthesis, discuss the chemical structure of these organics, explore the possible relationship between stellar organics and those found in the solar system, and speculate on the delivery of stellar organics to Earth and its implications on the origin of life on Earth.

4.2.2 LATE STAGES OF STELLAR EVOLUTION

Stars like our Sun maintain their luminosities by generating energy through fusing H into He in the core. After the supply of H is exhausted in the core, H is converted into He in a shell surrounding the inert He core. The outer envelope of the star expands, and the luminosity increases to several hundred times the current solar luminosity (L_\odot). This stage is called the

red giant phase. Further contraction of the core leads to the ignition of He in a shell, and He is converted into carbon (C) through the triple- α reaction. The envelope of the star expands to a size more than one astronomical unit (AU, the distance between the Earth and the Sun) and the luminosity climbs to more than $3000 L_\odot$. As the result of size expansion, the surface temperature of the star drops to 3000 K, with its emerging radiation shifting from the visible to the infrared, peaking at a wavelength of $\sim 1 \mu\text{m}$. This is referred to in astronomical nomenclature as the asymptotic giant branch (AGB) phase.

A strong stellar wind develops during the late AGB phase, ejecting mass in the stellar envelope into interstellar space. For stars with initial mass under eight times the mass of the Sun, this mass loss process can remove most of the envelope mass before the ignition of C and avoids the fate of becoming a supernova. This path of evolution is followed by over 95% of all stars in our Milky Way Galaxy.

After the complete depletion of the H envelope by mass loss, a faster wind develops and compresses and accelerates the previously ejected circumstellar material into a high-density shell. As the core is gradually exposed by its diminishing envelope, the star increases its temperature from 3000 K to over 100,000 K (Figure 4.2.1). The increasing ultraviolet (UV) radiation output from the star photoionizes the circumstellar gas,

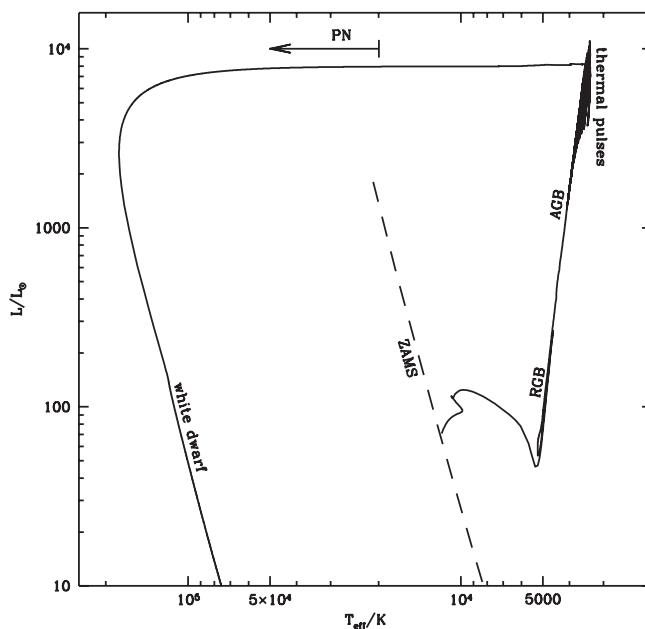

FIGURE 4.2.1 The evolutionary track of a 3-solar-mass star on a plot of luminosity (vertical axis) versus temperature (horizontal axis) from the zero age main sequence (ZAMS), through the red giant branch (RGB) and asymptotic giant branch (AGB) to planetary nebulae (PN) and ending as a white dwarf (Figure from T. Blöcker). The beginning of the planetary nebulae phase is indicated by the end of an arrow, when the star reaches a temperature of $\sim 20,000$ K, with sufficient output of UV photons to photoionize the surrounding nebula. The evolutionary stage between the end of the AGB and the beginning of planetary nebulae phases is called proto-planetary nebulae phase (Kwok 1993). During this phase, the circumstellar nebulae have no atomic line emission and are only illuminated by scattered starlight.

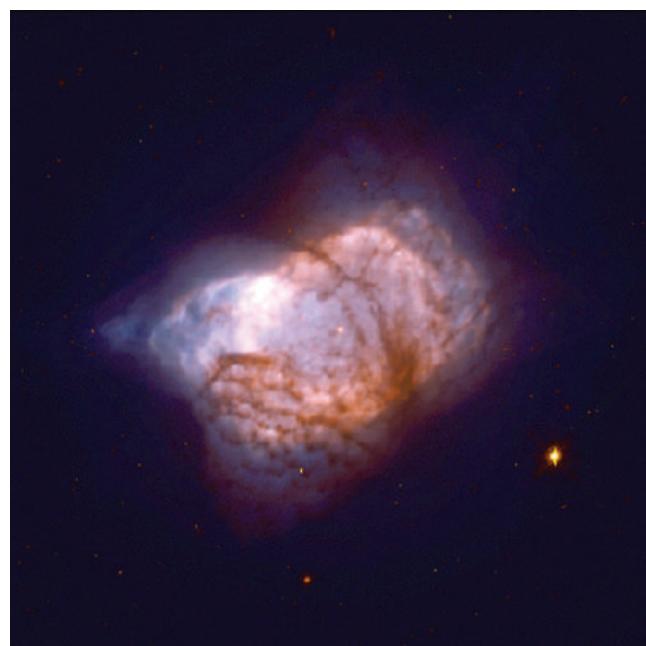

FIGURE 4.2.2 A composite color image of the planetary nebula NGC 7027. The color of the nebula is due to emission lines from ions of H, O, and N. Unidentified infrared emission (UIE) bands were first discovered in the spectrum of this nebula.

and the resulting strong atomic emission lines create a bright optical nebula called planetary nebula (Figure 4.2.2). Planetary nebula is a short-lived phase of stellar evolution, lasting only about 20,000 years, before it disperses into the interstellar medium. The hot central star (core of the progenitor AGB star) gradually burns out its H fuel and becomes a white dwarf. A detailed description of the late stages of evolution leading to the formation of planetary nebulae is given in Kwok (2000).

4.2.3 CIRCUMSTELLAR SYNTHESIS OF MOLECULES AND MINERALS

Carbon atoms synthesized in the core of AGB stars are dredged up to the stellar surface through the process of convection. In the low-temperature atmosphere of AGB stars, simple molecules such as C_2 , C_3 , and CN can form. As the envelope is ejected by the stellar wind, further chemical reactions have been observed to take place in the circumstellar envelope, leading to a rich variety of chemical species. As the gas expands and cools, atoms combine to form molecules and gas condenses directly into solid phase to form micron-size solid grains. Solid particles in the stellar wind can be identified by their lattice vibrational modes in the infrared through infrared spectroscopy. The rotational transitions of gas-phase molecular species can be detected by millimeter- and submillimeter-wave spectroscopy. As of 2018, approximately 80 molecular species have been detected in the circumstellar environment of evolved stars. The detected molecular species include inorganics (CO , SiO , SiS , NH_3 , and AlCl , etc.), organics (C_2H_2 , CH_4 , H_2CO , CH_3CN , etc.), radicals (CN , C_2H , C_3 , HCO^+ , etc.), chains (HCN , HC_3N , HC_5N , etc.), and rings (C_3H_2) (Ziurys 2006; Ziurys et al. 2016).

Micron-size solid-state particles (commonly referred to as dust in the astronomical literature) can be directly detected by their thermal radiation in the infrared. The first circumstellar solids discovered were amorphous silicates, which were identified by their Si–O stretching and the Si–O–Si bending modes at 9.7 and 18 μm , respectively (Woolf and Ney 1969). These features are detected in over 4,000 O-rich AGB stars by the Low-Resolution Spectrometer (LRS) on board of the *Infrared Astronomical Satellite (IRAS)* all-sky survey (Kwok et al. 1997). These features can be in emission or in self-absorption, depending on the amount of mass in the circumstellar envelope (Figure 4.2.3).

A variety of refractory oxides (corundum α -Al₂O₃, spinel MgAl₂O₄, and rutile TiO₂) are also detected in the envelopes of AGB stars (Posch et al. 1999, 2002). Crystalline silicates such as pyroxenes and olivines have sharper features and are also detected in the circumstellar environment (Jäger et al. 1998). The wide detection of minerals in stars by infrared

techniques led to the emergence of the field of astromineralogy (Henning 2009).

In C-rich stars, where the atmospheric C abundance exceeds that of O, all O atoms are tied up in CO and the surplus C atoms form C-based molecules and solids. The most common C-based solid is silicon carbide (SiC), for which 11.3 μm emission feature is observed in over 700 C-rich stars in the *IRAS LRS* survey (Kwok et al. 1997). For highly evolved C-rich stars, the dust component is believed to be dominated by amorphous carbon, which emits a strong featureless continuum in the infrared (Volk et al. 2000). The circumstellar dust can completely obscure the optical surface (photosphere) of the star and convert all its energy output to the infrared. These highly evolved stars have no optical counterparts and can be detected only in the infrared. They are referred to as extreme carbon stars. It is also during this very late AGB evolution stage that the molecule acetylene (C₂H₂) is seen (Figure 4.2.4).

In the terrestrial environment, the formation of molecules and solids is the result of three- or multi-body collisions. The densities of the stellar winds, however, are much too low ($<10^6$ H atoms per c.c.) for such processes. From observations of novae, we learn that silicate dust condenses as soon as the radiation temperature drops below the condensation temperature, regardless of the density conditions. The emergence of a dust spectrum from a pure-gas spectrum in novae can take place over a time span as short as a few days (Ney and Hatfield 1978). From mapping of molecular distribution in the circumstellar envelopes of AGB stars by millimeter-wave interferometric techniques, we can set limits to the formation time of circumstellar molecules as hundreds of years, based on the sizes of the molecular emitting regions and expansion velocities of the envelopes. These observations suggest that

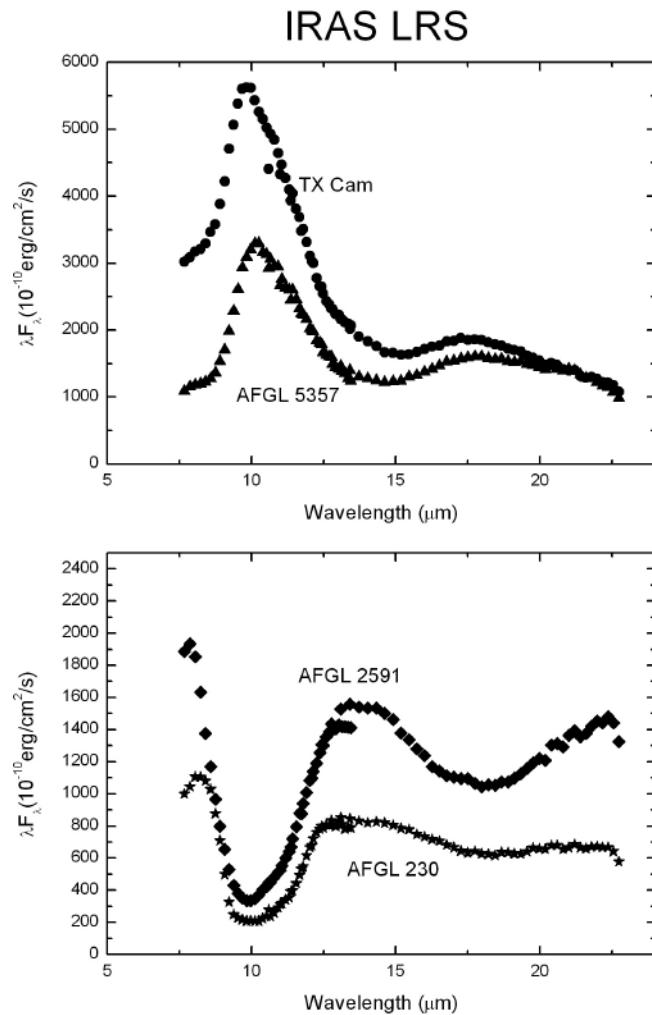

FIGURE 4.2.3 Infrared spectra of amorphous silicates. The 9.7 and 18 μm features of silicates can be seen both in emission (top panel) and in self-absorption (bottom panel). Data obtained from the Low-Resolution Spectrometer observations from the *Infrared Astronomical Satellite*.

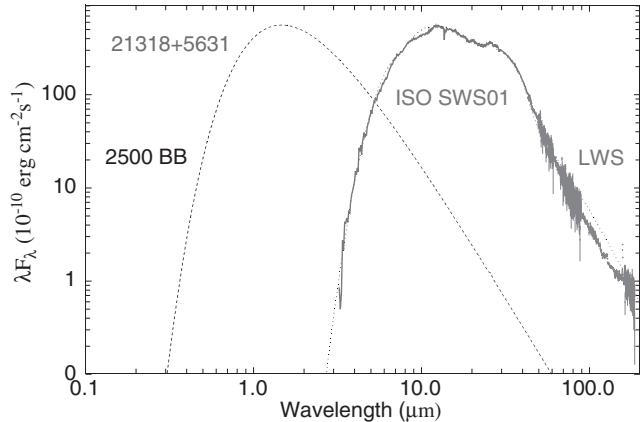

FIGURE 4.2.4 The extreme carbon star IRAS 21318 + 5631 is an example of a star so obscured by its own ejected circumstellar dust envelope that the central star becomes undetectable in the optical region. Its infrared spectrum (solid line) is completely due to dust emission and has a color temperature of 300 K. The dotted line represents the theoretical fit to the spectrum, based on a one-dimensional (1-D) radiation transfer model, with a hidden 2500 K central star (dashed line) as the energy source. The absorption feature near the peak of the spectrum is the 13.7 μm band of acetylene.

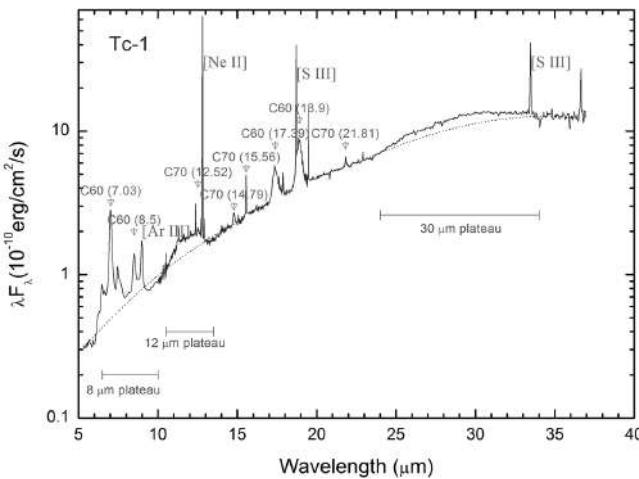

FIGURE 4.2.5 A composite image of the planetary nebula NGC 7027 based on narrow-band images due to emission lines from ions of H, O and N. Unidentified infrared emission (UIE) bands were first discovered in the spectrum of this nebula.

molecule and solid syntheses in the circumstellar environment can be extremely efficient, in spite of the low-density environment.

Since the initial discovery of fullerenes in the laboratory (Kroto et al. 1985), there have been strong interests in searching for this molecule in space. C_{60} is now unambiguously detected in planetary nebulae (Cami et al. 2010; Garcíá-Hernández et al. 2010), in reflection nebulae (Sellgren et al. 2010), and in proto-planetary nebulae (Zhang and Kwok 2011, 2013). These cage-like molecules are detected through either the C–C or the C–H stretching vibrational modes in the infrared. With 60 or more C atoms, fullerenes are the heaviest molecular species detected in the envelopes of stars. The paths of synthesis of C_{60} have been suggested to be either top-down (as breakdown products of complex organics) or bottom-up (built up from small C-based molecules) (Bernard-Salas et al. 2012; Garcíá-Hernández et al. 2012). As broad plateau emission features always accompany C_{60} features (Figure 4.2.5), it is possible that C_{60} synthesis is related to the unidentified infrared emission (UIE) phenomenon (see Section 4.2.4).

In a circumstellar environment, H can easily attach to the fullerene molecule and become hydrogenated fullerene (or fullerane, $C_{60}H_m$, $m = 1\text{--}60$). The theoretical vibrational spectra of fullerenes can be calculated and compared with observed astronomical spectra, resulting in the suggestion that fullermane may be common in the circumstellar environment (Zhang and Kwok 2013; Zhang et al. 2017).

4.2.4 UNIDENTIFIED INFRARED EMISSION BANDS

Due to the low-density and high-UV-radiation background of the interstellar medium, complex organic molecules and solids were not believed to be able to exist in space. The detection of the UIE features in the spectra of planetary nebulae, now attributed to organics, came as a complete surprise. A family

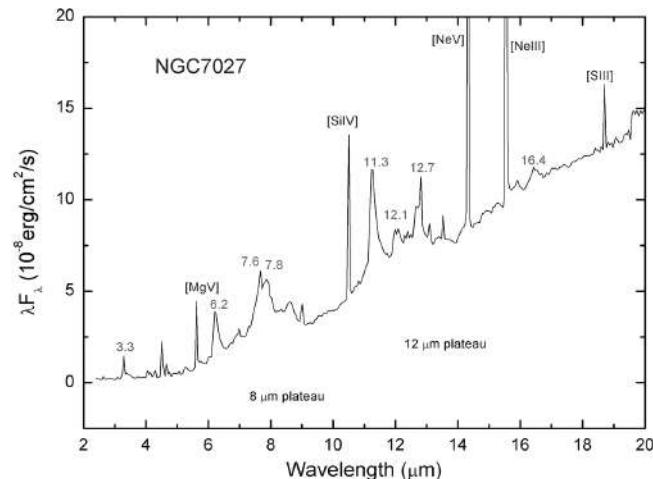

FIGURE 4.2.6 *Infrared Space Observatory* (ISO) spectrum of the planetary nebula NGC 7027 showing the UIE bands (labeled in red, with the wavelength of peak emission in units of microns). Broad emission plateaus around 8 and 12 μm as well as a strong underlying continuum can be seen. The narrow lines (in blue) are atomic lines.

of broad infrared bands at 3.3, 6.2, 7.7, 8.6, and 11.3 μm was first found in the spectrum of the planetary nebula NGC 7027 (Russell et al. 1977) (Figures 4.2.2 and 4.2.6). Shortly after discovery, it was recognized that the UIE bands probably arise from the vibrational modes of organic compounds (Knacke 1977; Duley and Williams 1979). More specifically, the UIE features are suggested to be originating from stretching and bending vibrational modes of aromatic compounds (Duley and Williams 1981).

Also present in spectra are emission features around 3.4 μm, which arise from symmetric and anti-symmetric C–H stretching modes of methyl and methylene groups (Puettner et al. 1979; Geballe et al. 1992). The bending modes of these groups also manifest themselves at 6.9 and 7.3 μm (De Muizon et al. 1990; Chiar et al. 2000). In addition, there are weaker unidentified emission features at 15.8, 16.4, 17.4, 17.8, and 18.9 μm, which probably arise from C-skeleton vibrational modes.

The emission bands themselves are often accompanied by strong, broad emission plateaus features at 6–9, 10–15, and 15–20 μm. The first two plateau features have been identified as superpositions of in-plane and out-of-plane bending modes emitted by a mixture of aliphatic side groups attached to aromatic rings (Kwok et al. 2001).

The UIE bands are extremely prominent in the spectra of C-rich planetary nebulae (Figure 4.2.6). They are not seen in AGB stars but emerge during the proto-planetary nebula phase. Their existence suggests that organic compounds can be efficiently synthesized in the circumstellar environment over very short (10^3 year) timescales.

The UIE and the plateau emission features lie on top of a strong continuum that extends from the near-infrared to millimeter wavelengths. This continuum emission must be due to thermal emission from micron-size solid grains, similar to those observed in AGB stars (Figure 4.2.4). In planetary nebulae or

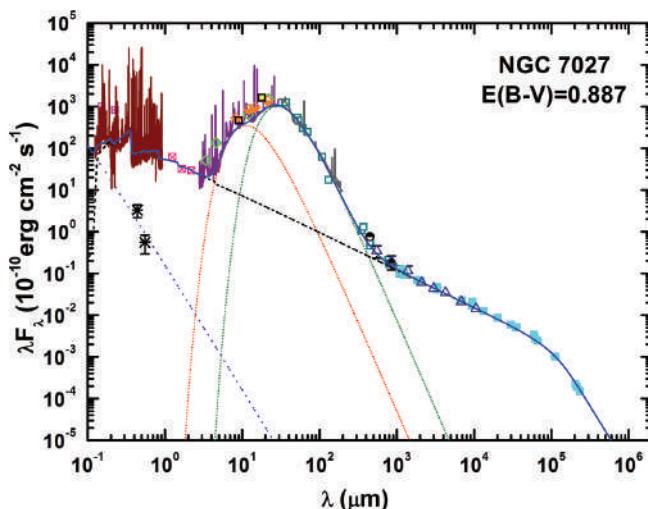

FIGURE 4.2.7 The spectral energy distribution of the planetary nebula NGC 7027 from wavelength 0.1 μm (ultraviolet) to 10 cm (radio). The continuum emission of the object is shown in a red line. The continuum shortward of wavelengths of 3 μm is due to bound-free gas emission. Between wavelengths 1 μm and 1 mm, the continuum is due to solid-state particle (dust) emission. At wavelengths longward of 1 mm, free-free gas emission dominates. We can see that most of the energy output is emitted by a dust component that is approximated by a sum of two blackbodies (dotted lines) of 246 K and 97 K. The narrow lines above the continuum are atomic lines and UIE bands.

active galaxies, most of the output energy of the object is emitted through this continuum component (Figure 4.2.7). Even in the diffuse interstellar medium, the strengths of the UIE features are strongly correlated with the dust continuum, suggesting that the heating source for the UIE carriers and the dust continuum must be the same (Kahanpää et al. 2003).

4.2.5 CARRIER OF THE UNIDENTIFIED INFRARED EMISSION BANDS

Noting that the astronomical UIE spectra resemble the spectra of automobile exhaust soot particles, Allamandola et al. (1985) suggested that the UIE carriers are simple polycyclic aromatic hydrocarbon (PAH) molecules. It is now widely believed in the astronomical community that the UIE features are due to infrared fluorescence of far-UV-pumped PAH molecules, each containing ~ 50 C atoms (Tielens 2008). These small gas-phase PAH molecules can be excited by a single incoming UV photon stochastically to a high temperature over a short time interval, therefore accounting for the strengths of the UIE features under low-temperature interstellar conditions (Sellgren 1984). By engaging a mixture of hundreds of PAH molecules of different sizes, structures (compact, linear, and branched), and ionization states, and broadened by artificial broad intrinsic line profiles, the PAH model can fit the astronomical UIE spectra.

The fitting of the astronomical UIE features by PAH molecules is not straightforward. Although PAH molecules were known to have C–H stretching modes around 3.3 μm , the actual wavelengths of the C–H stretching is shortward of the 3.3 μm UIE band (Sakata et al. 1990; Kwok and Zhang

2013). Polycyclic aromatic hydrocarbon molecules generally have out-of-plane bending modes around 10–14 μm , but to fit the observed UIE 11.3 μm feature requires exotic mix of PAH molecules (Sadjadi et al. 2015b). The assignments of the 6.2, 7.7, and 8.6 μm UIE features to PAH molecules are even more difficult. It was suggested that the 6.2 μm feature is due to C–C stretching and the 8.6 μm feature is due to C–H in-plane bending modes of PAH molecules (Léger and Puget 1984). The 7.7 μm UIE feature has no obvious counterpart in PAH spectra and has been suggested to be due to blending of several C–C stretching modes (Allamandola et al. 1989). Since C–C stretching modes in PAH molecules are generally very weak, it was later proposed that the 6.2 and 7.7 μm bands are due to ionized PAH molecules, which tend to show stronger C–C stretching modes (Hudgins and Allamandola 1999; van Diedenhoven et al. 2004). However, experimental results show that the C–C vibrational modes of PAH ions generally occur at wavelengths longer than 6.2 μm (Bauschlicher 2002; Hudgins et al. 2005). By increasing the size of the molecules, the peak of the band can shift to shorter wavelengths but never as short as 6.2 μm (Hudgins et al. 2005). In order to account for this discrepancy, it was suggested that some of the C atoms in specific positions in the ring be replaced by nitrogen (N), and this modified PAH model is referred to as the PANH model.

In addition, the PAH hypothesis suffers from the following problems: (1) PAH molecules have well-defined sharp features, but the UIE features are broad; (2) PAHs are primarily excited by UV, with little absorption in the visible, but UIE features are seen in proto-planetary nebulae and reflection nebulae, objects with very little UV background radiation, and the shapes and peak wavelengths of UIE features are independent of temperature of the exciting stars (Uchida et al. 2000); (3) the strong and narrow PAH gas-phase features in the UV are not seen in interstellar extinction curves to very low upper limits (Clayton et al. 2003; Gredel et al. 2011; Salama et al. 2011); (4) no specific PAH molecule has been detected, in spite of the fact that the vibrational and rotational frequencies of PAH molecules are well known; (5) there are great difficulties in reconciling the band positions or relative intensities of laboratory PAH spectra with astronomical UIE spectra (Wagner et al. 2000); (6) the large number of free parameters in the PAH model fitting suggests that such fittings are not very meaningful (Zhang and Kwok 2015).

In response to these criticisms, the PAH model has been revised to incorporate ionization states and large sizes to increase the absorption cross-sections in the visible; introduce dehydrogenation, superdehydrogenation and minor aliphatic side groups to explain the aliphatic features; and appeal to a large mixture of different PAH molecules to explain the lack of detection of individual PAH molecules. Since known PAH molecules have problems reproducing the wavelengths of the UIE bands, a large mixture of diverse PAH molecules is needed to fit the observed astronomical spectra. Heteroatoms such as N and O are also introduced to explain the 6.2 and 11.3 μm features. The PAH hypothesis therefore has moved away from the chemical definition of PAH molecules to a hybrid to save the hypothesis.

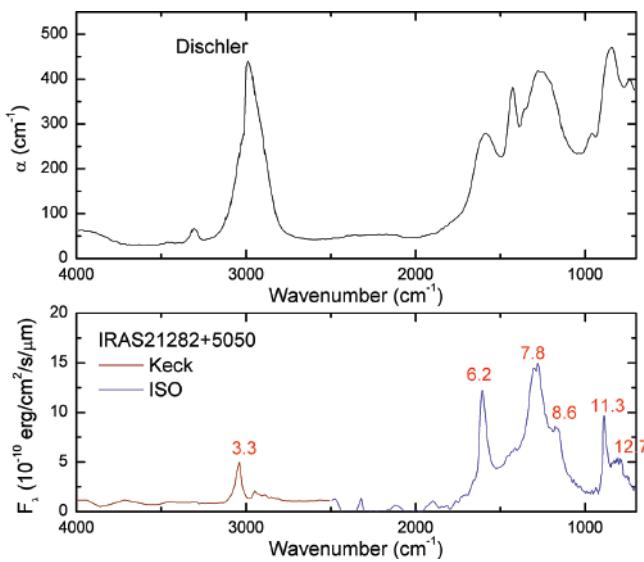

FIGURE 4.2.8 Laboratory infrared spectra (inverted from absorption) of hydrogenated amorphous carbon (top, from Dischler et al. 1983) compared with the astronomical spectrum of the planetary nebula IRAS 21282 + 5050 (bottom panel). The UIE bands are labeled by their wavelengths in micrometers.

In order to identify possible carriers of the UIE bands, it would be useful to see what carbonaceous products can naturally exist in the interstellar medium. By introducing H into graphite and diamond (both crystalline forms of pure carbon), a variety of amorphous C–H alloys can be created (Robertson and O'Reilly 1987; Jones et al. 1990; Jones 2012a, 2012b, 2012c; Jones et al. 2013). Different geometric structures with long and short ranges can be created by varying the aromatic to aliphatic and C to H ratios. The infrared spectra of these amorphous carbonaceous materials (Dischler et al. 1983) show resemblance to the astronomical UIE bands seen in planetary nebulae and proto-planetary nebulae (Figure 4.2.8). Since these amorphous carbonaceous solids have absorption bands in the visible, they can be easily excited by visible light from stars.

By the early 1980s, it was known that carbon clusters can be produced by laser vaporization of graphite, followed by supersonic expansion into an inert gas. The employment of this technique has led to the discovery of fullerene, a new form of carbon (Kroto et al. 1985). Since then, various techniques based on laser pyrolysis of gas-phase hydrocarbons, followed by condensation, have been used to create laboratory counterparts of cosmic organic dust (Jäger et al. 2009). These include the quenching of plasma of 4-torr methane (Sakata et al. 1987), hydrocarbon flame or arc discharge in a neutral of hydrogenated atmosphere (Colangeli et al. 2003; Mennella et al. 2003), laser ablation of graphite in a hydrogen atmosphere (Scott and Duley 1996; Mennella et al. 1999), infrared laser pyrolysis of gas-phase hydrocarbon molecules (Herlin et al. 1998), and photolysis of methane at low temperatures (Dartois et al. 2004).

Amorphous carbonaceous solids are known to be naturally produced through the process of combustion. Soot is formed by igniting a mixture of gas-phase hydrocarbons with oxygen,

resulting in amorphous structures consisting of islands of aromatic rings linked by aliphatic chains (Pino et al. 2008).

In addition to soot, there are also other natural decayed products of living organisms such as coal and kerogen that have similar amorphous mixed aromatic/aliphatic properties (Painter et al. 1981). The infrared spectra of soot (Keifer et al. 1981), coal (Guillois et al. 1996; Ibarra et al. 1996; Papoular 2001), and petroleum and asphaltenes (Cataldo et al. 2002, 2013), all show spectral features similar to the astronomical UIE bands.

As the results of these laboratory developments, alternate models for the UIE phenomenon have been proposed. These include hydrogenated amorphous carbon (HAC, Duley 1993); soot and carbon nanoparticles (Hu and Duley 2008); quenched carbonaceous composite particles (QCCs, Sakata et al. 1987); kerogen and coal (Papoular et al. 1989); petroleum fractions (Cataldo et al. 2002), and mixed aromatic/aliphatic organic nanoparticles (MAONs, Kwok and Zhang 2011, 2013). In the coal, petroleum, and MAON models, other elements such as O, S, and N are also incorporated into the hydrocarbon compounds. In a natural environment such as circumstellar envelopes of evolved stars, where a mix of cosmic elements is present, it is expected that any organic product of synthesis will contain other elements beyond C and H. A schematic illustration of part of a MAON structure is shown in Figure 4.2.9.

The advantages of such amorphous models are that the vibrational bands are naturally broad and do not need to be artificially broadened, as in the case of PAH molecules. The disadvantages are that although some experimental spectra of these materials have been obtained in the laboratory, the exact vibrational modes of the features are not known.

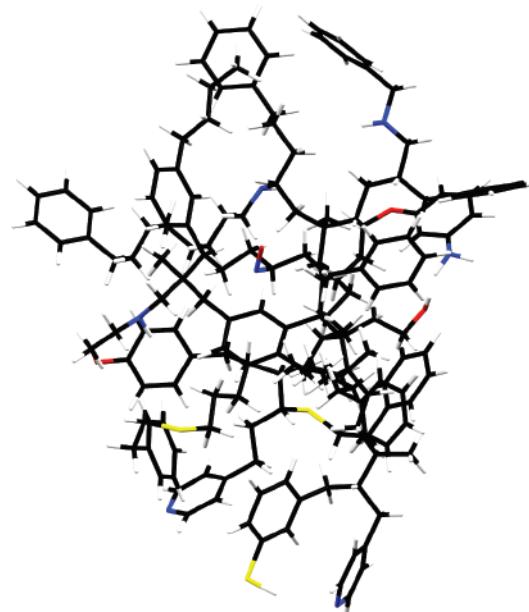

FIGURE 4.2.9 A three-dimensional (3-D) illustration of a possible partial structure of a MAON particle. Carbon atoms are represented in black, hydrogen in light gray, sulfur in yellow, oxygen in red, and nitrogen in blue. There are 169 C, 225 H, 7 N, 4 O, and 3 S atoms in this example.

Theoretical calculations are needed to analyze the vibrational modes of HACs, QCCs, and MAONs (Sadjadi et al. 2015a). If these molecules are too large to be transiently heated by single-photon excitation, alternative excitation mechanism such as chemical excitation needs to be considered (Duley and Williams 1988, 2011).

4.2.6 OTHER UNIDENTIFIED CIRCUMSTELLAR SPECTRAL PHENOMENA

There are a number of unidentified circumstellar spectral phenomena whose carriers are likely to be organic compounds. The 30 μm feature was discovered in C-rich AGB stars and planetary nebulae (Forrest et al. 1981), and the 21 μm feature was discovered in proto-planetary nebulae (Kwok et al. 1989). High-resolution *Infrared Space Observatory* (*ISO*) and *Spitzer* observations have found that all observed 21 μm features have the same intrinsic profile and peak wavelength (20.1 μm) (Volk et al. 1999; Hrivnak et al. 2009). An example of the 21 and 30 μm features is shown in Figure 4.2.10. Strong 8 and 12 μm plateau features are seen, suggesting that there is a link between the 21 and 30 μm features and the UIE phenomenon.

These two unidentified emission features can carry a large fraction of the total energy output of the central stars – up to 8% for the 21 μm and 20% for the 30 μm features (Hrivnak et al. 2000). This implies that carrier must be made of common elements. The fact that the features are seen only in C-rich (based on photospheric absorption spectrum) objects suggests that the carrier is carbonaceous.

The extended red emission (ERE) is a broadband optical emission seen in reflection nebulae and planetary nebulae. It is likely to be the result of photoluminescence from semiconductor solid particles (Witt et al. 1998). Some of the over-

500 unidentified diffuse interstellar bands (DIBs, Sarre 2006) observed in absorption in the diffuse interstellar medium are also seen in circumstellar envelopes (Van Winckel et al. 2002), suggesting that some of the carriers of DIBs are also synthesized in circumstellar envelopes.

4.2.7 TIME SEQUENCE OF CIRCUMSTELLAR ORGANIC SYNTHESIS

The detection of simple molecules in early AGB stars to complex organics in planetary nebulae suggests that the synthesis of organic dust is not a breakdown of biological compounds but a bottom-up synthesis from simple molecules. The formation of the linear molecule acetylene in highly evolved AGB stars (Volk et al. 2000) is the first step for the formation of benzene (Cernicharo et al. 2001), the simplest aromatic molecule, in proto-planetary nebulae. The emergence of aromatic and aliphatic bands in the transition from AGB to planetary nebulae suggests that small rings group into larger aromatic islands, attached with aliphatic side groups. Since circumstellar chemical synthesis must occur over timescales much shorter than the dynamical timescale of expansion of the nebula and evolution timescales of the central star, we know that circumstellar organic synthesis occurs at 10^3 – 10^4 year timescales.

4.2.8 RELATIONSHIP BETWEEN STELLAR, INTERSTELLAR, AND SOLAR SYSTEM ORGANICS

Although it was commonly believed that solar system objects were made of minerals, metals, and ices, we now know that meteorites, asteroids, comets, planetary satellites, and interplanetary dust particles contain organic materials. Since the early discoveries of hydrocarbons and amino acids in meteorites (Nagy et al. 1961; Kvenvolden et al. 1970), we now know that meteorites contain rich assortment of prebiotic compounds, which are entirely of abiotic origin. In the soluble component of carbonaceous chondrites, almost all biologically relevant organic compounds can be found (Schmitt-Kopplin et al. 2010).

The insoluble organic matter (IOM) of carbonaceous chondrites is composed of highly substituted single-ring aromatics, substituted furan/pyran functional groups, highly branched oxygenated aliphatics, and carbonyl groups (Cody et al. 2011). The 3.4 μm feature found in proto-planetary nebulae, in planetary nebulae, and in the diffuse interstellar medium is also detected in meteorites (Cronin and Pizzarello 1990; Ehrenfreund et al. 1991), interplanetary dust particles (Flynn et al. 2003), comets (Keller et al. 2006), and the haze of Titan (Kim et al. 2011) and Saturn (Kim et al. 2012). The relative elemental abundance in the IOM ranges from $\text{C}_{100}\text{H}_{70}\text{N}_3\text{O}_{12}\text{S}_2$ for Murchison meteorite to $\text{C}_{100}\text{H}_{46}\text{N}_{10}\text{O}_{15}\text{S}_{4.5}$ for the Tagish Lake meteorite (Pizzarello and Shock 2017). The detection of anomalous isotopic ratios in elements in IOM suggests that at least part of the IOM is of presolar origin.

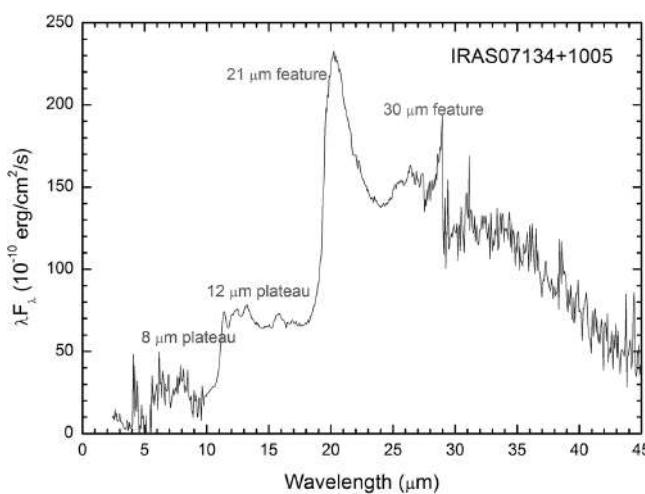

FIGURE 4.2.10 Combined *ISO* SWS and LWS and *Spitzer* IRS spectra of the proto-planetary nebula IRAS07134 + 1005, showing the 21 and 30 unidentified emission features. No atomic line is seen in the infrared spectrum of this proto-planetary nebula. Also seen in the spectra are broad plateau emission features around 8 and 12 μm . All these features sit on top of a strong continuum.

4.2.9 DELIVERY OF STELLAR ORGANICS TO THE SOLAR SYSTEM

Since most (~95%) stars in our galaxy go through the AGB and planetary nebulae phases of evolution, large amounts of mineral and organic solids are produced by ordinary stars over the last 10 billion years in our Milky Way Galaxy. These products are ejected into the interstellar medium and spread throughout the galaxy, and evolved stars therefore represent a major source of molecules and solids in the galaxy. Direct evidence for stellar grains to have traveled across the galaxy to arrive at the solar system and to Earth can be found in the form of presolar grains in meteorites. Presolar grains are grains of diamonds, silicon carbide, corundum, and spinel that have isotopic abundances not typical of the solar system but consistent with origin in AGB stars (Zinner, 1998; Davis 2011). Since macroscopic organics such as MAON, kerogen, and IOM are extremely sturdy, they are therefore likely to be able to transverse across interstellar space, even under high-UV-radiation background and dynamical shock conditions. Stardust therefore plays an important role in the chemical enrichment of the galaxy and possibly also of the primordial solar system (Kwok 2004; Ziurys et al. 2016).

Possible links between solar system organics and stellar organics can be tested by isotopic ratios. The isotopic signatures of IOM in the Murchison meteorite are consistent with at least in part being presolar in origin (Pizzarello and Shock 2017). Further work is needed to determine the origin of solar system organics, whether these organics were made in the early solar system or were delivered from stellar sources.

4.2.10 ORGANIC RESERVOIR ON EARTH

The Earth has a large reservoir of organics, almost all of which are biological in origin. The total amount of C in the living biosphere (Earth's crust, ocean, and atmosphere) is about 1000 Gigatons (GT). In addition, there are about 4000 GT of fossil fuels in the form of petroleum, coal, and natural gases. The majority of which – 15,000,000 GT – are in the form of kerogen, a macromolecular compound found in sedimentary rocks (Falkowski et al. 2000). Although kerogen and fossil fuels are all remnants of past life, there is a small amount of hydrocarbons found in hydrothermal vents that is of abiological origin (Sherwood Lollar et al. 2002).

The possibility that there may be primordial organics in Earth was suggested by Gold (1999). At that time of Gold's writing, gas-phase organic molecules had already been known to be widely present in interstellar space. Gold suggested that the early Earth might have trapped inside a large reservoir of methane, which could serve as a precursor of fossil fuels, which later flowed from the interior to the surface. This theory was never taken seriously by geologists, because interstellar methane gas would have great difficulty surviving the high temperature and shock during the coalescence process of Earth formation.

At a more general level, although abiotic theories of the origin of oil were seriously discussed in the Soviet Union, they were never popular in the West, in part because of the

well-established links between petroleum and life in the form of nickel- and vanadium-porphyrin complexes in petroleum, iron-porphyrin and hemoglobin in animals, and magnesium chlorophyll in plants. However, in addition to biological formation of fossil fuels, there exists the additional possibility of primordial organics deep inside the Earth. If the primordial hydrocarbon was in the form of a macromolecular compound, its chances of survival during Earth's formation would have been much higher than that in the case for methane. If such primordial macro-organics are embedded deep inside the Earth, they would be difficult for us to discover with present technology. If such primordial organics does exist and can be retrieved, the economic impact could be immense.

4.2.11 EFFECTS OF STAR DUST ON THE ORIGIN OF LIFE ON EARTH

Since the Oparin–Haldane hypothesis (Haldane 1929; Oparin 1938) and the Miller–Urey experiment (Miller 1953), it has been commonly assumed that life on Earth originated from chemical reactions of simple ingredients in a suitable environment (primordial soup). The theory of endogenous synthesis as the basis of origin of life has been the dominant theory in the past 50 years. However, with the observation of stellar synthesis of organics and the wide presence of complex organics among solar system objects, the exogenous delivery hypothesis has been gaining acceptance. The most widely discussed agents for exogenous delivery are comets, asteroids, interplanetary dust particles, and micrometeorites. The influx rate at present for micrometeorites is estimated to be ~30,000 tons year⁻¹, but the rates were much higher during the early 500 million years of the Earth's history during the period of heavy early bombardment. Stellar MAON-like materials embedded in comets and asteroids have a good chance of survival upon impact.

We cannot rule out the possibility that the planetismals that aggregated to form the primordial Earth may have contained remnants of macromolecular star dust. These organics could well survive the heat and shock conditions during the Earth-formation process. If this is the case, then there could exist primordial organics deep inside the interior of the Earth (Kwok 2017).

Under suitable temperature and pressure conditions, for example, those in hydrothermal vents, organic components such as hydrocarbons; dicarboxylic acids; N-, O-, and S-containing aromatic compounds; as well as ammonia can be released from macromolecular compounds (Yabuta et al. 2007; Pizzarello et al. 2011). These prebiotic materials could form the ingredients of the first steps to life in the early Earth. Whether life on Earth originated on the surface in water, or deep inside the Earth, is an interesting question for further exploration.

4.2.12 CONCLUSIONS

In the early twentieth century, the discipline of astrophysics was born out of development of atomic and nuclear physics. The discipline of astrochemistry, or the study of molecules and minerals in space, began only 50 years ago as the result of advances in observing capabilities in the infrared and

millimeter-wave regions of the electromagnetic spectrum. The discipline of astrobiology, trying to bridge the gap between molecules and life, is still in its infancy. The unexpected discovery of common presence of organics in the solar system and in the interstellar medium gives us the optimism and hope for the future of this new discipline.

From the analysis of organic matter in meteorites and other solar system objects, we now know that abiotic synthesis can create a wide range of organic compounds far beyond those found on Earth. This hints that the degrees of complexity and diversity of prebiotic organics are much larger than previously thought (Meringer and Cleaves 2017). It is therefore not surprising that there still remains a number of unexplained astronomical spectral phenomena, as the carrier of these phenomena may be organic compounds that we are unfamiliar with in the terrestrial environment.

The circumstellar envelopes of evolved stars provide the only laboratory where such abiotic organic synthesis is directly observed to take place. Based on spectroscopic observations of evolved stars in different stages of evolution, we learn that organic molecules and solids can be synthesized in near-vacuum conditions over very short timescales. This suggests that our understanding of chemical reactions based on terrestrial conditions is inadequate to explain chemistry at work in the universe.

From the fact that UIE features are seen in galaxies, with redshifts as high as 2, we know that organic synthesis took place soon after the nucleosynthesis of the element carbon, as early as 10 billion years ago (Kwok 2011). Since our Sun and our solar system came into existence only 4.6 billion years ago, life could have emerged a very long time ago elsewhere in our galaxy and beyond. Since terrestrial biochemistry only represents a very small branch of the possible biochemical pathways in the universe, life as we know it can be totally different from life evolved from similar prebiotic ingredients but under different conditions and pathways. If some of these extraterrestrial lives had developed into intelligent life, the level of extraterrestrial intelligence is far beyond our imagination. Our present study of the abiotic synthesis of complex organics in the circumstellar environment therefore represents a small but important step in our understanding of intelligent life in the universe.

4.3.1 INTRODUCTION

Life emerged on the early Earth ~3.8 to ~3.5 billion years ago (Schidlowski 1988; Rosing 1999; Furnes et al. 2004; Rosing and Frei 2004; Westall et al. 2006, 2011a, 2011b; Sugitani et al. 2009; Javaux et al. 2010; Wacey et al. 2010). The building blocks necessary for the first living organisms to self-assemble and for life to emerge may have been provided by two main sources: endogenous and exogenous (Cleaves and Lazcano 2009). The atmosphere of the primitive Earth, before the rise of the oxygen ~2.5 billion years ago, is thought to have been relatively non-reducing, that is, mainly composed of molecular nitrogen, carbon dioxide and water vapour (Kasting et al. 1993; Olson 2006; Zahnle et al. 2010). In these conditions, only limited amounts of organic compounds may have been produced (Schlesinger and Miller 1983a, 1983b;

Plankensteiner et al. 2004; Cleaves et al. 2008). Submarine hydrothermal systems may have also contributed to the synthesis of organic molecules on the early Earth. However, there is little consensus on the real likelihood of this (Bernhardt et al. 1984; White 1984; Miller and Bada 1988; Bada et al. 1995; Imai et al. 1999; McCollom et al. 1999; Ito et al. 2006; Aubrey et al. 2009; Kopetzki and Antonietti 2011).

The primitive Earth may have also received the necessary organic molecules via exogenous delivery, as it was bombarded by comets, asteroids and their fragments (i.e., meteorites, micrometeorites and interplanetary dust particles [IDPs]) between 4.56 and 3.8 billion years ago (Schidlowski 1988; Chyba and Sagan 1992; Schopf 1993). Comets are known to contain several extra-terrestrial molecules (Crovier and Bockelée-Morvan 1999; Bockelée-Morvan et al. 2004;

Crovisier et al. 2009; Mumma and Charnley 2011). Comet Wild-2 contains glycine (Elsila et al. 2009), while comet 67P/Churyumov–Gerasimenko has carbon-rich species (e.g., alcohols, carbonyls, amines, nitriles, amides and isocyanates), the polymer polyoxymethylene (Goesmann et al. 2015; Wright et al. 2015), phosphorus and glycine (Altwegg et al. 2016). Although, to date, no other amino acids besides glycine have been detected in comets, amino acid precursors have been observed in comets (Bockelée-Morvan et al. 2000; Mumma et al. 2003; Crovisier et al. 2009). Furthermore, *ab initio* molecular dynamics simulations showed that shock waves passed into ice mixtures, representative of comets, could theoretically yield amino acids (Goldman et al. 2010). This was confirmed by hypervelocity impact shock experiments simulating comet impacts, which proved that the impact of comets produces α -amino acids (Martins et al. 2013) and that glycine oligomerisation up to trimers is possible (Sugahara and Mimura 2014). Micrometeorites and IDPs are a set of extra-terrestrial particles known to contain organic molecules, including ketones, aliphatic and polycyclic aromatic hydrocarbons (PAHs) and their alkylated derivatives. Amino acids were also identified at low abundances, or their detection was tentatively. In any case, it is not certain whether any of these molecules are indigenous to the micrometeorites and IDPs or terrestrial contamination (Clemett et al. 1993, 1998; Brinton et al. 1998; Flynn et al. 2003, 2004; Glavin et al. 2004; Keller et al. 2004; Matrajt et al. 2004, 2005). Ultra-carbonaceous Antarctic Micrometeorites (UCAMMs) are also a set of extra-terrestrial particles that contain up to ~80% of carbonaceous material, which is one of the highest organic matter contents detected in an extra-terrestrial body (Duprat et al. 2010; Dartois et al. 2013). They contain unusually high nitrogen- and deuterium-rich organic matter (Dartois et al. 2013). Meteorites have also been extensively analysed, and they contain extra-terrestrial organic matter, including organic compounds that presently have a role in terrestrial biochemistry.

4.3.2 METEORITES

Meteorites are extra-terrestrial objects that survive the passage through the Earth's atmosphere and impact the Earth's surface. Most are chondrites (more than 86%), which are primitive samples that have not been melted and are named after the chondrules that almost all of them contain (i.e., silicate millimetre-sized spherules, formed by melting or partial melting before accretion into the meteorite parent bodies). The remaining meteorites (less than 14%) have experienced melting and differentiation (McSween and Huss 2015). Chondrites are divided into ordinary (O), enstatite (E), carbonaceous (C), Rumuruti (R) and Kakangari (K) chondrites. The O, E and C chondrites are all further subdivided, according to their bulk chemical composition (Bischoff et al. 2011; Krot et al. 2014; McSween and Huss 2015). Carbonaceous chondrites contain a large variety of groups named after their type specimen (CI, CM, CK, CO, CR and CV), two unusual groups that have been affected by impact processes

(CH and CB) as well as grouplets and ungrouped carbonaceous chondrites (Choe et al. 2010 and references therein). Chondrites are also classified and grouped into petrographic types, according to the intensity of thermal metamorphism or aqueous alteration that occurred on the meteorite parent body and range from types 1 to 6 (McSween 1979; Browning et al. 1996). A petrologic type from 3 to 1 indicates increasing aqueous alteration, due to the melting of ices in the meteorite parent bodies, which occurred most likely due to the heating from the decay of short-lived radionuclides (e.g., ^{26}Al) (Grimm and McSween 1989). A petrologic type from 3 to 6 indicates increasing thermal metamorphism, that is, is the adjustment of the minerals (with the formation of anhydrous secondary phases, in most cases) in response to the increased temperatures in the meteorite parent body. Chondrites may be further subdivided into petrologic subtypes (Sears et al. 1980; Browning et al. 1996; Rubin et al. 2007; Alexander et al. 2013). Thermal metamorphism and aqueous alteration seem to influence the chemical content of chondrites (Browning et al. 1996; Palmer and Lauretta 2011; Vinogradoff et al. 2017).

4.3.3 CHEMICAL COMPOSITION AND ORGANIC MATTER IN CARBONACEOUS CHONDRITES

The chemical compositions of carbonaceous chondrites match the chemistry of the Sun more closely than of any other class of chondrites, with their bulk chemical compositions being very similar to that of the solar photosphere, except for the gaseous elements (e.g., H and He) (Lodders 2003). Therefore, carbonaceous chondrites are the most primitive meteorites, having preserved the history of the early solar system. They are usually composed of chondrules, calcium-aluminium-rich inclusions (CAIs) (most are up to 1-centimetre irregular-shaped white inclusions, composed mainly of oxides and silicates of calcium, aluminium, magnesium and titanium) and a fine-grained matrix of phyllosilicates, oxides, sulphides and carbonates (King et al. 2017). Carbonaceous chondrites, as the name indicates, have relatively high carbon content (~3.5 wt.%) (Alexander et al. 2017), which is present in different forms, including silicon carbide, graphite, diamonds, carbonate and organic matter (Smith and Kaplan 1970; Lewis et al. 1987; Fredriksson and Kerridge 1988; Grady et al. 1988; Amari et al. 1990, 1993; Anders and Zinner 1993; Zinner et al. 1995; Hoppe et al. 1996; Benedix et al. 2003). More than 70% of the organic matter is composed of solvent-insoluble organic matter (IOM) (Gardinier et al. 2000; Cody et al. 2002; Cody and Alexander 2005), which can be isolated from the meteorite by using hydrochloric acid (to remove carbonates) and hydrofluoric acid (to remove silicates) (Robert and Epstein 1982). Alternatively, caesium fluoride may be used at room temperature (Cody et al. 2002). The remaining less than 30% is a mixture of solvent-soluble organic compounds, which may be extracted and isolated by using organic solvents of different polarities.

4.3.4 INSOLUBLE ORGANIC MATTER IN CARBONACEOUS CHONDRITES

The insoluble organic material in carbonaceous chondrites contains carbon, hydrogen, nitrogen, oxygen and sulphur. These elements vary within carbonaceous chondrites, with the bulk compositions of their IOMs (normalised to 100 carbons) in the range of $C_{100}H_{75-79}N_{3-4}O_{11-17}S_{1-3}$ for the most primitive chondrites, $C_{100}H_{70}N_3O_{12}S_2$ for Murchison (a CM2) and $C_{100}H_{70-80}N_{3-4}O_{15-20}S_{1-4}$ for CR chondrites (Pizzarello et al. 2006; Alexander et al. 2007, 2017). The IOM contains graphitic flakes, spheres, tubes (Nakamura et al. 2002; Garvie and Buseck 2004) and macromolecular organic compounds. The determination of the functional groups of the macromolecular organic compounds may be done by using thermal or chemical degradation methods, which are used to break the IOM down into smaller components. Chemical degradation studies (e.g., oxidation reactions with $Na_2Cr_2O_7$, CuO or RuO_4) have shown that the IOM is composed of aromatic compounds, bridged by short, highly branched aliphatic linkages that contain ether or ester functional groups (Hayatsu et al. 1977, 1980; Remusat et al. 2005a; Huang et al. 2007).

Pyrolysis has also been used to identify the main components of the IOM in carbonaceous chondrites, and two fractions have been identified: one labile (i.e., liberated by pyrolysis and enriched in deuterium D, ^{13}C and ^{15}N) and one refractory (i.e., more resistant to pyrolysis and depleted in ^{13}C and ^{15}N) (Sephton et al. 2003, 2004). Aromatic molecules with 1–3 rings and short aliphatic side chains have been identified as the dominant fraction in IOM pyrolysates (Komiya et al. 1993; Komiya and Shimoyama 1996; Remusat et al. 2005b; Wang et al. 2005). On the other hand, Okumura and Mimura used gradual and stepwise pyrolysis and found that the linkage and substituent portion of the IOM consisted of saturated and unsaturated aliphatic hydrocarbons up to C_8 , substituted and non-substituted aromatic hydrocarbons with up to six rings, sulpho and thiol groups and carboxyl and hydroxyl groups (Okumura and Mimura 2011). Remusat et al. (2005b) performed pyrolysis analysis to reveal ester and ether functional groups as linkages between the aromatic units, which is in agreement with chemical degradation studies. In addition to conventional pyrolysis, hydrous pyrolysis (i.e., high temperature in the presence of pressurised water) and hydrolysis (i.e., high-pressure H_2) have been used. The free radical that is formed during pyrolysis when an IOM bond is cleaved will react with the available hydrogen from the water or the H_2 , respectively, preserving the structural features of the pyrolysates (Sephton et al. 1998, 2000, 2004, 2005, 2015; Sephton and Gilmore 2000, 2001; Yabuta et al. 2007). Hydrous pyrolysis analysis of the IOM of the carbonaceous meteorite Murray (CM2) revealed the presence of C_3-C_{17} alkyl dicarboxylic acids; N- and O-containing hydroaromatic and N-, O- and S-containing aromatic compounds; a series of PAHs of up to five rings, together with non-condensed aromatic species such as substituted benzenes, biphenyl and terphenyls, as well as their substituted homologs; and hydrated PAHs (Yabuta et al. 2007). On the other hand, hydrolysis analysis of the IOM

of the carbonaceous meteorite Murchison released one- to six-ring aromatic hydrocarbons and their methyl-substituted homologues (Sephton et al. 2004, 2005, 2015).

Non-destructive techniques have also been used to analyse the IOM: nuclear magnetic resonance (NMR) (Cronin et al. 1987; Gardiner 2000; Cody et al. 2002, 2011; Cody and Alexander 2005), Raman spectroscopy (Quirico et al. 2003; Bonal et al. 2006, 2007, 2016), high-resolution transmission electron microscopy (HRTEM) (Garvie and Buseck 2004; Derenne et al. 2005), Fourier-transform infrared spectroscopy (FTIR) (Pendleton et al. 1994; Kebukawa et al. 2011; Orthous-Daunay et al. 2013), X-ray absorption near-edge spectroscopy (XANES) (Cody et al. 2008; Orthous-Daunay 2010; Bose et al. 2014; Le Guillou and Brearley 2014; Le Guillou et al. 2014) and electron paramagnetic resonance (EPR) (Binet et al. 2002, 2004a, 2004b; Gourier et al. 2008). Nuclear magnetic resonance analysis has shown that the IOM contains small, highly substituted aromatic units and that the aliphatic component is short and highly branched (Gardiner et al. 2000; Cody et al. 2002; Cody and Alexander 2005). Furthermore, two-dimensional solid-state H and ^{13}C NMR analysis showed that the IOM of Murchison is composed primarily of highly substituted single-ring aromatics, substituted furan/pyran moieties, highly branched oxygenated aliphatics and carbonyl groups (Cody et al. 2011).

Carbonaceous chondrites contain small regions of the IOM that are extremely isotopically enriched relative to the surrounding matter (the so called “hotspots”), with δD values of up to $\sim 20,000\text{\textperthousand}$ and $\delta^{15}N$ values of $2000-3200\text{\textperthousand}$ (Busemann et al. 2006; Floss et al. 2014). D and ^{15}N enrichments of the bulk and of hotspots suggest that the IOM was formed in the interstellar medium (ISM) and/or in the outer solar system, being subsequently modified by nebular and parent body processes (Robert and Epstein 1982; Yang and Epstein 1983; Remusat et al. 2006; Alexander et al. 2007). Indeed, it has been suggested that there is a connection between the origin of chondritic IOM and comets (Alexander et al. 2017). This is supported by the elemental compositions of the comet Halley CHON particles being $\sim C_{100}H_{80}N_4O_{20}S_2$ (Kissel and Krueger 1987) as well as by the refractory carbon in comet 67P/Churyumov–Gerasimenko that is similar to chondritic IOM (Fray et al. 2016).

4.3.5 SOLUBLE ORGANIC COMPOUNDS IN CARBONACEOUS CHONDRITES

The soluble organic matter (SOM) in the CM2 chondrite Murchison has a bulk composition of $\sim C_{100}H_{155}O_{20}N_3S_3$, with a high molecular diversity of tens of thousands of different molecular compositions (Schmitt-Kopplin et al. 2010). Carbonaceous chondrites contain an extensive list of indigenous soluble organic compounds: carboxylic acids, amino acids, diamino acids, dipeptides, diketopiperazines, sulphonic and phosphonic acids, purines, pyrimidines, sugars and sugar-related compounds, hydrocarbons, alcohols, amines, amides, aldehydes and ketones. Four approaches may be used

to determine if these organic compounds are indigenous to the carbonaceous chondrites (i.e., that they are not terrestrial contamination) (Martins et al. 2007a; Martins and Sephton 2009): (1) detection of molecules that are unusual in the terrestrial environment; (2) comparison of the absolute abundances of organic molecules in the meteorites with the abundances found in the fall site; (3) determination of enantiomeric ratios for chiral molecules and (4) measurement of the compound-specific carbon, hydrogen or nitrogen isotopic compositions. Stable isotope compositions are expressed in δ (‰) values, according to the following formula:

$$\delta(\%) = \frac{(R_{\text{sample}} - R_{\text{standard}})}{R_{\text{standard}}} \times 1000$$

where R stands for D/¹H for hydrogen, ¹³C/¹²C for carbon and ¹⁵N/¹⁴N for nitrogen. The standards used are the Vienna standard mean ocean water (VSMOW) for hydrogen, Vienna Pee Dee Belemnite (VPDB) for carbon and atmospheric nitrogen for nitrogen. The soluble organic compounds indigenous to carbonaceous meteorites are enriched in D, ¹³C and ¹⁵N (e.g., Yuen et al. 1984; Krishnamurthy et al. 1992; Cronin et al. 1993; Cooper et al. 1997). D and ¹⁵N enrichments of the SOM suggest low-temperature formation of precursors in the ISM (e.g., gas-phase ion-molecule reactions), in which chemical fractionation is efficient (Tielens 1983; Yang and Epstein 1983; Millar et al. 1989; Terzieva and Herbst 2000; Sandford et al. 2001; Robert 2003; Aléon and Robert 2004).

4.3.5.1 MONOCARBOXYLIC ACIDS

Carboxylic acids are the most abundant class of soluble compounds in carbonaceous chondrites. Monocarboxylic acids were first reported in carbonaceous meteorites by Yuen and Kvenvolden (1973), followed by studies from Lawless and Yuen (1979) and Yuen et al. (1984). The CM2 Murchison and Murray were analysed, and they contained a limited number of straight- and branched-chain monocarboxylic acids with two to eight carbon atoms and abundances ranging from about 10 to 60 parts per million (ppm) for each individual compound (Yuen and Kvenvolden 1973). Shimoyama and co-authors analysed the monocarboxylic acid content of a few Antarctic carbonaceous chondrites. Yamato (Y)-791198 (CM2) contained aliphatic and aromatic monocarboxylic acids. The aliphatic monocarboxylic acids included saturated straight and branched-chain structures, ranging from 2 to 12 carbon atoms, with most structural isomers of C₄, C₅ and C₆ identified. The aromatic monocarboxylic acids included benzoic acid, methylbenzoic acid and phenylacetic acid (Shimoyama et al. 1986). Y-74662 (CM2) had several monocarboxylic acids, including aliphatic and aromatic structures. The aliphatic carboxylic acids contained saturated straight- and branched-chain structures in the range of C₂ to C₁₂. The four aromatic carboxylic acids were benzoic acid and *o*-, *m*- and *p*-methylbenzoic acids (Shimoyama et al. 1989). Y-793321 (CM2) was also analysed, and it contained no

monocarboxylic acids (Shimoyama et al. 1989). Naraoka et al. (1999) reported more than 30 monocarboxylic acids in Asuka (A)-881458 (CM2), including aliphatic and aromatic acids with various structural isomers. The straight-chain aliphatic monocarboxylic acids present in A-881458 had 2–12 carbon atoms, while the branched-chain structures had 4–9 carbon atoms. Aromatic monocarboxylic acids included benzoic acid and all three isomers of toluic acid. Two other CM2 chondrites (A-881280 and A-881334) were depleted in monocarboxylic acids, and Naraoka et al. (1999) suggested that these two chondrites may have been subjected to aqueous alteration or metamorphism on their meteorite parent bodies. More recently, Huang et al. (2005) identified more than 50 monocarboxylic acids on Murchison, using solid-phase micro-extraction (SPME). Martins et al. (2006) detected aromatic monocarboxylic carboxylic acids in the Murchison meteorite, including benzoic acid and all three isomers of methylbenzoic acid and hydroxybenzoic acid, while Orgueil (CI1) contained only benzoic acid and very small amounts of methylbenzoic acids and methylhydroxybenzoic acids. Aponte et al. (2011) analysed the monocarboxylic acid content of six carbonaceous chondrites with a range of classifications: Murchison (CM2), Elephant Moraine (EET) 87770 (CR2), Allan Hills (ALH) 83034 (CM1), ALH 83033 (CM2), Meteorite Hills (MET) 00430 (CV3) and Wisconsin Range (WIS) 91600 (CM2). These authors found an overall abundance of branched monocarboxylic acids over straight-chain ones and that EET 87770 and Murchison contained high concentrations and a complete suite of monocarboxylic acids. The remaining four meteorites (ALH 84034, ALH 84033, MET 00430 and WIS 91600) were depleted of high-molecular-weight branched monocarboxylic acids relative to their straight-chain counterparts (Aponte et al. 2011). Ivuna (CI1) was also analysed for these compounds, and it contained monocarboxylic acids with chain lengths from 1 to 10 carbon atoms, with few and less branched molecular species when compared with the Murchison meteorite (Monroe and Pizzarelli 2011).

4.3.5.1.1 Stable Isotope Measurements of Monocarboxylic Acids

The bulk $\delta^{13}\text{C}$ and δD values of the monocarboxylic acids' fraction in the Murchison meteorite ranged from $-3\text{\textperthousand}$ to $+6.7\text{\textperthousand}$ and from $+377\text{\textperthousand}$ to $+697\text{\textperthousand}$, respectively (Epstein et al. 1987; Krishnamurthy et al. 1992). Stable isotope values of individual monocarboxylic acids were also obtained. Yuen et al. (1984) obtained the first $\delta^{13}\text{C}$ values for six monocarboxylic acids (acetic acid, propionic acid, isobutyric acid, butyric acid, isovaleric acid and valeric acid), ranging from $+4.5\text{\textperthousand}$ to $+22.7\text{\textperthousand}$, while Huang et al. (2005) obtained $\delta^{13}\text{C}$ values for 48 individual monocarboxylic acids in the Murchison meteorite, ranging from $-31.8\text{\textperthousand}$ to $+32.5\text{\textperthousand}$. These authors also obtained δD values for the monocarboxylic acids in Murchison, which ranged from $-76.5\text{\textperthousand}$ to $+2024.0\text{\textperthousand}$ (Huang et al. 2005). They noted that, in general, straight-chain monocarboxylic acids had a relationship between increasing chain length and enrichment in lighter isotopes, supporting a

kinetically controlled carbon-addition reaction involving radicals, as has been suggested by Yuen et al. (1984). Huang et al. observed that the branched monocarboxylic acids were significantly more enriched in the heavier isotopes of carbon and deuterium than the straight-chain ones, which suggested different synthetic pathways for the two sets of monocarboxylic acids (Huang et al. 2005). More recently, Aponte et al. (2011) determined the δD and $\delta^{13}C$ values for straight- and branched-chain monocarboxylic acids for six carbonaceous chondrites: Murchison, EET 87770, ALH 83034, ALH 83033, MET 00430 and WIS 91600. The δD values ranged from -76.6 to $+1778.7\text{\textperthousand}$ (Murchison), $+302.5$ to $+1632.2\text{\textperthousand}$ (EET 87770), -212.2 to $+432.4\text{\textperthousand}$ (ALH 83034), -65.1 to $+646.2\text{\textperthousand}$ (ALH 83033), -156 to $+539.1\text{\textperthousand}$ (MET 00430), -37.8 to $+787.6\text{\textperthousand}$ (WIS 91600), while the $\delta^{13}C$ values ranged from -25.9 to $+11.3\text{\textperthousand}$ (Murchison), -70.0 to $+7.5\text{\textperthousand}$ (EET 87770), -64.0 to $+12.2\text{\textperthousand}$ (ALH 83034), -79.3 to $+0.4\text{\textperthousand}$ (ALH 83033), -80.8 to $+5.5\text{\textperthousand}$ (MET 00430), -36.8 to $+8.6\text{\textperthousand}$ (WIS 91600). Aponte et al. noted that Murchison and EET 87770 had the highest deuterium enrichments in their monocarboxylic acids; this was consistent with their relatively pristine nature. These authors also noted that branched monocarboxylic acids were more D-enriched than their straight-chain counterparts and that generally δD values decreased with increasing number of carbons (Aponte et al. 2011). Regarding the $\delta^{13}C$ for the monocarboxylic acids, the values were mostly in the range for terrestrial matter (Sephton and Botta 2005). Aponte et al. (2011) suggested two possible causes: (1) contribution of monocarboxylic acids from terrestrial sources (in which case, only the carbon isotopic compositions of the meteoritic monocarboxylic acids were lowered, and not the hydrogen isotopic compositions), or (2) the isotopic ratios reflect the original values (which would indicate different precursor compositions and synthetic pathways). The free monocarboxylic acids of the Lonewolf Nunataks (LON) 94101 (CM2) meteorite were also analysed, and they had δD values ranging from $+381\text{\textperthousand}$ to $+1720\text{\textperthousand}$ (Aponte et al. 2014a).

Overall, the carboxylic acids present in carbonaceous meteorites are enriched in deuterium and ^{13}C ; this is consistent with an interstellar origin or formation from interstellar precursors. Ethanoic acid and formic acid have been detected in the ISM (Zuckerman et al. 1971; Winnewisser et al. 1975; Turner 1989; Wootten et al. 1992; Mehringer et al. 1997). Data from Huang et al. (2005) and Aponte et al. (2011) support the suggestion by Cronin and Chang (1993) that random gas-phase reactions involving radicals and ions were responsible for the production of meteoritic monocarboxylic acids, prior to parent body accretion and processing. Alternatively, carboxylic acids may be formed by processing on the meteorite parent body by two methods: (1) Via hydrolysis of precursor molecules: Carboxylic and dicarboxylic acids can be formed via hydrolysis of carboxamides (Cooper and Cronin 1995). Also, α -hydroxycarboxylic acids could be formed via the Strecker-cyanohydrin reaction (Peltzer and Bada 1978; Peltzer et al. 1984; Cronin et al. 1993), which is supported by the presence of α -amino acids and iminodicarboxylic acids in carbonaceous meteorites (Lerner and Cooper 2005). However, the δD

and $\delta^{13}C$ values of α -hydroxycarboxylic acids were significantly lower than the ones for α -amino acids (Epstein et al. 1987; Pizzarelli et al. 1991), which would suggest different precursors for these two classes of compounds. (2) By the oxidation of hydrocarbons from the IOM or the oxidation of free hydrocarbons by oxidised fluids or minerals, via alcohol and ketone intermediaries (Martins et al. 2006).

4.3.5.2 DICARBOXYLIC ACIDS AND HYDROXYCARBOXYLIC ACIDS

Branched- and straight-chained aliphatic dicarboxylic acids were first detected in the Murchison meteorite (Lawless and Zeitman 1974). Further studies confirmed this detection and that the aliphatic dicarboxylic acids had up to nine carbon atoms (Martins et al. 2006; Peltzer et al. 1984; Shimoyama and Shigematsu 1994). The Murchison meteorite also had aromatic dicarboxylic acids, including methylphthalic acid and all three isomers of phthalic acid (Martins et al. 2006). Dicarboxylic acids were found in Ivuna, with linear alkyl-chain lengths of 4 to 14 carbon atoms and with several branched species up to 8 carbon atoms (Monroe and Pizzarelli 2011). Dicarboxylic acids present in Sutter's Mill (CM2) were almost exclusively linear species of 3 to 14 carbon atoms, with concentrations typically less than 10 nmole/g of meteorite (Pizzarelli and Garvie 2014).

Peltzer and Bada first detected seven α -hydroxycarboxylic acids in the Murchison meteorite, at the same concentration as hydrolysed amino acids (14.6 ppm in total) (Peltzer and Bada 1978). This number was later expanded by Cronin et al. (1993), who found almost 60 α -hydroxymonocarboxylic acids, with carbon chains through C_8 . Cronin et al. also found more than 50 α -hydroxydicarboxylic acids in Murchison, with carbon chains up to C_8 or C_9 . These authors showed that the hydroxycarboxylic acids and the hydroxydicarboxylic acids had a carbon-chain structure that corresponded to α -amino acids (α -aminocarboxylic acids and α -aminodicarboxylic acids, respectively), which suggested that they all share a common Strecker-cyanohydrin reaction pathway during aqueous alteration on the meteorite parent body (Peltzer and Bada 1978; Peltzer et al. 1984; Lerner et al. 1993). Hydrocarboxylic acids were also investigated in the Graves Nunataks (GRA) 95229 (CR2) and LaPaz Icefield (LAP) 02342 (CR2) meteorites (Pizzarelli et al. 2008, 2010). Results showed that 2-H-2-OH acids have distributions close to those of amino acids, supporting the hypothesis that these two groups of compounds were formed from common aldehyde precursors. Monroe and Pizzarelli detected several hydroxycarboxylic acids in Ivuna, which were the most abundant group of compounds in this meteorite (Monroe and Pizzarelli 2011).

4.3.5.2.1 Stable Isotope Measurements of Dicarboxylic Acids and Hydroxycarboxylic Acids

The bulk $\delta^{13}C$ and δD values of the combined hydroxydicarboxylic and dicarboxylic acids fractions in Murchison were $-6\text{\textperthousand}$ and $+357\text{\textperthousand}$, respectively, while the bulk $\delta^{13}C$ and

δD values of the hydroxycarboxylic acid fraction in the same meteorite were +4‰ and +573‰, respectively (Cronin et al. 1993). Dicarboxylic acids from Murchison had $\delta^{13}\text{C}$ values ranging from +19.1‰ to +28.1‰ and δD values ranging from +389‰ to +1550.7‰ (Pizzarello et al. 2001; Pizzarello and Huang 2002). ^{13}C and D isotopic enrichments were detected for several of the hydroxycarboxylic acids in the GRA 95229 (CR2) and LAP 02342 (CR2) meteorites, and the highest δD value (+3450‰) was displayed by GRA 95229 2-OH-2-methylbutyric acid (Pizzarello et al. 2010).

4.3.5.3 PYRIDINE CARBOXYLIC ACIDS

Pyridine carboxylic acids were detected in eight CM2 carbonaceous chondrites: ALH 85013, Dominion Range (DOM) 03183, DOM 08003, EET 96016, LAP 02333, LAP 02336, Lewis Cliff (LEW) 85311 and WIS 91600. Pyridine monocarboxylic acids negatively correlated with the degree of aqueous alteration of CM2-type meteorite parent bodies, suggesting that aqueous alteration may have destroyed some of these compounds (Smith et al. 2014).

4.3.5.3.1 Stable Isotope Measurements of Pyridine Carboxylic Acids

Pizzarello et al. (2004) have determined $\delta^{13}\text{C}$ values for nicotinic acid and methylnicotinic acid ($+20.3\pm1.7\text{\%}$ and $+20.3\pm1.2\text{\%}$, respectively) in Murchison. δD values were also determined for nicotinic acid in Murchison (+129‰) and for nicotinic methyl homologue in Murray (+621‰) Pizzarello and Huang (2005).

4.3.5.4 AMINO ACIDS

Kvenvolden et al. (1970) analysed the amino acid content of samples of the Murchison meteorite that had fallen in Australia the year before. These authors detected almost equal amounts of the enantiomers of D- and L-valine, proline, alanine and glutamic acid, which suggested an extra-terrestrial origin for these compounds. Furthermore, the presence of the non-proteinogenic amino acids 2-methylalanine and sarcosine was also indicative of a possible abiogenic synthesis. Samples of the Murchison meteorite were re-analysed in the next few years by different groups. Oro' et al. (1971) found similar results as the ones published by Kvenvolden et al. in 1970. Further studies by Kvenvolden et al. (1971) found a total of 18 amino acids in Murchison, including 12 non-proteinogenic amino acids. Lawless found at least 35 amino acids (i.e., 17 amino acids in addition to the 18 already detected in the Murchison meteorite by Kvenvolden et al. (1971)), which included a wide variety of linear and cyclic difunctional and polyfunctional amino acids (Lawless 1973). Since then, Murchison has been extensively analysed for amino acids (e.g., Glavin et al. 2006, 2010; Martins and Sephton 2009), and more recently, a new family of extra-terrestrial hydroxy amino acids has been detected in this meteorite (Koga and Naraoka 2017). Analyses by several groups have determined

a total amino acid abundance of around 60 ppm and identified more than 80 different amino acids, with carbon number from C₂ through C₈, complete structural diversity and a decrease in concentration with increasing carbon number within homologous series. Overall, they can be divided into two structural types (i.e., monoamino alcanoic acids and monoamino dialcanoic acids), with branched-chain amino acid isomers more abundant than straight-chain ones and with structural α configuration more abundant than γ configuration, which in turn is more abundant than the β configuration (e.g., Cronin et al. 1988; Cronin and Chang 1993; Martins and Sephton 2009).

Other carbonaceous chondrites have also been extensively analysed for amino acids (e.g., Martins and Sephton 2009). The CM2 chondrites have total amino acid abundances that vary, ranging from 71 ppm for Y-791198, (Shimoyama et al. 1985; Shimoyama and Ogasawara 2002) to nearly depleted for Y-79331 and Belgica (B-) 7904 (Shimoyama and Harada 1984). Other CM2 chondrites include Murray (Cronin and Moore 1971; Botta et al. 2002), Y-74662 (Shimoyama et al. 1979a, 1979b), LEW 90500 (Botta and Bada 2002; Glavin et al. 2006), Essebi, Mighei, Nogoya (Cronin and Moore 1976; Botta et al. 2002), Allan Hills (ALH) 77306 (Cronin et al. 1979; Holzer and Oro' 1979; Kotra et al. 1979), LON 94102 (Glavin et al. 2010), ALH 83100 (Glavin et al. 2006), Sutter's Mill (Burton et al. 2014) and Paris (Martins et al. 2015). CM1 chondrites (ALH 88045, Meteorite Hills (MET) 01070, LAP 0227 and Scott Glacier (SCO) 06043) are almost depleted of amino acids (Botta et al. 2007; Glavin et al. 2010). Aqueous alteration in the parent body of CM chondrites seems to contribute, at least partially, to the amino acid content and distribution, for example, the relative abundance of β -alanine increases with increasing aqueous alteration in the parent body of CM chondrites (Glavin et al. 2006; Martins et al. 2007a, 2015; Elsila et al. 2016). Increasing aqueous alteration may lead to the destruction of α -amino acids (previously formed by the Strecker-cyanohydrin synthesis; Peltzer and Bada 1978; Peltzer et al. 1984; Lerner et al. 1993) and the synthesis of β - and γ -amino acids in the parent body of carbonaceous chondrites (Cooper and Cronin 1995; Cronin and Chang 1993). Indeed, the CI1 chondrites Orgueil and Ivuna have high abundances of β -alanine and γ -aminobutyric acid (γ -ABA) (Lawless et al. 1972a; Ehrenfreund et al. 2001; Burton et al. 2014). Other two CI1 carbonaceous chondrites, Y-86029 and Y-980115, were analysed by liquid chromatography with fluorescence detection and time-of-flight mass spectrometry and contained low levels of L-amino acids, suggesting a terrestrial origin. Their lack of amino acids was explained by the fact that these two meteorites showed evidence of parent body heating, in combination with aqueous alteration (Burton et al. 2014).

The amino acid content of several CR chondrites has been determined. The CR2 EET 92042 and GRA 95229 were analysed for the first time for amino acids, and they had total concentrations of 180 ppm and 249 ppm, respectively, with the α -amino acids glycine, isovaline, α -AIB and alanine as the most abundant amino acids (Martins et al. 2007a). Similar amino acid abundances and distributions were found for the CR2 Miller Range (MIL) 090657 (Burton et al. 2016). Linear

α -amino acids were the most abundant amino acids in the CR2 LAP 02342 (Pizzarello and Holmes 2009), while glycine and α -AIB were the most abundant for Queen Alexandra Range (QUE) 99177, which had total amino acid abundances of 81 ppm (Glavin et al. 2010). Shisr 033, a CR2 chondrite from the Omani desert, had a small fraction of indigenous amino acids, as indicated by the presence of α -AIB, but overall, its amino acid content was similar to the one from the meteorite fall site soil (Martins et al. 2007b). Glycine, γ -ABA, and L-glutamic acid were the most abundant amino acids in the CR2 Renazzo (Botta et al. 2002). Finally, the CR1 Grosvenor Mountains (GRO) 95577 had very low amino acid content (i.e., total amino acid abundance of 900 parts per billion [ppb]), which included α -AIB, isovaline, γ -ABA and α -AIB (Martins et al. 2007a).

The CV3 Allende and Mokoia were found to be depleted in amino acids (Cronin and Moore 1971, 1976). Several years later, Burton et al. analysed several type 3 CV and CO carbonaceous chondrites: ALH 84028 (CV3), EET 96026 (CV3), LAP 02206 (CV3), GRA 06101 (CV3), Larkman Nunataks (LAR) 06317 (CV3), Allan Hills A (ALHA) 77307 (CO3), MIL 05013 (CO3) and DOM 08006 (CO3). They found total amino acid concentrations ranging from 300 ppb to 3200 ppb, with small, straight-chain, amine terminal (n - ω -amino) amino acids as the dominant amino acids detected (Burton et al. 2012). Similar results were found by Chan et al. (2012), who analysed the CO3 carbonaceous chondrites Colony and Ornans. They found high relative abundances (to glycine) of β -alanine and γ -ABA, suggesting that these amino acids may be formed from gas-grain reactions after the meteorite parent body cooled to much lower temperatures or during the cooling process (Chan et al. 2012). Burton et al. (2015) also found a similar amino acid distribution for R and CK chondrites. LAR 04318 (CK4), ALH 85002 (CK4), EET 92002 (CK5) and LAR 06872 (CK6) were depleted in amino acids, and NWA 5956 (CK3) experienced significant terrestrial amino acid contamination. PCA 82500 (CK4/5), LEW 87009 (CK6), LAP 03834 (R3) and LAP 031135 (R4) contained low levels of the straight-chain, amino-terminal (n - ω -amino) acids β -alanine and γ -ABA (Burton et al. 2015).

While most non-proteinogenic amino acids present in carbonaceous chondrites are racemic (i.e., equal amounts of D- and L-enantiomers), this is not true for all, and L-enantiomeric excesses have been reported for a few non-proteinogenic amino acids in Murchison, Murray and Orgueil (Martins and Sephton 2009). Cronin and Pizzarello found L-enantiomer excess for α -methylisoleucine and α -methylalloisoleucine (7.0% and 9.1%, respectively), as well as for isovaline and α -methylnorvaline in the Murchison meteorite (Cronin and Pizzarello 1997). Further analysis found L-enantiomer excesses (1.0%–9.2%) in six α -methyl- α -amino alkanoic acids (2-amino-2,3-dimethylpentanoic acid (both diastereomers), isovaline, α -methyl norvaline, α -methyl valine, and α -methyl norleucine) from Murchison and Murray by gas chromatography-mass spectroscopy (GC-MS) (Pizzarello and Cronin 2000). L-enantiomeric excesses of isovaline were found to range from 0% to 15.2%, using GC-MS, with a high variation within different stones of the same meteorites and within the same stone (Pizzarello

et al. 2003). In order to eliminate any experimental bias for these observations (i.e., interference from other C₅ amino acid isomers), Glavin and Dworkin used liquid chromatography-fluorescence detection (LC-FLD)/Time-of-Flight mass spectrometry (LC/ToFMS) and found L-enantiomeric excesses for isovaline of 18.5 ± 2.6% in Murchison and of 15.2 ± 4.0% in Orgueil (Glavin and Dworkin 2009). They found no L-enantiomeric excesses for isovaline in the unaltered Antarctic CR meteorites EET 92042 and QUE 99177, which suggested that amplification of a small initial L-enantiomeric isovaline excess occurred during aqueous alteration on the meteorite parent bodies. Similar conclusion was obtained by Martins et al. (2015), who analysed Paris, one of the least aqueously altered CM chondrites, and they found that isovaline was racemic (L-enantiomer excess = 0.35% ± 0.5%), supporting the hypothesis that aqueous alteration is responsible for the high L-enantiomer excess of isovaline observed in the most aqueously altered carbonaceous chondrites. Multidimensional GC, which is an improved method to accurately quantify amino acid enantiomers, was used by Myrgorodska et al. (2016), who found an L-enantiomeric excess of 4.61% ± 0.83% for isovaline in Murchison.

4.3.5.4.1 Stable Isotope Measurements of Amino Acids

Stable isotope analyses of individual amino acids in meteorites show that, with a few exceptions due to terrestrial contamination, they are enriched in D, ¹³C and ¹⁵N and have values in agreement with other meteoritic polar organic compounds (Sephton and Botta 2005). Engel and Macko (1997) determined $\delta^{15}\text{N}$ values for individual amino acids in Murchison, ranging from +37‰ to +184‰. Pizzarello et al. (2003) found individual D- and L-isovaline $\delta^{13}\text{C}$ values in Murchison of around +18‰, while the $\delta^{13}\text{C}$ values of more than 30 individual amino acids in the same meteorite ranged from +4.9‰ to +52.8‰ (Pizzarello et al. 2004). These authors observed that the α -methyl- α -amino acids were more enriched in ¹³C than the corresponding α -H- α -amino acids and that the ¹³C content declined with increasing chain length for the α -amino acids, which was in agreement with the trends observed for carboxylic acids and alkanes (Pizzarello et al. 2004). Ehrenfreund et al. (2001) determined the $\delta^{13}\text{C}$ values for β -alanine and glycine in Orgueil to be +18‰ and +22‰, respectively. $\delta^{13}\text{C}$ values were also determined for amino acids in EET 92042 and GRA 95229, and these ranged from +31.6‰ to +50.5‰ (Martins et al. 2007a). Overall, amino acids present in carbonaceous chondrites are outside the carbon isotopic range of terrestrial amino acids (−70.5‰ to +11.25‰) (Scott et al. 2006).

The δD values of more than 40 amino acids present in Murchison and Murray ranged from +181‰ to +3419‰ and from +60‰ to +3604‰, respectively, with higher D values for amino acids with branched alkyl chain (Pizzarello and Huang 2005). The enrichment in D (as well as in ¹⁵N) for amino acids in carbonaceous chondrites is in agreement with chemical fractionation of the amino acid precursors in the ISM (Terzieva and Herbst 2000; Sandford et al. 2001; Aléon and Robert 2004).

4.3.5.5 DIAMINO ACIDS

Diamino acids were detected in the Murchison meteorite by GC-MS analyses (Meierhenrich et al. 2004). These included DL-2,3-diaminopropanoic acid, DL-2,4-diaminobutanoic acid, 4,4'-diaminoisopentanoic acid, 3,3'-diaminoisobutanoic acid and 2,3-diaminobutanoic acid, and the chiral diamino acids were racemic. Meierhenrich et al. (2004) pointed out the poly-condensation reactions of diamino acids into early peptide nucleic acid material as one feasible pathway for the prebiotic evolution of DNA and RNA.

4.3.5.6 DIPEPTIDES AND DIKETOPIPERAZINES

The Y-791198 and Murchison meteorites were analysed for dipeptides and diketopiperazines (Shimoyama and Ogasawara 2002). Y-791198 contained 11 pmol/g and 18 pmol/g of glycylglycine (Gly-Gly) and cyclo(Gly-Gly), respectively, while Murchison contained 4 pmol/g and 23 pmol/g, respectively, of the same compounds. No other dipeptide and diketopiperazine were detected in this study. Shimoyama and Ogasawara suggested that the glycine dimers were formed by condensation of glycine monomers (Shimoyama and Ogasawara 2002).

4.3.5.7 SULPHONIC AND PHOSPHONIC ACIDS

Alkyl phosphonic acids and alkyl sulphonnic acids with carbon atoms up to C₄ were detected in the Murchison meteorite (Cooper et al. 1992). Five of the eight possible alkyl phosphonic acids and seven of the eight possible alkyl sulphonnic acids have been identified, with abundances decreasing with increasing carbon number. Concentrations range downward from approximately 380 nmol/gram in the alkyl sulphonnic acid series and from 9 nmol/gram in the alkyl phosphonic acid series (Cooper et al. 1992).

4.3.5.7.1 Stable Isotope Measurements of Sulphonic Acids

Cooper et al. (1997) observed that the δ¹³C values of sulphonnic acids in the Murchison meteorite decreased with increasing carbon number, with δ¹³C values of +29.8‰, +9.1‰, -0.4‰ and -0.9‰ for the methyl, ethyl, isopropyl, and n-propyl sulphonnic acids, respectively. δD values were also obtained in the same study: +483‰, +787‰, +536‰, and +852‰ for the methyl, ethyl, isopropyl, and n-propyl sulphonnic acids, respectively.

4.3.5.8 PURINES AND PYRIMIDINES

Purines and pyrimidines have been detected in several carbonaceous meteorites (Hayatsu 1964; Hayatsu et al. 1968, 1975; Folsome et al. 1971, 1973; Lawless et al. 1972b; Van der Velden and Schwartz, 1977; Stoks and Schwartz 1979, 1981; Shimoyama et al. 1990; Martins et al. 2008; Callahan et al. 2011). Purines and triazines were first isolated from the Orgueil meteorite and identified by paper chromatography by Hayatsu (1964). These results were confirmed by Hayatsu co-authors, who also detected guanylurea in the same meteorite

(Hayatsu et al. 1968). Folsome et al. (1971) extended the search to the Murchison meteorite and found 4-hydroxypyrimidine and two of its methyl-substituted isomers. These authors later extended their analysis to the Murchison, Murray and Orgueil meteorites and detected 4-hydroxypyrimidine, N,N,C-alkyl-ketohehexahydropyrimidines and a heterogenous class of (speculative) pyrimidines (Lawless et al. 1972b; Folsome et al. 1973), but no purines, triazines or guanylurea, which contrasted with the results from Hayatsu and co-authors (Hayatsu 1964; Hayatsu et al. 1968). In order to address this discrepancy in the results, Hayatsu et al. (1975) analysed Murchison by using mild extraction conditions (water or formic acid) and detection by mass spectrometry as well as paper chromatography and thin-layer chromatography. They only detected aliphatic amines and C₂-C₆ alkylpyridines. However, when they used drastic extraction conditions (hot, 3–6 M HCl or CF₃COOH), adenine, guanine, melamine, cyanuric acid, guanylurea and urea were detected, which suggested that these molecules were released from the macromolecular material. Furthermore, Hayatsu and co-authors suggested that the discrepancies were due to inadequate extraction conditions by Folsome and co-authors (Hayatsu et al. 1975). A couple of years later, Van der Velden and Schwartz (1977) again analysed the Murchison meteorite, this time using dual-column, ion-exclusion chromatography and ultraviolet (UV) spectroscopy. They detected for the first time xanthine in a formic acid extract. Guanine and hypoxanthine were also tentatively detected. Also, after silylation of a water extract, hydroxypyrimidines (4-hydroxypyrimidine, 4-hydroxy-2-methylpyrimidine and 4-hydroxy-6-methylpyrimidine) were identified, which suggested that these compounds previously detected in the Murchison meteorite were the result of contaminants present in the silylation reagent (Van der Velden and Schwartz 1977). Following this study, Stoks and Schwartz (1979) reinvestigated the presence of pyrimidines in extracts from Murchison, Murray and Orgueil by using fractionation techniques (i.e., activated charcoal, which separated the nucleobases from other organic compounds) and ion-exclusion chromatography with UV spectroscopy. They reported for the first time the presence of uracil in water and formic acid extracts of all three meteorites. Two years later, the same meteorites were analysed by Stoks and Schwartz (1981) by using GC, cation- and anion-exclusion liquid chromatography-mass spectrometry. Xanthine, adenine, hypoxanthine and guanine were detected in in formic acid extracts of all three meteorites. Hydroxypyrimidines and s-triazines were not detected in any of the extracts, and Stoks and Schwartz (1981) suggested that these molecules, previously detected by other authors, were formed during the experimental procedure. The search for purines and pyrimidines was then extended to other meteorites by other groups. Shimoyama et al. (1990) detected guanine and possible xanthine and hypoxanthine in Y-74662 and Y-791198 in formic acid extracts by using high-performance liquid chromatograph (HPLC) with UV spectroscopy. Y-793321 and B-7904 were also analysed, but no nucleobases were detected. Callahan et al. (2011) searched for nucleobases and nucleobase analogues in formic acid

extracts of several meteorites by liquid chromatography-mass spectrometry, including Orgueil, MET 01070, Scott Glacier (SCO) 06043 (CM1), ALH 83100, LEW 90500, LON 94102, Murchison, GRO 95577, EET 92042, GRA 95229 and QUE 99177 (CR3). Most of these meteorites contained adenine, while Murchison, LEW 90500 and LON 94102 had the most abundant concentrations of purines when compared with the other meteorites. Guanine, hypoxanthine, xanthine, adenine, purine and 2,6-diaminopurine were also detected in some of these meteorites (Callahan et al. 2011).

4.3.5.8.1 Stable Isotope Measurements of Purines and Pyrimidines

The variations in the content of purines and pyrimidines in fragments of the same meteorite indicated that the detected purines and pyrimidines may have had a terrestrial origin, either from direct contamination (since the meteorite fell to the Earth until it was analysed) and/or formed from impurities in the reagents used during the experimental procedure. This hypothesis remained opened until the beginning of the twenty-first century. Martins et al. (2008) performed for the first time compound-specific carbon isotope measurements of these compounds by using gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS), which is the ultimate way to determine the origin of purines and pyrimidines. These authors optimised the extraction and purification methods and detected purines and pyrimidines in formic acid extracts of the Murchison meteorite and of a soil collected in the proximity of the meteorite fall site. Carbon isotope ratios were obtained for uracil and xanthine in Murchison ($\delta^{13}\text{C} = +44.5\text{\textperthousand}$ and $+37.7\text{\textperthousand}$, respectively). On the other hand, uracil and thymine in the meteorite fall site had $\delta^{13}\text{C}$ values of $-10.6\text{\textperthousand}$ and $-15.9\text{\textperthousand}$, respectively, and xanthine was not detected. These results clearly showed that purines and pyrimidines detected in the Murchison meteorite were enriched in ^{13}C , that their $\delta^{13}\text{C}$ values fell outside of the terrestrial range and that they were indigenous to the meteorite.

4.3.5.9 SUGARS AND SUGAR-RELATED COMPOUNDS

Degens and Bajor (1962) detected sugars (70 ppm) in a sample of the Murchison meteorite by using paper chromatography. Sugars were also detected in eight carbonaceous chondrites (Orgueil, Cold Bokkeveld [CM2], Mighei [CM2], Murray, Mokoia [CV3], Felix [CO3.3], Lancé [CO3.5] and Warrenton [CO3.7]) in small quantities (5–26 ppm), with mannose and glucose as the most abundant (Kaplan et al. 1963). Several sugar-related compounds (sugar alcohols, sugar mono-acids, sugar di-acids and deoxysugar acids) and the simplest sugar molecule dihydroxyacetone were later detected in the Murchison and Murray meteorites as their trimethylsilyl (TMS) and/or tertiary butyl-dimethylsilyl (TBDMS) derivatives by using GC-MS (Cooper et al. 2001). Their indigeneity was indicated by the decrease of abundances with increase of carbon number within a class of compounds, almost complete structural diversity and stable isotopic values ($\delta^{13}\text{C} -5.89\text{\textperthousand}$ and $\delta\text{D} +119\text{\textperthousand}$) of a combined fraction of neutral polyols (Cooper et al. 2001).

4.3.5.10 HYDROCARBONS

The presence of *n*-alkanes in meteorites was first reported in analyses of Orgueil in 1961, and it was associated to biogenic activity (Nagy et al. 1961). Following this, Meinschein and co-authors analysed benzene extracts of the same meteorite and supported this conclusion by suggesting that the presence of the *n*-alkanes was evidence for biological activity in the meteorite parent body (Meinschein 1963a, 1963b; Meinschein et al. 1963). This was received with scepticism by other scientists, who did not agree with these conclusions (Anders 1962). Oró et al. (1966) analysed Orgueil, Murray, Mokoia, Alais (CI1), Ivuna, Al Rais (CR2-anomalous), Cold Bokkeveld, Mighei, Nogoya, Santa Cruz (CM2), Grosnaja (CV3), Kaba (CV3), Lancé (CO3.5), Ornans (CO3.4), Karoonda (CK4) and Warrenton (CO3.7) by using GC-MS. It was observed that all these meteorites contained paraffinic hydrocarbons; alkanes from C₁₅ to about C₂₅ were found in Orgueil, Murray and Mokoia; there was no predominance of odd over even carbon-number hydrocarbons, except in the C₂₂–C₂₇ normal alkane range of Orgueil; pristane and phytane, which are known to be degradation products of chlorophyll, were found in all meteorites, except Ornans; and the distribution of paraffinic hydrocarbons in some of these meteorites was found similar to that of microfossil-bearing pre-Cambrian rocks. Therefore, Oró et al. (1966) questioned whether the detected *n*-alkanes were indigenous to the meteorite or indeed terrestrial contamination. Support for the terrestrial contamination origin for the *n*-alkanes detected in meteorites came from further studies from Oró and Nooner (1967) and Nooner and Oró (1967). Their results showed that aliphatic hydrocarbons from several carbonaceous chondrites had the same chromatographic patterns as isoprenoids and other aliphatic hydrocarbons present in ancient sediments, crude oil, terrestrial graphite and other terrestrial samples. In addition, the external parts of the meteorites contained more aliphatic hydrocarbons than the inside, which supported a terrestrial contamination source (Nooner and Oró 1967; Oró and Nooner 1967). On the other hand, Studier et al. (1968, 1972) supported the hypothesis that the *n*-alkanes were indigenous to meteorites and were formed by abiotic processes. They found that the aliphatic hydrocarbons in the Murchison meteorite above C₈ included *n*-alkanes, mono- and dimethylalkanes and alkenes, while below C₈, the *n*-alkanes were absent. Isoprenoids from C₁₇ to C₂₀ occurred in a surface rinse and appeared to be terrestrial contaminants (Studier et al. 1972). Similar distribution was found in the Orgueil and Murray meteorites: aliphatic hydrocarbons above C₁₀ included paraffins and 2-methyl-, 3-methyl- and other slightly branched paraffins, while below C₁₀, the aliphatic hydrocarbons were not present (Studier et al. 1968). These authors considered the aliphatic hydrocarbon distribution found in the carbonaceous meteorites similar to the one synthesised from CO and D₂ in the presence of iron meteorite powder. According to them, this type of catalytic reactions (i.e., Fischer-Tropsch reaction) could have taken place in the solar nebula, converting CO to less volatile carbon compounds and further condensing in the inner solar system.

However, the Fischer-Tropsch hypothesis was not supported by experimental data, as the necessary catalysts were formed much later (i.e., by aqueous activity in the meteorite parent body, and not on the solar nebula) (Kerridge et al. 1979). The final word on the origin of the aliphatic hydrocarbons came years later from stable isotope measurements, which clearly indicated a terrestrial contamination origin.

Aromatic hydrocarbons were detected in the Murchison meteorite (Oró et al. 1971; Pering and Ponnampерuma 1971; Studier et al. 1972; Basile et al. 1984; Deamer and Pashley 1989). Basile et al. (1984) detected more than 30 aromatic hydrocarbons in solvent extracts of the Murchison meteorite, including several alkylated aromatic hydrocarbons. Pyrene and fluoranthene were also found in solvent extracts of Murchison (Deamer and Pashley 1989). Other carbonaceous chondrites were analysed for aromatic hydrocarbons, including Cold Bokkeveld (Commins and Harington 1966; Sephton et al. 2001), Orgueil (Commins and Harington 1966; Olson et al. 1967; Sephton et al. 2001), Murray, Santa Cruz, Boriskino (CM2), Mokoia (Olson et al. 1967), Y-791198 (Naraoka et al. 1988), Y-74662 and Y-793321 (Shimoyama et al. 1989) and Paris (Martins et al. 2015). Orgueil had relatively low-molecular-weight aromatic hydrocarbons, while Murray, Santa Cruz, Boriskino and Mokoia had higher-molecular-weight ones (Olson et al. 1967). Y-791198 contained up to 44 aromatic hydrocarbons and related compounds in the range of naphthalene and pyrene, including almost all structural isomers of methyl- and dimethyl-naphthalene (Naraoka et al. 1988). Y-74662 included around 50 aromatic hydrocarbons with various structural isomers: the smallest was naphthalene, while the largest was methylfluoranthene and/or methylpyrene. No aromatic hydrocarbon was detected in Y-793321 (Shimoyama et al. 1989). Supercritical fluid extraction was used to extract hydrocarbons from Orgueil and Cold Bokkeveld, which revealed a complex mixture of free non-polar organic molecules, including tetrahydronaphthalenes and aromatic hydrocarbons (Sephton et al. 2001). More recently, the Paris meteorite was analysed for both aliphatic and aromatic hydrocarbons. It contained *n*-alkanes ranging from C₁₆ to C₂₅ and 3- to 5-ring nonalkylated PAHs (Martins et al. 2015). The distribution of alkylated PAHs in CM2 chondrites seems to be related to the degree of aqueous alteration on its parent body (Martins et al. 2015).

4.3.5.10.1 Stable Isotope Measurements of Hydrocarbons

Solvent-soluble hydrocarbons in the Murchison meteorite were analysed after separation by silica gel chromatography into aliphatic, aromatic and polar hydrocarbon fractions. The aliphatic hydrocarbon fraction had δD values that ranged from +103‰ to +280‰ and δ¹³C values that ranged from -13‰ to -5‰. Pyrene, fluoranthene, phenanthrene and acenaphthene were the most abundant components in the aromatic fraction, which had δD values ranging from +244‰ to +468‰ and δ¹³C values ranging from

-6‰ to -5‰. Aromatic ketones, nitrogen and sulphur heterocycles were identified in the polar fraction, with δD values of +751‰ to +947‰ and δ¹³C values of +5‰ to +6‰ (Krishnamurthy et al. 1992). The carbon isotopic compositions of individual *n*-alkanes in several meteorites (Orgueil, Cold Bokkeveld, Murchison, Vigarano (CV3), Allende and Ornans) were determined years later. δ¹³C values for the individual *n*-alkanes ranged from -25.3‰ to -38.7‰, which means that they had a similar range as the *n*-alkanes in petroleum, clearly indicating a terrestrial origin for these compounds present in meteorites (Sephton et al. 2001).

Yuen et al. (1984) determined for the first time the δ¹³C value (-28.7‰) of benzene in Murchison. Years later, Gilmour and Pillinger determined the δ¹³C values of individual PAHs in the Murchison meteorite (ranging from -22.3‰ to -5.9‰) (Gilmour and Pillinger 1994). They observed that more complex PAHs became progressively enriched in ¹²C, which is consistent with a mechanism involving the synthesis of higher-molecular-weight compounds from lower homologues (Gilmour and Pillinger 1994). Those values were later confirmed by Sephton et al. (1998), who obtained δ¹³C values for aromatic hydrocarbons in Murchison, ranging from -28.8‰ to -5.8‰. Naraoka et al. (2000) analysed the A-881458 meteorite, which contained more than 70 individual PAHs. Their carbon isotopic compositions ranged from -26‰ to +8‰ (Naraoka et al. 2000). More recently, Huang et al. (2015) reported the δD and δ¹³C values for solvent-soluble aromatic compounds (PAHs and heteropolycyclic aromatic compounds [HACs]) in Murchison and LON 94101 (CM2). The δ¹³C values for Murchison ranged from -5‰ to -23‰, while for LON 94101, these values ranged from -1‰ to -18‰. The average δD values for PAHs and HACs in Murchison were +260‰ and +312‰ and in LON 94101 were +436‰ and +903‰ (Huang et al. 2015).

4.3.5.11 ALCOHOLS, ALDEHYDES AND KETONES

Alcohols and carbonyl compounds have been identified in carbonaceous chondrites. Jungclaus et al. (1976a) detected these compounds in the Murchison meteorite, including methanol, ethanol, 2-propanol, butyl alcohols, acetaldehyde, propionaldehyde, formaldehyde, acetone, 2-butanone, 2-pentanone and 3-pentanone. Aldehydes and ketones have been detected in Murchison (Jungclaus et al. 1976a; Pizzarelli and Holmes 2009), Ivuna (Monroe and Pizzarelli 2011), LAP 02342 and GRA 95229 (Pizzarelli and Holmes 2009). Pizzarelli and Holmes (2009) confirmed the results of Jungclaus et al. (1976a) for aldehydes and ketones in the Murchison meteorite and extended the list of these compounds, determining the total abundance of aldehydes and ketones to be 200 nmol/g. Ivuna had high abundances of formaldehyde and acetone (Monroe and Pizzarelli 2011), while LAP 02342 and GRA 95229 contained both aldehydes and ketones (total abundances of 534 nmol/g and 3168 nmol/g for LAP 02342 and GRA 95229, respectively). Acetone was the most abundant carbonyl-containing compound in

these meteorites, but the longer-chain-length ketones were less abundant than the corresponding molecular weight aldehydes (Pizzarello and Holmes 2009).

4.3.5.12 AMINES AND AMIDES

Jungclaus et al. (1976b) reported for the first time aliphatic amines in water extracts of the Murchison meteorite. Pizzarello et al. (1994) confirmed this detection, showing that Murchison contained a mixture of both primary and secondary isomers through C₅ at a total concentration of ≥ 100 nmol/g. Ammonia and tertiary amines were detected in LAP 02342 and GRA 95229, in which ammonia was the most abundant, followed by *sec*-butyl, butyl and isopropyl amines (Pizzarello and Holmes 2009). Aponte et al. (2014b) extracted aliphatic monoamines from the Murchison meteorite by using a novel GC method suited for the separation of aliphatic primary and secondary amines, including the enantiomeric separation of chiral amines. Results showed a complete suite of structural isomers, with a larger concentration of methylamine and ethylamine and decreasing amine concentrations with increasing carbon number. The same method was again applied by Aponte et al. (2015) to the Orgueil meteorite. Twelve amines were detected, with concentrations ranging from 1.1 nmol/g to 332 nmol/g. The enantiomeric composition for the chiral monoamines (R)- and (S)-*sec*-butylamine in Orgueil was also measured and was found to be racemic within experimental error (Aponte et al. 2015). Further analyses of aliphatic monoamines in hot acid-water extracts included the carbonaceous chondrites LAP 02342 (CR2), GRA 95229 (CR2), LON 94101 (CM2), LEW 90500 (CM2) and ALH 83100 (CM1/2) (Aponte et al. 2016). Results showed that (1) these CR2 chondrites contained higher concentrations of monoamines when compared with the CM2 chondrites analysed in the same study; (2) the concentration of monoamines decreased with increasing carbon number; (3) isopropylamine was the most abundant monoamine in these CR2 chondrites, while methylamine was the most abundant amine in these CM2 and CM1/2 chondrites; and (4) *sec*-butylamine, 3-methyl-2-butylamine and *sec*-pentylamine had racemic compositions (Aponte et al. 2016).

Linear and cyclic aliphatic amides were detected in the Murchison meteorite by Cooper and Cronin (1995), including monocarboxylic acid amides, dicarboxylic acid monoamides, hydroxy acid amides, lactams, carboxy lactams, lactims, N-acetyl amino acids and substituted hydantoins. Numerous isomers and homologues through at least C₈ were observed, except for the N-acetyl amino acids and hydantoins. These authors noted that the detected cyclic amides, given their potential for hydrogen-bonded pair formation, might be considered candidate bases for a primitive sequence coding system (Cooper and Cronin 1995).

4.3.5.12.1 Stable Isotope Measurements of Amines

The $\delta^{13}\text{C}$ values of aliphatic monoamines from the Murchison meteorite were measured and ranged from +21‰ to +129‰,

showing a decrease in ^{13}C with increasing carbon number. Aponte et al. (2014b) suggested that this relationship may be consistent with a chain-elongation mechanism under kinetic control, similar to the previously proposed mechanism for meteoritic amino acids. The compound-specific stable carbon isotopic ratios ($\delta^{13}\text{C}$) of five monoamines detected in Orgueil were also measured and had $\delta^{13}\text{C}$ values ranging from -20‰ to +59‰ (Aponte et al. 2015). Aponte et al. (2016) also analysed the LAP 02342 (CR2), GRA 95229 (CR2), LON 94101 (CM2), LEW 90500 (CM2) and ALH 83100 (CM1/2) meteorites. They found that the $\delta^{13}\text{C}$ values of monoamines in these CR2 chondrite did not correlate with the number of carbon atoms. On the other hand, in these CM2 and CM1/2 chondrites, the ^{13}C enrichment decreases with increasing monoamine carbon number. All amines in these CR2, CM2 and CM1/2 chondrites were enriched in ^{13}C , which supported their formation in cold interstellar environments (Aponte et al. 2016). Pizzarello and Yarnes (2016) determined $\delta^{13}\text{C}$ values of *sec*-butylamine in two CR meteorites (GRA 95229 and LAP 02342) and confirmed their indigeneity ($\delta^{13}\text{C} \sim +10\text{\textperthousand}$).

4.3.6 SUMMARY

This chapter provides an overview of the IOM and the solvent-soluble organic molecules present in carbonaceous meteorites. Their sources and formation are discussed. The delivery of these organic molecules to the early Earth and the contribution to the origin of life are briefly mentioned.

4.4.1 INTRODUCTION

Of key interest to astrobiology is the question: was the initiation of plate tectonics a critical component to shaping Earth's early biosphere? In the last decade, there has been dramatic advances in research areas that help address this question. Research in Archean and Paleoproterozoic paleobiology has provided a rich microfossil record (e.g., Knoll et al. 2016; Javaux and Lepot 2018) that may be integrated with environmental proxy data that indicate changes in redox conditions (e.g., Lyons et al. 2014). Geochemical data, as well as insights from molecular phylogeny, highlight important changes in electron donors and acceptors over Earth's history. In addition, our understanding of the geologic history of plate tectonics and of the evolution of the continental crust has advanced greatly, in part due to the rapid growth of U-Pb, O, and Hf isotope and trace element studies of zircons (e.g., Roberts and Spencer 2015; Van Kranendonk and Kirkland 2016; Hawkesworth et al. 2017; Iizuka et al. 2017), which leaves little doubt that plate tectonics has played an important role in influencing Earth's biosphere as we know it today. Tied to this is understanding the history of emergent crust early in Earth's history (e.g., Korenaga et al. 2017), which affects nutrient availability and weathering controls on climate. All of these components contribute to understanding the relations between plate tectonics and evolution of early life.

We focus this chapter on the evolution of the solid Earth, continental crust, plate tectonics, and the availability of key nutrients, such as P, for life. Starting with a review of evidence for plate tectonics on the early Earth, we address the issue of evolution of the continental crust, with specific attention to the composition of the crust and if it was emergent, based on the premise that such crust exerts a primary control on nutrient delivery to the biosphere. We then turn to the water envelope, exploring evolution of seawater as a recorder of weathering inputs to the marine environment. Our focus is largely on the Archean and Paleoproterozoic, with emphasis on primary productivity and oxygenic photosynthesis.

4.4.2 CRUST-MANTLE EVOLUTION AND ORIGIN OF PLATE TECTONICS

Planetary heat loss after completion of accretion and solidification of any magma ocean or mantle may be considered to be achieved via two end-member mechanisms: (1) a "stagnant lid" (e.g., O'Neill and Debaille 2014), where a thick conductive crust is immobile and mantle heat is primarily lost through magmatic resurfacing of that crust (e.g., as occurs on Venus: Herrick 1994; see also Fischer and Gerya 2016), and (2) "plate tectonics," where mantle convection ascends to very shallow levels, allowing extensive mantle melting that is accompanied by surface spreading, development of mid-oceanic ridges, and density-driven subduction after plate cooling (e.g., Korenaga 2013). The mantle potential temperature (T_p) is expected to be variable over time, reflecting the balance of radioactive heat production to heat loss, the latter of which may be impeded by a stagnant lid relative to that under plate tectonics. Whereas classical thermal modeling shows an asymptotic heat loss curve for Earth over time (Labrosse and Jaupart 2007), petrologic data from Archean lavas and other thermal modeling suggests that T_p could have increased from the time of Earth formation to the late Archean, after which a decrease in T_p would occur, arising from the possible onset of modern-style plate tectonics (Herzberg et al. 2010; Korenaga 2013). Modern-style plate tectonics is used here to refer to steep and deep subduction of cold oceanic lithosphere, down to the core-mantle boundary. This contrasts with a possible Archean style of plate tectonics, whereby thicker, more buoyant oceanic lithosphere was involved in shallow subduction at destructive plate margins.

Over the rest of Precambrian time, inferred swings in T_p have been ascribed to the supercontinent cycle, which affects mantle temperature through episodic pulses of widespread (and rapid) subduction, which cools the mantle, followed by pulses of mantle heating that accompany supercontinent disaggregation (Van Kranendonk and Kirkland 2016). The implication for life of varying T_p over time may be profound, because percent melting of the mantle scales with T_p , producing both thick crust at high T_p (which may have been

emergent) and low-density (Mg-rich) depleted and buoyant lithosphere that may be related to the development, stabilization, and preservation of cratons (Griffin and O'Reilly 2007; Herzberg and Rudnick 2012); both components bear on recent proposals that life may have originated on land that was emergent (e.g., Van Kranendonk et al. 2017), as well as on habitats and nutrient supplies for early life.

The role of water is critical both in facilitating the operation of plate tectonics (e.g., Bercovici 1998) and in the subduction process, where the water flux of slab dehydration into the overlying mantle wedge allows for melting in relatively cold subduction zones (e.g., Gill 1981). Production of magmas in subduction zones is the primary mechanism for generating silicic crust at sufficient volumes to develop increasing continental crust through time. The efficiency of this process depends upon normal faulting (that brings water to depths of 4 km; i.e., Lécuyer 2014) and on hydrothermal alteration of oceanic crust that is supported by an ambient ocean mass. As summarized by Campbell and Taylor (1983): “The Earth is the only planet with abundant granite and continents because it is the only planet with abundant water,” to which we should add “and plate tectonics.”

The question of when plate tectonics started on Earth has been the subject of much research and debate. The dramatic discovery of detrital zircons of Hadean age from Western Australia that had elevated $\delta^{18}\text{O}$ values, indicating the presence of liquid water on earth by ~4.2 Ga (Mojzsis et al. 2001; Wilde et al. 2001), turned the focus to the Hadean. The occurrence of zircons with these isotopic compositions as well as inferred crystallization temperatures have been used as evidence for plate tectonics in the Hadean (e.g., Harrison 2009). Such proposals are controversial, as they are based on what is now largely discredited data (Kemp et al. 2010), and conflict with models of stagnant lid tectonics for the Hadean (O'Neill and Deballie 2014) and evidence of vertical tectonics in some Archean terrains (e.g., Collins et al. 1998; Robin and Bailey 2009). More direct evidence for when an early form of plate tectonics seems to have arisen and when modern-style plate tectonics commenced comes directly from the Archean rock record.

Evidence for Archean plate tectonics was recognized quite early on from Archean high-grade gneiss terrains, based on the following: the presence of large-scale recumbent isoclinal folds associated with crustal thickening (Bridgwater et al. 1974; Myers 1976; Wilks 1988; Hanmer and Greene 2002); voluminous sodic granitoids derived from high-pressure melting of basalt (Martin et al. 2005; Rapp et al. 1991); high-pressure metamorphism (Riciputi et al. 1990; Harley 2003; Tappe et al. 2011); and structures and geochronological evidence consistent with terrane accretion (Nutman et al. 2002; Windley and Garde 2009). Over the past three decades, evidence for Archean plate tectonics has also been found in some granite-greenstone belts in the form of fossil subduction zones, accreted terranes, rift sequences, and subduction-zone magmatism (Card 1990; Calvert et al. 1995; White et al. 2003; Smithies et al. 2005a; Brown 2006; Stachel et al. 2006; Wyman et al. 2006; Van Kranendonk et al. 2007a, 2010).

However, an absence of hallmark characteristics of modern subduction-accretion zones in many granite-greenstone terrains (Hamilton 1998; McCall 2003; Stern 2005), the autochthonous nature of some major greenstone successions (Van Kranendonk et al. 2007b, 2015a), dome-and-keel structural map patterns (Bouhallier et al. 1995; Van Kranendonk et al. 2004; Van Kranendonk 2011), modeling of crustal thermal behavior (Sandiford et al. 2004), and suggestions that mantle roots form through in-situ melting events rather than by subduction stacking (Griffin and O'Reilly 2007) indicate at least some crustal development as volcanic plateaus, in many cases developed on older continental basement (e.g., Blenkinsop et al. 1993; Bleeker et al. 1999; Van Kranendonk et al. 2002, 2007a, 2015b; Barnes et al. 2012; Smithies et al. 2018). Indeed, many studies suggest that some Archean crust contains features that cannot be ascribed to uniformitarian, Phanerozoic-type, plate tectonics, but rather formed as a result of large-scale intracrustal differentiation accompanying periods of mantle plume-related magmatism (Stein and Hofmann 1994; Whalen et al. 2002; Rey et al. 2003; Smithies et al. 2005b; Van Kranendonk et al. 2009). The fact that different processes have been recognized from studies of different pieces of Archean crust indicates that there was no single Archean tectonic process, but rather that – as with modern Earth – Archean continental crust formed through a variety of processes, including plate tectonics and mantle-derived upwelling, and the probable interaction between these two end-member processes (e.g., Van Kranendonk 2010).

Much of the evidence for Archean plate tectonics comes from the Neoarchean, except for the well-documented case of the Isukasia Terrane of the North Atlantic Craton in Western Greenland (Nutman et al. 2002; Polat et al. 2002). An onset of modern-style plate tectonics at 3.2–3.0 Ga was first suggested for the Pilbara Craton of Western Australia, based on geochemical, geochronological, and structural grounds (Smithies et al. 2005a; Van Kranendonk et al. 2007a, 2007b), but this is now supported by a variety of evidence from different terrains and global datasets from around the world (e.g., Shirey and Richardson 2011; Dhuime et al. 2012; Naeraa et al. 2012; Van Kranendonk et al. 2015a; Van Kranendonk and Kirkland 2016). Significantly, this time coincides with a crossover point between the modeled heat production from the Earth and the amount of heat that can be lost through conduction via the oceanic crust (Labrosse and Jaupart 2007).

Temporal variations in the age and chemical and isotopic compositions of the continental crust have been closely connected to discussions on when plate tectonics began on Earth. It has long been known that histograms of U-Pb ages for crustal rocks show distinct peaks, and these have been interpreted to record episodic subduction and/or periodicity in the supercontinent cycle (e.g., O'Neill et al. 2007; Condie and Aster 2010; Condie et al. 2015). With the rapid increase in database size of combined U-Pb, O, trace element, and Hf isotope data from igneous and detrital zircons, periodicity is now clear in terms of age and isotopic compositions, which provide insight into primitive orogenic cycles and crustal recycling (e.g., Dhuime et al. 2012; Van Kranendonk and

Kirkland 2013, 2016; Roberts and Spencer 2015; Gardiner et al. 2016; Hawkesworth et al. 2017; Iizuka et al. 2017). This record, however, has been interpreted quite differently, where some workers argue that periodicities do not reflect changes in crustal growth but mixing of sources and crustal reworking (e.g., Hawkesworth et al. 2017), whereas others interpret periodicities in U-Pb ages and isotopic compositions to be correlated with episodic changes in mantle dynamics and continental amalgamation and dispersal (e.g., Van Kranendonk and Kirkland 2013, 2016; Gardiner et al. 2016; Puetz et al. 2017). Arguments against periodicity in continental crustal growth point to the expected smooth cooling of the mantle, but, in detail, modeling shows that T_p and crustal growth may be episodic due to the interplay between mantle creep, lateral heat flow, mantle cooling, and punctuations in the effect of water on the peridotite solidus (Van Kranendonk and Kirkland 2016; Walzer and Hendel 2017).

In the context of the zircon record, most pertinent to the evolution of the biosphere are O isotope compositions, because they provide evidence for weathering processes and fluid-rock interaction. Such evidence is somewhat indirect in the sense that a high- $\delta^{18}\text{O}$ zircon reflects crystallization from a magma that assimilated sedimentary rocks (so-called “S-type” magmas). The preponderance of Archean zircons with high- $\delta^{18}\text{O}$ values, however, suggests that the sedimentary reservoir was extensive enough that the probability would be so great that high- $\delta^{18}\text{O}$ crust would be intersected by ascending magmas. A dominance of mantle-like $\delta^{18}\text{O}$ values for Archean zircons, characteristic of “I-type” magmas, compared with elevated $\delta^{18}\text{O}$ values for Proterozoic and Phanerozoic zircons, has been taken to indicate limited weathering and crustal recycling in the Archean, as compared with younger times (e.g., Valley et al. 2005). More recent compilations have generally confirmed this view, where the rise in $\delta^{18}\text{O}$ values of igneous and detrital zircons in the transition from the Archean to the Proterozoic is taken to record a marked increase in crustal thickening and reworking during the onset of collisional tectonics and initiation of the supercontinent cycle (Van Kranendonk and Kirkland 2013; Spencer et al. 2014). It must be remembered, however, that high- $\delta^{18}\text{O}$ zircons are known back to 4.3 Ga (e.g., Cawood et al. 2005), and recent work on very old cratons documents high- $\delta^{18}\text{O}$ crust of 3.6–3.8 Ga (Bolhar et al. 2017) and 3.2 Ga (Van Kranendonk et al. 2015a) age. An important component to this discussion is recognition that biases exist in the detrital zircon record in terms of magma composition and temperature, which affect zircon saturation in magmas, where it is likely that the proportion of felsic Archean or Hadean crust is markedly underestimated from the zircon record (Keller et al. 2017).

Changes in the composition of the continental crust through time have been assessed through direct studies of igneous and metamorphic rocks, although more commonly through use of sedimentary rocks, based on the premise that they represent samples of large areas of exposed crust at various times in the past (e.g., Taylor and McLennan 1985). Broadly, such studies suggest that Archean crust exposed

to weathering was mafic in bulk composition (high MgO and low SiO₂) but that Proterozoic and Phanerozoic crust exposed to weathering became more silicic (low MgO and high SiO₂) over time. Such conclusions have been reinforced through studies of trace elements, mapping these to predicted major element compositional changes for magmatic evolution (e.g., Dhuime et al. 2015; Tang et al. 2016a). These studies have, in turn, concluded that the apparent increase in abundance of silicic continental crust between 3.0 Ga and 2.5 Ga coincided with the initiation of plate tectonics, solidifying the expected connection between silicic magma genesis and subduction processes (Van Kranendonk and Kirkland 2016).

Returning to an isotopic approach, which has the capability of capturing a wider range of information than measured bulk compositions, Greber et al. (2017) reported on a new proxy for tracing crustal composition, stable Ti isotopes. They noted that $^{49}\text{Ti}/^{47}\text{Ti}$ ratios, expressed as $\delta^{49}\text{Ti}$ values, correlate strongly with SiO₂ contents in igneous rocks, reflecting the well-known process of increasing crystallization of Fe-Ti oxides with SiO₂ in magmas. Although it is not yet clear if there may be differences in $\delta^{49}\text{Ti}$ values for I- and S-type magmas, which can change saturation of different Fe-Ti oxides, the $\delta^{49}\text{Ti}$ values of shales have been invariant since 3.5 Ga, and this is explained by a consistently high abundance of silicic crust since the Paleoarchean (Greber et al. 2017). Drawing again on the connection between abundance of silicic continental crust and plate tectonics, an early initiation of plate tectonics >3.5 Ga is proposed (Greber et al. 2017), which is consistent with evidence from West Greenland but contrasts with the more commonly proposed time of ~3 Ga or younger from other datasets.

We conclude this section with a discussion of the emergence of Archean continental crust, which is dependent on its compositional and thermal structure. If the early Archean continental crust was thin and mafic (e.g., Dhuime et al. 2015), isostatic principles would predict that such crust would be largely submerged. Thermal modeling appears to support this conclusion (Flament et al. 2008); however, it is important to note that there exist examples of exposed land surfaces by 3.5 Ga (Buick et al. 1995; Djokic et al. 2017) and that commonly cited thermal modeling assumes that the crustal geotherm was relatively high (Flament et al. 2008); such an assumption is not supported by petrologic or thermobarometric studies of Archean terrains (Burke and Kidd 1978; Galer and Mezger 1998; Brown 2007; Satkoski et al. 2017), which indicate that Archean crust was relatively thick, on the order of ~40 km or more (Champion and Smithies 2007; Van Kranendonk et al. 2015b), with crustal geotherms similar to those of today. This line of argument reflects the fact that the majority of heat loss from the Earth occurs in the oceans and not through the continents. There is increasing evidence, therefore, that early Archean crust was likely more silicic and emergent than previously thought, a model that can be tested through study of the chemical and isotopic compositions of seawater – this would then affect how we view the nutrient delivery to an early biosphere.

4.4.3 THE ATMOSPHERE-WATER ENVELOPE

Perhaps the canonical change in the surface of the Precambrian Earth is the rise of atmospheric oxygen, the first stage of which has been termed the “Great Oxidation Event” (GOE) and has been proposed to have occurred in the Paleoproterozoic at ~2.3 Ga (e.g., Bekker et al. 2004; Holland 2006). There is a vast and extensive literature on the rise of oxygen in the atmosphere (e.g., Holland 1984; Canfield 2005; Lyons et al. 2014, to name a very small fraction). It is commonly accepted that the primary driver of the rise in atmospheric oxygen was oxygenic photosynthesis (e.g., Farquhar et al. 2010), but much debate exists as to when this metabolism first evolved, as oxygen levels were suppressed by the presence of vast reductive sinks until the GOE. Fischer et al. (2016), for example, caution about relying too heavily on redox proxies in the rock record and emphasize that all known phototrophic groups were derived late in the phyla in which they occur, suggesting a relatively late evolution. An increasing body of data from geochemical redox proxies and field evidence, however, suggests that oxygenic photosynthesis arose much earlier than the GOE (e.g., Lyons et al. 2014; Homann et al. 2015). In this context, the oldest known marine redox gradient, inferred to record a gradient in ocean oxygen contents, dates back to 3.2 Ga (Satkoski et al. 2015), suggesting a >3.2 Ga origin for oxygenic photosynthesis, an age supported by molecular clock studies of cyanobacteria (Schirrmeister et al. 2015). Interestingly, this age corresponds with a rapid evolutionary innovation via genetic expansion in microbial life (David and Alm 2011), as explored more fully in this section.

If we accept an origin for oxygenic photosynthesis far earlier than the GOE, the first question is: what kept atmospheric oxygen levels low for perhaps one billion years? The solution lies in understanding the sources and sinks of oxygen. The obvious source for O₂ is oxygenic photosynthesis, which requires the reactants CO₂ and H₂O, presumably always in excess abundance in the Archean Earth. Much of the discussion of primary productivity in the early Earth has therefore focused on limiting nutrients. Over geologic timescales, P is the limiting nutrient over N (Tyrell 1999), and many models for oxygen evolution in the Precambrian explicitly assess P as the key limiting nutrient (e.g., Planavsky et al. 2010; Jones et al. 2015; Laasko and Schrag 2017; Poulton 2017; Reinhard et al. 2017). Additional sources of oxygen include burial of organic C in sedimentary rocks, a source that becomes quite important if the early biosphere was limited in size by nutrients such as P (e.g., Hayes and Waldbauer 2006; Husson and Peters 2017). In addition, subduction of organic C into the mantle may be a source for oxygen (Duncan and Dasgupta 2017); however, this is not detected in the redox state of the mantle (e.g., Nicklas et al. 2018).

Keeping oxygen “in check” before the GOE requires sinks, and numerous options have been proposed. The interplay between CH₄ and O₂ is important not only in moderating the levels of these two gases in the atmosphere and ocean, but also in terms of climate in the early Earth when solar luminosity was lower (e.g., Olson et al. 2013, 2016; Daines and

Lenton 2016; Ozaki et al. 2017). Reaction between O₂ and aqueous Fe²⁺ in the oceans prior to the GOE may produce banded iron formations and was likely an important sink for oxygen; however, oxidation of Fe²⁺ may also occur by anoxygenic phototrophy (e.g., Konhauser et al. 2017). Oxygen consumption by reduced volcanic gases has also been extensively discussed (e.g., Kasting et al. 1993; Holland 2002; Kump and Barley 2007; Gaillard et al. 2011). Early mafic crust has been proposed as an oxygen sink, where the GOE is interpreted to record a decrease in O₂ sinks through emergence of granitic continental crust near the Archean/Proterozoic boundary (e.g., Kamber 2010; Lee et al. 2016; Smit and Mezger 2017).

Turning to the water envelope (oceans), as far as is known, water provides a first-order control on the presence or absence of a biosphere on a planet. To some degree, water might be considered the ultimate “limiting nutrient” for life. Looking beyond the presence of water, the supply of nutrients, as well as electron donors and acceptors, to the marine realm is considered the major driver of the biosphere. The chemistry of the oceans reflects an array of inputs and sinks, with major influences today via continental weathering and hydrothermal systems (e.g., Holland 1984). The conventional view that the continents in the early Archean were small, mafic in composition, and predominantly (though not exclusively) submerged puts severe constraints on the availability of key components for the early biosphere, leading to the model that the earliest oceans were “mantle buffered” (e.g., Shields 2007). A variation on this theme of a “mantle-dominated” early Archean ocean can be found in proposals of emergent, but mafic/ultramafic, oceanic crust (e.g., Kamber 2010). The previous discussion, however, suggests that we must now reconsider an important role for early, emergent, and silicic continental crust in determining the chemistry of the early Archean oceans.

The radiogenic isotopic composition of Sr of seawater (expressed as ⁸⁷Sr/⁸⁶Sr ratios) has long been used as a tracer of the relative contributions of element fluxes to the oceans from oceanic and continental crust through time (e.g., Shields 2007). Because the residence time of Sr in the oceans is long (i.e., several million years), relative to mixing times of the oceans (e.g., Holland 1984), seawater ⁸⁷Sr/⁸⁶Sr ratios are globally homogeneous at any one time but change over m.y. timescales due to changes in the proportion of mantle and crustal components. In essence, seawater ⁸⁷Sr/⁸⁶Sr ratios serve as a global-averaged recorder of mantle and crustal inputs to the oceans. Most commonly, marine carbonates are used to infer seawater ⁸⁷Sr/⁸⁶Sr ratios, but other lithologies such as barite are also useful. Unfortunately, the seawater ⁸⁷Sr/⁸⁶Sr record for the Archean has been plagued with difficulties due to the effects of carbonate alteration and incorporation of radioactive clays, issues that are particularly problematic for very old rocks (Shields and Veizer 2002). The result has been that many workers gave up on determining the seawater Sr isotope curve for the early Archean.

Recently, however, the Archean Sr isotope seawater curve has been re-investigated using marine barite and carbonate, where the effects of hydrothermal alteration and clay contamination have been assessed using C, O, S, and

Rb isotopic analysis (Satkoski et al. 2016, 2017). This work shows that early Archean seawater had significantly higher $^{87}\text{Sr}/^{86}\text{Sr}$ ratios than the mantle. Satkoski et al. (2016) estimated a Sr oceanic/continental flux ratio of 2–3 at 3.2 Ga, about 5–7 times lower than that of previous estimates that assumed mantle-like $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for early Archean seawater (Kamber 2010). Additional work on 2.94, 2.80, and 2.6–2.55 Ga marine carbonates produces similarly low oceanic/continental Sr flux ratios (Kamber and Webb 2001; Satkoski et al. 2017), suggesting that the contribution of evolved continental crust to seawater chemistry has been much higher than previously thought, back to at least 3.2 Ga. Significant weathering of silicic continental crust is consistent with evidence for high- $\delta^{18}\text{O}$ crust of 3.6–3.8 Ga age, as determined in zircons (see [Section 4.4.2](#); Bolhar et al. 2017), as well as the chemical alteration indices of 3.2 Ga clastic deposits (Hessler and Lowe 2006).

With the majority of attention on O_2 in the atmosphere, relatively few studies have attempted to quantify O_2 contents in the photic zone of the oceans. Recently, however, multiple isotopic systems (S, Fe, Cr, Mo, and U) now consistently indicate free O_2 in the photic zone, at least episodically, as far back as 3.2 Ga, continuing through the Meso- and Neoarchean, rising during the GOE, then returning to low, but significant levels post-GOE (e.g., Czaja et al. 2012, 2013; Canfield et al. 2013; Li et al. 2013; Planavsky et al. 2014; Scott et al. 2014; Satkoski et al. 2015; Tang et al. 2016b; Yang et al. 2017; Eickmann et al. 2018). These results suggest a more pervasively oxygenated photic zone before the GOE than envisioned by early proposals of “oxygen oases” (Kasting et al. 1992). Modeling shows that an Archean photic zone that has O_2 on the order of 1–10 μM could exist beneath an anoxic atmosphere (Olson et al. 2013). A key component to the consumption of O_2 may have been aerobic respiration and methanotrophy, the latter of which is suggested by the highly negative $\delta^{13}\text{C}$ values of Neoarchean organic C (Hayes 1994; Daines and Lenton 2016); however, much of the most negative $\delta^{13}\text{C}$ values appear to have developed within lakes (Flannery et al. 2016). If photic zone O_2 sinks were significant, primary productivity in the Archean may have been much higher than previously thought, based on assumed limitations in P (e.g., Laakso and Schrag 2017), consistent with evidence from $\delta^{13}\text{C}$ values from carbonates and organic carbon through to the earliest Precambrian (e.g., Hayes et al. 1983). In addition, there is increasing evidence for a diverse biosphere on land in the Neoarchean, with a major role for methanotrophy, which would consume oxygen (e.g., Hayes 1994; Stüeken et al. 2017). Broadly, the Meso- to Neoarchean biosphere now appears to have been remarkably diverse long before the GOE.

A proposed link between Precambrian Earth geodynamics and fluctuating atmospheric oxygen levels suggests that the supercontinent cycle had a major influence on the source of reductive sinks, which varied in step with the supercontinent cycle and controlled (in part) the levels of atmospheric oxygen (Van Kranendonk et al. 2012; Van Kranendonk and Kirkland 2016). In this model, Earth has operated in a conditioned duality between two states. Periods of supercontinent aggregation

are accompanied by rapid, global subduction, resulting in increased levels of reducing volcanic gasses, a greenhouse atmosphere, and low levels of atmospheric oxygen. Formed supercontinents are accompanied by mantle cooling, arising from the preceding global subduction of cool oceanic lithosphere and from mantle insulation from core heat by slab graveyards across the core-mantle boundary. This results in cooling of the crust, leading to periodic ice ages – sometimes global and long-lived (Hoffman et al. 1998; Kirschvink et al. 2000) – accompanied by a rise in atmospheric oxygen. But the supercontinents insulate the mantle, and in the second state, conductive heating of the slab graveyards returns the mantle to warm conditions, leading to a renewed burst of volcanic activity, supercontinent breakup, melting of ice ages, and a return to a greenhouse atmosphere. These states cycle over time and help drive biological diversification and evolution.

4.4.4 SUMMARY

We summarize temporal variations in a number of solid and surface Earth parameters from 4 to 2 Ga in [Figure 4.4.1](#). As discussed by Konhauser et al. (2017), there is increasing evidence that the shallow oceans (photic zone) became progressively enriched in O_2 from the Paleo- to Neoarchean, perhaps reaching ~10% of present ocean level (POL) before the GOE. The first evidence for photic zone oxygenation at ~3.2 Ga correlates with an increase in $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for seawater, which is inferred to record the initiation of plate tectonics, and fits some models for the first rapid increase in emergent land. The relatively high proportion of felsic continental crust between 3.5 Ga and 3 Ga, relative to previous estimates, is consistent with the elevated $^{87}\text{Sr}/^{86}\text{Sr}$ ratios for seawater during this time. This, in turn, suggests a significant P_2O_5 flux from the continents, even in the Paleo- and Mesoarchean. From 3 Ga to 2 Ga, the P_2O_5 flux from the continents to the oceans increased, in part reflecting the decrease in T_p , which decreases percent mantle melting, which, in turn, further enriches the crust in incompatible elements such as P. Collectively, these changes indicate an increasing size and diversity of the biosphere, which are likely to have been driven by continental growth via plate tectonics that began in the early Archean.

In terms of specific metabolisms during the time period illustrated in [Figure 4.4.1](#), anoxygenic phototrophy is likely to have preceded oxygenic photosynthesis (e.g., Widdel et al. 1993), and evidence for this can be found in Fe isotope compositions of Paleoarchean iron formations (Czaja et al. 2013; Li et al. 2013). Based on Fe and U isotopes in Mesoarchean iron formations, it has been proposed that oxygenic photosynthesis arose by 3.2 Ga (Satkoski et al. 2015). Microbial Fe reduction has been identified as an early metabolism that likely was extensive by the Mesoarchean (Konhauser et al. 2017). An active methane cycle, including methanogenesis and methanotrophy, was also important prior to the GOE and was closely tied to O_2 balances, as discussed earlier. Looking past the GOE, oxygenic photosynthesis was firmly established over anoxygenic phototrophy as the major driver of

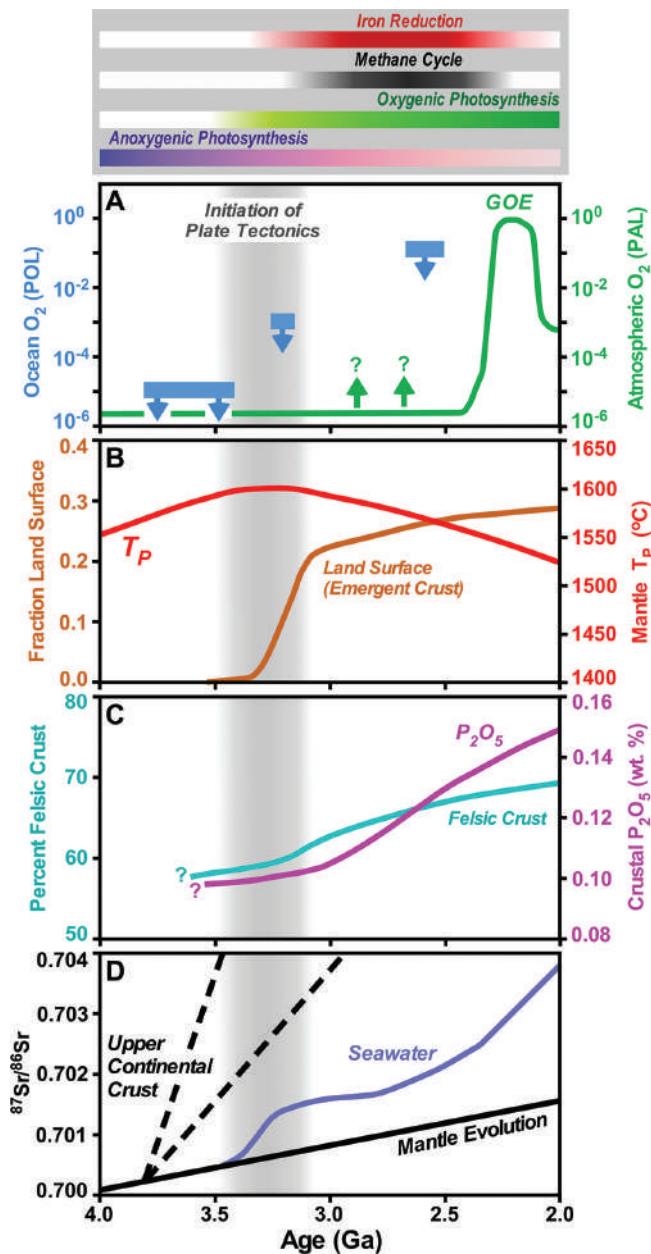

FIGURE 4.4.1 Changes in the solid and surface Earth from 4 Ga to 2 Ga. Upper gray panel shows temporal changes in various microbial pathways. Initiation of plate tectonics inferred to have occurred between 3.5 Ga and 3.2 Ga (see text). (a) Variations in ocean O_2 (relative to present ocean level, POL) and atmospheric O_2 (relative to present atmosphere level, PAL). (Adapted from Konhauser et al., based on previous work [Czaja, A.D. et al., *Geochim. Cosmochim. Acta*, 86, 118–137, 2012; *Earth Planet. Sci. Lett.*, 363, 192–203, 2013; Li, W. et al., *Geochim. Cosmochim. Acta*, 120, 65–79, 2013; Satkoski, A.M. et al., *Earth Planet. Sci. Lett.*, 430, 43–53, 2015; Konhauser, K.O. et al., *Earth Sci. Rev.* 172, 140–177, 2017.] (b) Changes in mantle potential temperature (T_p) and fraction of land surface relative to total Earth surface area. T_p (Korenaga 2013) modified to change transition from stagnant lid to plate tectonics at ~3.3 Ga. Land surface adapted from a fast plate tectonic model, with constant continental crust density (Korenaga et al. 2017), and crustal growth model from Campbell (2003), parameters that favor early emergent crust. (c) Proportions of felsic crust (of total continental crust) and wt. % P_2O_5 for total continental crust, based on modeling Ti isotope variations in shales. (From Greber, N.D. et al., *Science*, 357, 1271–1274, 2017.) (d) $^{87}Sr/^{86}Sr$ evolution curves for mantle and seawater from several sources. (From Shields, G., and Veizer, J., *Geochem. Geophys. Geosyst.*, 3, 2002; Kamber and Webb 2001; Satkoski, A.M. et al., *Earth Planet. Sci. Lett.*, 454, 28–35, 2016; *Geochim. Cosmochim. Acta*, 209, 216–232, 2017.) The highest slope upper continental crustal evolution curve calculated using >3.5 Ga juvenile upper crust ($Rb = 71$ ppm and $Sr = 251$ ppm; Condie 1993), evolving from the mantle at 3.8 Ga. The lower slope upper continental crust curve based on extrapolation of modern silicate weathering composition ($^{87}Sr/^{86}Sr = 0.7178$; Palmer and Edmond 1989), back to the mantle at 3.8 Ga.

primary productivity, methane was effectively scrubbed from the atmosphere, and microbial Fe reduction contracted in its footprint to suboxic environments.

4.5.1 INTRODUCTION

The nature of Earth's Hadean (>4.0 Ga) atmosphere remains poorly known, as we have no direct samples of it to study and as the geologic record itself is nearly nonexistent during this time period. But we can make inferences about the Hadean atmosphere based partly on theory and partly on geologic evidence from the ensuing Archean Eon (4.0–2.5 Ga). Whether or not this lack of knowledge about conditions during the Hadean presents a problem for origin of life studies depends on when life on Earth originated. The earliest convincing evidence for life comes from stromatolites (laminated structures created by mat-forming organisms), which date back to 3.3–3.5 Ga (Buick et al. 1981; Hofmann et al. 1999; Allwood et al. 2006, 2009). But ¹³C-depleted organic carbon has been found in sedimentary rocks near Isua, West Greenland (Rosing 1999), and this is interpreted by some authors as being biologically generated. So, life may well have originated back during the time for which we have no direct record.

One might ask what good it does to speculate about early atmospheric composition if we have no way of checking the results. The answer is that some theories of the origin of life (e.g., Oparin 1938; Miller 1953, 1955; Pownall et al. 2009; Sutherland 2016) depend critically on this parameter. Other theories in which life originates within submarine hydrothermal vents (e.g., Russell and Hall 1997; Martin et al. 2008) are less sensitive to the nature of the early atmosphere. But even those theories depend indirectly on atmospheric composition, because it helps to define free-energy gradients that are needed to power early metabolisms. In this chapter, I will briefly summarize constraints on early atmospheric composition and climate and then discuss how the atmosphere might have played a role in establishing these critical free-energy gradients. I will also employ the methodology of (Hoehler

2004) to argue that some of these free-energy gradients may have been less useful to the biota than previously advertised (including by this author) because of kinetic barriers imposed by the limited concentrations of required reactants. This, in turn, may have helped guide biological evolution toward more productive methods of carbon fixation, particularly ones involving photosynthesis.

4.5.2 COMPOSITION OF THE EARLY ATMOSPHERE

During the Archean Eon, the geologic record provides some information about both atmospheric composition and climate. Most importantly, it tells us that the atmosphere contained very little free O₂, as evidenced by the survival of detrital reduced minerals such as pyrite (FeS₂) and uraninite (UO₂) and by the preservation of sulfur mass-independent fractionation (MIF) (Cloud 1972; Farquhar et al. 2000; Pavlov and Kasting 2002; Holland 2006; Catling and Kasting 2017, Ch. 10). The mechanism for producing the sulfur MIF is under reinvestigation; it may result from elemental sulfur chain formation rather than from SO₂ photolysis (Babikov 2017; Harman et al. 2018). But the conclusion from (Pavlov and Kasting 2002) remains valid: sulfur must exit the atmosphere in a variety of different compounds in order to produce MIF, and this implies O₂ concentrations <10⁻⁵ Present Atmospheric Level (PAL).

The lack of free O₂ in the Archean atmosphere, and presumably in the Hadean as well, does *not* imply that the atmosphere was strongly reduced, i.e., rich in hydrogen-containing compounds such as CH₄ and NH₃. A strongly reduced atmosphere was favored for many years by biologists interested in the origin of life (e.g., Oparin 1938) and by geochemists who performed early origin-of-life experiments (Miller 1953, 1955). (Harold

Urey's name is usually attached to Miller's experiments also, as Miller was his graduate student.) Some authors continue to support this idea (Shaw 2008, 2014), but theory suggests that Earth's mantle was oxidized relatively early in its history (Wade and Wood 2005) and that the dominant volcanic gases were H₂O, CO₂, and N₂ (Rubey 1951; Walker 1977; Holland 1984; Kasting 1993; Catling and Kasting 2017, Ch. 7). The early atmosphere may have been formed by impact degassing of incoming planetesimals (Zahnle et al. 2007, 2010), but this does not change the basic conclusion. Strongly reduced atmospheres on rocky planets turn into weakly reduced atmospheres within geologically short time periods as a consequence of photolysis of H₂O, followed by escape of hydrogen to space. Strongly reduced atmospheres can persist on gas giant planets such as Jupiter and Saturn, because hydrogen does not escape and because photolysis of CH₄, NH₃, H₂S, and H₂O is balanced by reformation of these molecules deep within the planet's atmosphere.

The composition of weakly reduced atmospheres can be estimated by using photochemical models. A typical result is shown in [Figure 4.5.1](#).

The atmosphere depicted has a surface pressure of 1 bar, like today's atmosphere. The specification of a 1-bar surface pressure is arbitrary; the real Hadean atmosphere may have had a pressure of several bars or more as a result of release of CO₂ during impacts (Kasting 1990; Zahnle et al. 2007, 2010; Wong et al. 2017), combined with the smaller estimated surface area of continents on which silicate weathering could occur (Flament et al. 2008). But CO₂ should have been removed by seafloor weathering, as well, at rates that are difficult to estimate but that could have been relatively fast (Sleep and Zahnle 2001; Coogan and Gillis 2013; Coogan and Dosso 2015). By the late Archean (2.7 Ga), atmospheric pressure appears to have been relatively low: Som et al. (2012) estimated a surface pressure <2 bar based on fossil raindrop imprints, whereas this same group has

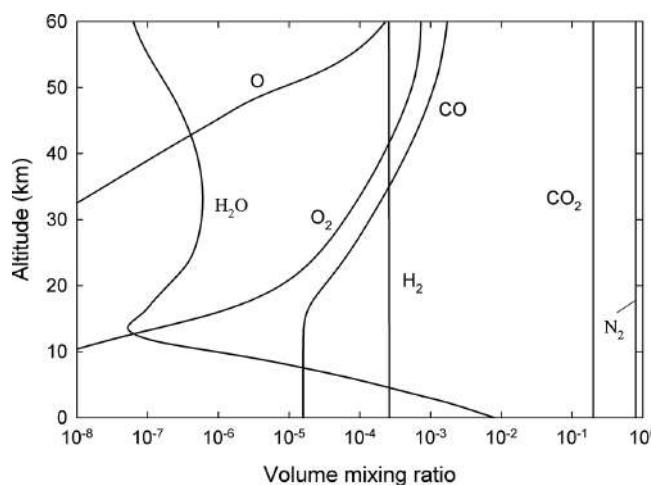

FIGURE 4.5.1 Vertical profiles of major atmospheric species for a typical early Archean model atmosphere. A surface pressure of 1 bar was assumed. Other parameters for the calculation are described in the text. (Reprinted from Kasting, J.F., *Geol. Soc. Am. Spec. Pap.*, 504, 19-28, 2014. With permission of the Geological Society of America.)

estimated <0.5 bar based on gas vesicles in submarine basalts (Som et al. 2016). It remains to be seen whether these empirical estimates of surface pressure are robust.

The H₂ mixing ratio in the atmosphere depicted in [Figure 4.5.1](#) was determined by balancing the outgassing rates of H₂ and other reduced gases with escape of hydrogen to space, following the methodology outlined in Chapter 8 of (Catling and Kasting 2017). A total H₂ outgassing flux of 1.7×10^{12} mol/year was assumed (*ibid.*, Table 7.3), and the escape rate was set by the diffusion-limited flux (*ibid.*, eqs. 8.6 and 8.7). Global redox balance was ensured by making sure that the net transfer of reducing power from the atmosphere to the ocean was zero.

4.5.3 CLIMATE ON THE EARLY EARTH

If the composition of the Hadean atmosphere is uncertain, then the climate is even more so. In a predominately CO₂-N₂ atmosphere, the surface temperature depends most strongly on the CO₂ partial pressure, along with solar luminosity. Solar luminosity can be estimated from the formula (Gough 1981):

$$\frac{S}{S_0} = \frac{1}{1 + 0.4(t/4.6)} \quad (4.5.1)$$

Here, S is the solar flux at Earth's orbit, S_0 is the modern value, ~1365 W/m², and t is time before present in Ga. Although dated, Gough's formula agrees well with more recent models (Bahcall et al. 2001). Equation 4.5.1 predicts that the Sun was about 80% of its present luminosity at 2.8 Ga. If one combines that with the 0.2-bar CO₂ atmosphere shown in [Figure 4.5.1](#), this would produce a mean surface temperature of ~0°C (Kasting, 2013). Prior to 2.8 Ga, significantly higher CO₂ partial pressures would have been required to keep Earth's surface from freezing. Even 10 bar of CO₂ would only have produced a mean surface temperature of ~85°C at 4.6 Ga, when the Sun was ~70% of its present brightness (Kasting and Ackerman 1986). So, the Hadean surface temperature could have been either quite warm or quite cold, depending on how fast CO₂ was removed from the atmosphere by seafloor weathering.

Once we get into the Archean, the climate record improves, but interpretations remain controversial. Oxygen isotopes in cherts suggest that the climate was extremely warm, 70 ± 15°C at 3.3 Ga (Knauth and Lowe 2003; Knauth 2005). But this result is in apparent conflict with evidence for glaciation at 3.5 Ga (De Wit and Furnes 2016), 2.9 Ga (Young et al. 1998), and 2.7 Ga (Ojakangas et al. 2014). The glacial evidence is more convincing, as the oxygen isotope record could be influenced by changes in seawater oxygen isotopic composition over time (Jaffres et al. 2007; Veizer and Prokoph 2015). (For counter-arguments, see Gregory and Taylor 1981 and Muehlenbachs 1998.) If we accept that continental glaciers were present at least some of the time during the Archean, then it seems likely that mean surface temperatures were within 10 or 15 degrees of the present value, 15°C.

The Archean geologic record also provides some direct constraints on atmospheric CO₂ by way of paleosols (ancient soils).

Soils are usually not preserved, because they erode away on relatively short timescales. But occasionally, a soil will become covered by a lava flow from a nearby volcano, preventing it from eroding. If this sequence is later buried, it can be preserved in the geologic record. One can then analyze the amount of silicate weathering that occurred within the soil and use this to estimate atmospheric CO₂. This type of analysis has been done for one Archean paleosol (Driese et al. 2011) and for several younger Proterozoic paleosols (Sheldon 2006) (see Figure 4.5.2).

The Driese et al. result suggests 10–50 PAL of CO₂ at 2.7 Ga. Here, 1 PAL is defined at 370 ppmv CO₂, so this prediction corresponds to a CO₂ partial pressure of about 0.004–0.02 bar. This is a factor of 10–50 lower than the 0.2 bar of CO₂ required to keep the Earth from freezing at 2.8 Ga. If correct, this would imply that other greenhouse gases, e.g., CH₄, would have been needed to keep the surface temperature above freezing at this time. That is not impossible. Several years ago, we showed that 1000 ppmv of CH₄ combined with 0.02 bar of CO₂ could have produced a mean surface temperature of ~286 K, not far from today's value of 288 K (Haqq-Misra et al. 2008). Such a CH₄ concentration could plausibly have been produced by methanogens living within an anaerobic marine biosphere (Kharecha et al. 2005). (See further discussion of this topic in Section 4.5.4.1 below.) So, relatively low atmospheric CO₂ concentrations are not necessarily inconsistent with the Archean climate record.

On the other hand, a more recent reanalysis of this same suite of paleosols by (Kanzaki and Murakami 2015) predicts Archean and Proterozoic CO₂ levels 10–20 times higher than those estimated by (Driese et al. 2011) and (Sheldon 2006), both of whom used a similar methodology to analyze their samples. This methodology, developed originally by (Holland and Zbinden 1988), essentially assumes that every CO₂

molecule that enters the soil reacts with a silicate mineral. It thus really produces only a lower bound on atmospheric CO₂. If the efficiency of silicate weathering reactions is less than assumed, then higher pCO₂ values are allowed. So, it seems likely that the Sheldon's and Driese's estimates of pCO₂ are too low and that those of (Kanzaki and Murakami 2015), which themselves have large error bars, may be more accurate. In either case, the problem of countering reduced solar luminosity during the Archean appears to have viable solutions.

4.5.4 REDOX COUPLES FOR ORIGINATING AND SUSTAINING LIFE

As mentioned at the beginning of this chapter, one of the main reasons that we care about the nature of the early atmosphere is that it helped to establish free-energy gradients that could have been critical to originating and then sustaining life. Let us briefly consider how such gradients fit into the broader picture of life's origin.

Theories of the origin of life are sometimes divided into two classes: (1) information (or genes) first, and (2) metabolism first. Researchers pursuing the first class of hypotheses stress that nothing can be considered alive unless it possesses the ability to pass on its characteristics to its offspring. Modern organisms do this by using DNA as the information molecule. But RNA is similarly able to encode information, and because it is single-stranded, it can perform catalysis as well (Cech and Bass 1986). Thus, most researchers agree that once RNA had evolved, with its four nucleobases for storing information, life would have been off to a good start.

Another view of the origin of life holds that metabolism is the key concept. Organisms depend on sources of thermodynamic free energy to drive their metabolisms. Some proponents of this view (e.g., Smith and Morowitz 2016) argue that life arises in response to free-energy gradients in the environment. This concept plays a major role in the hydrothermal vent model for life's origin (Russell and Hall 1997; Martin et al. 2008; Lane et al. 2010), as strong free-energy gradients are arguably present in such environments. These gradients involve both redox gradients that drive transfer of electrons and pH gradients that drive transfer of protons. Both types of gradients play important roles in modern biochemistry. In the hydrothermal vent model, pH gradients between alkaline vent fluids and slightly acidic seawater constitute the most likely initial source of free energy for life. To move out of the vents, though, organisms would have needed to take advantage of redox gradients to obtain their free energy. In this chapter, I shall focus on these gradients.

Importantly, redox gradients themselves are constrained in their biological use by two different factors (Hoehler 2004 and references therein). The first is the available thermodynamic free energy. Hoehler terms this the *biological energy quantum* (BEQ). This constraint comes from the fact that the energy needed to synthesize adenosine triphosphate (ATP) from adenosine diphosphate (ADP) is 35.6 kJ/mol. ATP is the universal energy currency of metabolism, and so, all organisms need to be able to make it. Organisms are able to store electrochemical energy internally and then combine

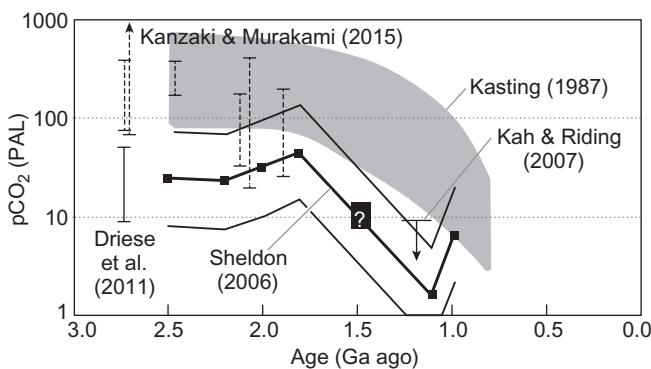

FIGURE 4.5.2 CO₂ estimates from paleosols compared with those from the climate model of (Kasting 1987). (Modified from Sheldon, N.D., *Precambrian Res.*, 147, 148–155, 2006.) Sheldon's estimates (with error bars) are shown by the dark squares connected by the solid black line. The downward arrow at 1.2 Ga is the upper limit on pCO₂ from cyanobacterial sheath calcification (Kah and Riding 2007). The bar in the middle left is the paleosol estimate at 2.7 Ga from (Driese et al. 2011). Bars in the upper left are paleosol estimates from (Kanzaki and Murakami 2015). (Reprinted from Catling, D. and Kasting, J.F., *Atmospheric Evolution on Inhabited and Lifeless Worlds*, Cambridge, UK, Cambridge University Press, 2017. With permission.)

n different quanta together to produce the required total yield to make ATP; however, in practice, n is a small number. Thus, the minimum Gibbs free energy required to power actively growing cultures is about 20 kJ/mol, whereas static or starving cultures can subsist on 12–15 kJ/mol. By analogy with electrical systems, BEQ can be associated with the *voltage* of a system. Indeed, this connection is direct, because voltage differentials, E^0 , and free-energy changes, ΔG^0 , are related through the Nernst equation, $E^0 = -\Delta G^0/nF$, where n is the number of moles and F is Faraday's constant, 9.6485 × 10⁴ C/mol.

Hoehler also defines a *maintenance energy* (ME) requirement for different microbial ecosystems (Hoehler 2004). This is a kinetic limitation, rather than a thermodynamic one: If critical metabolic substrates (e.g., H₂ for methanogenesis) are not available in sufficient quantity, then the rate of metabolism in an organism/culture will not be adequate to allow that culture to survive or grow. By analogy to electrical systems, ME is like *current*. Maintenance energy is more difficult to calculate than BEQ, because it depends on the size of the organisms and the nature of the metabolic reaction. But it has been estimated for a few anaerobic metabolisms, including methanogenesis, and I will use these values in the remainder of this subsection. Importantly, the relative values of ME for growth, maintenance, and survival are 1000, 1, and 0.001–0.01, respectively, according to Hoehler. The ME for growth of laboratory microbial cultures is surprisingly high, ~127 J/g dry biomass/h, as compared with a typical human energy budget of 12.5 J/g dry biomass/h. But microbial populations in natural environments are able to persist at ME values several orders of magnitude lower, so it may be the maintenance ME threshold that is most relevant for the present analysis.

4.5.4.1 H₂-BASED METHANOGENESIS

Let us now apply these concepts to specific metabolic reactions that have been proposed for early life. One reaction that has been recognized by many authors is H₂-based methanogenesis:

Virtually, all modern methanogens are capable of performing this reaction. Phylogenetic sequencing suggests that H₂-using methanogens evolved sometime during the Archean (House et al. 2003; Battistuzzi et al. 2004), if not earlier. This reaction is strongly exergonic under standard conditions; it has $\Delta G_R^0 = -130.5$ kJ/mol at 298 K. (Thermodynamic data are taken from the National Institute of Standards (NIST) Chemistry Webbook on-line. I use gas phase concentrations for convenience [except for water], even though the reaction is assumed to occur in aqueous solution. This is allowed, because at Henry's Law equilibrium, the free energy of a gas and its dissolved counterpart are the same.)

The actual amount of free energy available to organisms from reaction (4.5.2) depends on the concentrations of the

reactants and the products. The free energy of the reaction, ΔG_R , is related to the standard free-energy change by:

$$\Delta G_R = \Delta G_R^0 + RT \ln Q \quad (4.5.3)$$

Here, R is the universal gas constant, 0.008314 kJ/mol, T is temperature in Kelvin, and Q is the reaction quotient, which for this reaction is given by $Q = p\text{CH}_4/(p\text{CO}_2 \cdot p\text{H}_2^4)$. The activity of liquid water is assumed to be unity.

To calculate the energy available from this reaction, we need to estimate the amount of methane in the early atmosphere. That, in turn, depends on its source. The present CH₄ flux, which is mostly biological, is estimated to be 535 Tg(CH₄)/year (Houghton et al. 1994) or 3.3 × 10¹³ mol/year. This is accompanied by a much smaller abiotic CH₄ flux produced by serpentinization reactions deep within submarine hydrothermal systems (McDermott et al., 2015). By ratioing to the better-known flux of H₂ produced by these systems, Catling and Kasting (2017, p. 211) estimated an abiotic CH₄ flux of 3 × 10¹⁰ mol/year, about 1000 times smaller than the biological flux. Converting to photochemists' units (10¹² mol/year = 3.74 × 10⁹ molecules cm⁻²s⁻¹), the abiotic CH₄ flux is ~1 × 10⁸ cm⁻²s⁻¹. Putting this flux into a photochemical model similar to that used to produce Figure 4.5.1 gives an atmospheric CH₄ mixing ratio of 5 × 10⁻⁷, or 0.5 ppmv (Catling and Kasting 2017, Figure 9.9). I shall use that value for the analysis.

Now, let us calculate the free-energy yield from reaction (4.5.2). For a case that might be representative of the late Archean atmosphere, we can use the values in Figure 4.5.1: $p\text{CO}_2 = 0.2$ atm and $p\text{H}_2 = 2.6 \times 10^{-4}$ atm. Evaluating at 298 K, we have $Q = 5.5 \times 10^8$, $RT \ln Q \approx 50$ kJ/mol, and hence, $\Delta G_R \approx -80$ kJ/mol. This is almost equal to the ~97 kJ/mol estimated to be available for methanogenesis within modern submarine hydrothermal vent plumes (McCollom 2000). Methanogens thrive within these modern plumes, and so, from a BEQ standpoint, the global Archean surface ocean should have readily been able to sustain methanogens. Implementation of this BEQ limit in a model led Kharecha et al. (2005) to predict that a methanogen-based ecosystem (their Case 1) or a methanogen- and acetogen-based system (their Case 2) could have produced a methane flux comparable to the present-day flux.

From an ME's standpoint, the prospects for widespread methanogenesis in the Archean oceans is less clear. Hoehler (2004) argues that a minimum internal dissolved H₂ concentration for methanogens is ~10⁻⁸ M. For 0.5-μm diameter cells, this requires [H₂] = 3 × 10⁻⁸ M externally for maintenance and 1000 times that level for growth. The value of $p\text{H}_2$ from Figure 4.5.1 is 2.6×10^{-4} atm, and the solubility of H₂ is ~7.8 × 10⁻⁴ M/atm (Kharecha et al. 2005), so the ambient dissolved H₂ concentration would be 2 × 10⁻⁷ M. This exceeds the maintenance ME requirement by a factor of 7 but is more than two orders of magnitude lower than the corresponding growth requirement. In the Case 1 model of Kharecha et al., the methanogens draw down atmospheric H₂ to as low as 40 ppmv (4×10^{-5} atm), which would put ambient [H₂] right at the maintenance ME value. Given that these requirements

are not very precise, it is not obvious what this implies about the viability of a global, methanogen-based biosphere. But it may be that the CH₄ production rates estimated by Kharecha et al. for their Case 1 and Case 2 biospheres are somewhat overestimated. By contrast, their Case 3 biosphere, which assumed that primary production was dominated by anaerobic, H₂-utilizing phototrophs, should be largely unaffected by either the BEQ or ME constraint. So, if anoxygenic photosynthesis originated early, as seems likely, then the prediction of high methane levels in the Archean atmosphere should remain valid.

Note that the ME limitation for methanogenesis is much less severe in modern hydrothermal vents. There, the concentration of dissolved H₂ ranges from ~2 mM in hot, axial vent fluids (von Damm 1990, 1995) to ~15 mM in cooler, alkaline off-axis vents (Cannat et al. 2010). Even if mixing with ambient seawater dilutes these concentrations by a factor of 70 (for axial vent fluids) or 500 (for off-axis fluids), [H₂] remains above the growth threshold. Thus, it is easy to see why methanogens thrive in these environments.

Reaction (4.5.2) has also been proposed as a possible driver for the origin of life (Lane et al. 2010). Or, more accurately, these authors have proposed that this reaction allowed organisms to escape their dependence on the pH gradients in the hydrothermal vents and thereby to spread out to the global environment. But this suggestion seems unlikely for at least two reasons: First, reaction (4.5.2) involves a transfer of eight electrons, which may not have been possible until sophisticated biochemical machinery evolved to perform this task. And, second, Nitschke and Russell (2013) argue that neither methanogenesis nor its cousin, acetogenesis, appears to be particularly ancient, based on the observation that the C₁ branch of the Wood-Ljungdahl (WL) pathway is not conserved between acetogens and methanogens. The WL pathway produces acetyl-coenzyme A (CoA) in these and other organisms and is considered primitive because it starts from CO₂ and H₂. By contrast, the part of the WL pathway that involves CO is conserved between these two groups (*ibid.*), suggesting that CO metabolism may be quite ancient. But CO is arguably more available in the surface environment than in vents. This leads naturally to the next section of this chapter.

4.5.4.2 THE WATER-GAS SHIFT REACTION

A second chemical reaction that could have been used metabolically over much of the early Earth's surface environment is the reaction of CO with H₂O to produce CO₂ and H₂:

This reaction, which is used industrially in the manufacture of ammonia, hydrocarbons, methanol, and hydrogen, is sometimes referred to as the “water-gas shift” reaction.

I have analyzed this reaction previously (Kasting 2014), so the present discussion can be brief. Under standard conditions, this reaction has a Gibbs free-energy change, ΔG_R^0 , of -20.1 kJ/mol.

For a case that might be representative of the late Archean atmosphere, we can use the gas concentrations shown in Figure 4.5.1: pCO₂ = 0.2 atm, pCO = 1.6 × 10⁻⁵ atm, and pH₂ = 2.6 × 10⁻⁴ atm. Evaluating at 298 K, we get Q = 3.25 and $\Delta G_R \cong -17$ kJ/mol. While less than the 20 kJ/mol required for active growth, this is still well above BEQ requirement of 12-15 kJ/mol for static ecosystems.

From the standpoint of ME, the reaction is less favorable. The minimum substrate concentration is proportional to $(D\Delta G_R)^{-1}$, where D is the diffusivity of the substrate (CO in this case) and ΔG_R is energy of the reaction (Hoehler 2004). The free energy for reaction (4.5.4) is lower than that for reaction (4.5.2) by a factor of (17/80), and the diffusivity of CO is lower than that of H₂ by a factor of (1.9/5) (Kharecha et al. 2005, Table 1); thus, the minimum substrate concentration is higher by a factor of 12. For H₂, the ME maintenance limit was 3 × 10⁻⁸ M, so for CO, the corresponding limit should be ~4.6 × 10⁻⁷ M. With a CO solubility of 1 × 10⁻³ mol/L/atm (*ibid.*), the dissolved CO concentration corresponding to Figure 4.5.1 is only 1.6 × 10⁻⁸ M. This is a factor of 30 smaller than the ME limit. This suggests that CO abundances equal to those shown in Figure 4.5.1 could *not* have sustained a global biosphere.

Before giving up on CO, though, let us consider why the composition of the early atmosphere should favor this reaction and why we may have underestimated it in the above analysis. The reason that this free-energy gradient should have existed is three-fold: First, CO would have been produced in copious quantities in the early stratosphere by photolysis of CO₂: CO₂ + hν → CO + O. Second, the direct recombination of CO with O is spin-forbidden and slow; hence, CO would have flowed down into the troposphere, where it could recombine with OH produced by water vapor photolysis: CO₂ + OH → CO₂ + H. And third, H₂ was always escaping to space; hence, its atmospheric concentration was limited by the balance between escape and outgassing from volcanoes. All of these factors tend to drive reaction (4.5.4) to the right.

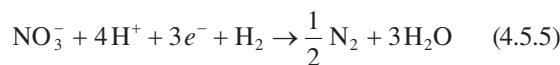

With this in mind, let us also remember that the free-energy yield estimated here is appropriate for some time during the late Archean. The amount of free energy available during the Hadean could have been significantly higher, particularly if large amounts of CO were generated by impacts (Kasting 1990). Indeed, the early atmosphere could have been CO-dominated if the CO production rate from impacts exceeded the rate at which H₂O was photolyzed to produce OH (*ibid.*). Furthermore, reaction (4.5.4) involves a transfer of only two electrons and hence should be biochemically simpler than reaction (4.5.2). As mentioned in the previous section, the branch of the WL pathway that involves CO is considered to be evolutionarily ancient (Nitschke and Russell 2013). Others have also identified this reaction as being of possible early biological importance (Huber and Wachtershauser 1997, 1998). So, even if this reaction was not a viable source of energy for an Archean global biosphere, it might well have been important during the earliest stages of biological evolution, particularly if life originated within the surface environment, as opposed to a midocean ridge hydrothermal vent system. The jury is still out on that important

question. We may learn the answer to this question from studies of Europa and Enceladus, both of which are uninhabitable at their surfaces but are expected to have hydrothermal vent systems similar to those on Earth.

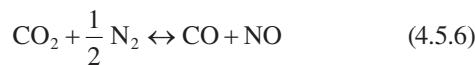

4.5.4.3 NITRATE AS AN ENERGY SOURCE FOR POWERING METABOLISM

A third source of thermodynamic free energy on the early Earth would have been reactions between nitrogen oxides produced photochemically within the atmosphere and reductants such as H₂, Fe⁺², and CH₄ (Nitschke and Russel 2013; Wong et al. 2017). Nitschke and Russell argue that the reaction of NO with CH₄, a form of *methanotrophy*, may have been one of the earliest bioenergetic pathways.

We can get some idea of the energetics of these reactions by looking at a representative reaction in which nitrate reacts with molecular hydrogen to form N₂:

This reaction is not, to my knowledge, performed by any individual organism; however, modern consortia of microorganisms accomplish essentially this same thing. Nitrate would have been produced in the primitive atmosphere by a sequence of reactions initiated by lightning. In the high-temperature core of a lightning bolt, N₂ would have reacted with CO₂ to produce nitric oxide:

The rate at which NO was produced can be estimated by scaling to the modern atmosphere, in which N₂ reacts with O₂ to produce NO under these circumstances. The modern NO production rate by lightning, in photochemists' units, is about 6 × 10⁸ cm⁻²s⁻¹ (Wong et al. 2017). These authors estimate prebiotic NO production rates of 7 × 10⁶–2 × 10⁹ cm⁻²s⁻¹ by using a three-dimensional general circulation model coupled to a photochemical model. By comparison, Kasting (1990) estimated an NO production rate of 5 × 10⁸ cm⁻²s⁻¹ for a 0.2-bar CO₂ atmosphere and 2 × 10⁹ cm⁻²s⁻¹ for a 2-bar CO₂ atmosphere. Let us use the lower of these two values to remain consistent with the atmosphere shown in Figure 4.5.1. A rate of 5 × 10⁸ cm⁻²s⁻¹ is equivalent to ~1.3 × 10¹¹ mol/year, or 1.9 Tg(N)/year.

The next step in forming nitrate is to react NO with H to produce nitroxyl, or HNO. HNO then dissolves in rainwater and goes into the ocean, where it disproportionates to form nitrate, nitrite, and N₂O (Mancinelli and McKay 1988). Assume for simplicity that it all forms nitrate. Nitrate will then build up in the ocean, until it encounters a sink that balances production. Wong et al. (2017) assume that the ultimate sink for nitrate on the prebiotic Earth would be cycling through the hot, axial hydrothermal vents at the midocean ridges. (A similar assumption was made by Kasting et al. [1993, Sect. 5iv]. We reevaluate this assumption below.) According

to these authors, the rate of seawater circulation through the axial vents is 7.2 × 10¹² kg/year. The mass of the oceans is 1.4 × 10²¹ kg, so the entire ocean circulates through the vents in about 200 Myr. The loss rate of nitrate is equal to the flow rate through the vents, multiplied by the nitrate concentration in seawater. Balancing this loss with the production rate from the previous paragraph yields a dissolved nitrate concentration of ~20 mM. Kasting et al. (1993) assumed a faster flow rate through the ridges, corresponding to a 10-Myr lifetime and predicted about 1 mM of nitrate in the oceans.

Now, let us return to reaction (4.5.5), the reaction of nitrate with H₂. Using electrochemical data (www2.ucdsb.on.ca/tiss/stretton/database/Standard_reduction_potentials), I calculate $\Delta G_R^0 \cong -92.6$ kJ/mol for the reduction of NO₃⁻ to gas-phase NO. Then, reduction of NO to N₂ yields an additional −323.8 kJ/mol, giving a ΔG_R^0 for reaction (4.5.5) of −416.4 kJ/mol. This is an enormous number. To calculate the reaction quotient for reaction (4.5.5), we need to put everything in units of mol/l. Assuming an ocean pH of 7 (because of the high pCO₂) and using Henry's Law constants of 7.8 × 10⁻⁴ mol/L/atm for H₂ and 7 × 10⁻³ mol/L/atm for N₂, I get $Q = 2.2 \times 10^{10}$, $RT \ln Q = 59$ kJ/mol, and $\Delta G_R \cong -357$ kJ/mol. This is still an enormous number. If correct, this would imply that nitrate was an extremely potent oxidant on the early Earth.

There is a reason, however, to doubt these numbers. Dissolved ferrous iron should have oxidized spontaneously in the presence of solar ultraviolet (UV) radiation on the early Earth (Braterman et al. 1983), releasing H₂. If nitrate (or nitrite) was present, then it seems likely that it would have been used as the oxidant in place of H₂O. As nitrate was being deposited directly into the surface ocean, its actual lifetime may have been only a few days. Assume 30 days to be generous. In that case, the nitrate concentration would be reduced by a factor of 0.1 year/(2 × 10⁸ year) = 5 × 10⁻¹⁰. So, instead of 20 mM nitrate, one would have 0.01 nM nitrate. Q would increase by a factor of 1/(5 × 10⁻¹⁰) = 2 × 10⁹, $RT \ln Q$ would increase by 53 kJ/mol, and ΔG_R would be −304 kJ/mol. This number remains enormous. The BEQ constraint for microbial metabolism should easily be satisfied by reaction (4.5.5) or any number of related reactions between nitrogen oxides and available reductants.

But now, consider this reaction from the ME standpoint. Take −320 kJ/mol as an estimate for ΔG_R . This is four times higher than the corresponding value for methanogenesis. But the diffusivity of nitrate, 1.7 × 10⁻⁵ cm²/s (<http://bionumbers.hms.harvard.edu>), is a factor of three lower than that for H₂, so to first order, the minimum nitrate concentration required for maintenance should be the same as that for H₂, 3 × 10⁻⁸ M. This constraint would be easily satisfied if nitrate were as abundant as estimated by (Wong et al. 2017). But if the much lower concentration calculated above is correct, then the average concentration of nitrate in the oceans would be less than the ME requirement by a factor of 3000. Thus, given a short lifetime, nitrate could not have sustained a global biosphere. The question of whether the lifetime of nitrate was short or long could readily be answered by irradiating water containing Fe⁺² and NO₃⁻ with UV light, following (Braterman et al. 1983), and seeing whether nitrate is consumed in the process.

This same analysis suggests that nitrogen oxides might *not* have made a good redox partner for CH₄ within hydrothermal vents, as suggested by (Nitschke and Russell 2013). These compounds might have been abundant in the surface ocean, following thunderstorms, but they would not have been around long enough to make it into the deep ocean and circulate through submarine vents. The lifetime of nitrate should be reevaluated as part of pursuing this hypothesis.

4.5.4.4 OTHER POTENTIAL OXIDANTS ON THE EARLY EARTH

Finally, nitrogen oxides would not have been the only oxidants produced within a weakly reduced primitive atmosphere. Sulfate and hydrogen peroxide would have been generated photochemically (Pavlov and Kasting 2002; Segura et al. 2003), and O₂ would have been produced by photochemistry and lightning (Haqq-Misra et al. 2011). Sulfate is a less potent oxidant than nitrate, and I shall simply neglect it here. O₂ is a powerful oxidant, though, so let us briefly consider it. The reaction

has a standard free energy of -237 kJ/mol . Surface concentrations of O₂, $\sim 10^{-13} \text{ atm}$, are too low to be seen in Figure 4.5.1. However, as with nitrate, localized O₂ concentrations could have been much higher than this in the immediate aftermath of thunderstorms. And downward transport of O₂ from the stratosphere in the polar night region could have produced a surface O₂ concentration of $\sim 3 \times 10^{-6} \text{ atm}$ (*ibid.*). Using this concentration, along with $p\text{H}_2 = 2.6 \times 10^{-4} \text{ atm}$ from Figure 4.5.1, gives $Q = 1/(p\text{H}_2 \cdot p\text{O}_2^{0.5}) = 1.3 \times 10^9$, $RT \ln Q = 52 \text{ kJ/mol}$, and $\Delta G_R \approx -185 \text{ kJ/mol}$. As with nitrate, this reaction is extremely favorable from a BEQ standpoint.

Now, calculate the ME limit. For a solubility of $2.6 \times 10^{-4} \text{ mol/L/atm}$ and $p\text{O}_2 = 3 \times 10^{-6} \text{ atm}$, the dissolved O₂ concentration is $8 \times 10^{-10} \text{ M}$. The diffusivity of O₂ is about 2.5 times lower than that of H₂, but the free-energy change for reaction (4.5.7) is 2.5 times higher than that for methanogenesis; thus, the critical [O₂] for maintenance should be like that of H₂, $3 \times 10^{-8} \text{ M}$. Thus, the ambient dissolved O₂ concentration is ~ 40 times below the ME limit. Like nitrate, O₂ would not have been able to sustain a global biosphere. And, like nitrate, O₂ would probably have been consumed within the surface ocean during UV oxidation of ferrous iron, so it would be unlikely to have been present in appreciable concentrations in the deep ocean. Thus, O₂ is also not a probably redox partner for reactions important to the origin or early evolution of life.

4.5.5 CONCLUSIONS

Earth's Archean atmosphere was probably a weakly reduced mixture of CO₂ and N₂, with smaller amounts of H₂, CO, and CH₄. The Hadean atmosphere was similar except that it was richer in CO₂ (and maybe CO) and poorer in CH₄.

Climate during the Archean was probably similar to that of more recent times, with periods of glaciation interspersed with periods of warmth. The faintness of the young Sun was offset by the increased greenhouse effect from CO₂ and CH₄. Climate during the Hadean is essentially unknown. Theory suggests that a multi-bar CO₂ atmosphere produced warm surface temperatures early on but that drawdown of CO₂ by seafloor weathering cooled the Earth to near-modern temperatures by $\sim 3.5 \text{ Ga}$.

Earth's atmosphere was always more oxidized than gases coming out of Earth's interior because of photolysis of H₂O, followed by escape of hydrogen to space. The redox gradients set up in this manner could have played an important role in originating and sustaining life. Of the reactions discussed here, the water-gas shift reaction, in which CO combines with H₂O to produce CO₂ and H₂, shows the most promise of being relevant to the origin of life, particularly if life originated in the surface environment, as opposed to hydrothermal vents. Methanogenesis was probably a somewhat later invention (though still early in biological evolution), and it may have played a major role in producing the methane that helped to keep the Archean climate warm. Although strong oxidants such as nitrate and O₂ were produced by photochemistry and lightning within the Archean and Hadean atmospheres, these species were likely short-lived and are unlikely to have played a major role in either originating or sustaining life. Laboratory experiments to simulate UV radiation impinging on a Fe⁺²-rich early ocean are needed to determine whether this last proposition is correct.

5.1.1 INTRODUCTION

Life belongs to the very fabric of the universe.

Christian de Duve (de Duve 1991)

Without doubt, explaining how life appeared on our planet is highly problematic, so daunting that some think it impossible. This fundamental question would fall outside the domain of science if the origin of life were the result of a highly improbable, almost unrepeatable phenomenon. In this case, we would lose all hope of finding an answer. However, the materialistic and evolutionary view adopted by contemporary scientists suggests that the origin of life is a chemical enigma of a historical nature, which, despite its intrinsic contingencies, we can understand and even test experimentally. It is a chemical enigma because the origin of life sprang from the transition from inert chemical matter (*i.e.*, cosmo- and geochemistry) to the most primitive biochemical systems. It is historical since this is an evolutionary transition, *that is*, a long series of successive, contingent stages of increasing complexity, each one genealogically depending on the previous one (Lazcano 2010b), and since this took place on our planet in the past, more than 3,500 million years ago (see this Handbook, [Section 8](#)).

These chemical and historical facets of the riddle of life's beginnings were obvious to Charles Darwin (Peretó et al. 2009). He was always reluctant to publicly express his ideas on the origin of life, but in a letter dated 1871 to his friend and colleague, the botanist Joseph Hooker, Darwin described a set of conditions and ingredients necessary to spark evolution: "It is often said that all the conditions for

the first production of a living organism are now present, which could ever have been present. But if (and oh what a big if) we could conceive in some warm little pond with all sorts of ammonia and phosphoric salts, –light, heat, electricity, etc. present, that a protein compound was chemically formed, ready to undergo still more complex changes, at the present day such matter would be instantly devoured, or absorbed, which would not have been the case before living creatures were formed." (Letter reproduced in full in Peretó et al. 2009.)

Like Darwin, we accept that the primitive Earth was governed by the same laws of physics and chemistry as they are today. Those chemical events of the past are, thus, amenable to scientific examination and understanding, and therefore, any narration of the transition from inert to living matter must be compatible with all our scientific knowledge of the material world. Eventually, any model we propose must not only be plausible but also empirically verifiable. This does not mean that the answer to the origin-of-life enigma will be a detailed account of what exactly happened somewhere on the primitive Earth. This is something we will never know for certain in full detail, not only because of the complete absence of a chemical record of the first steps of life and the many unknowns about Archaean Earth's physicochemical constraints but, essentially, also because of the historical nature of the problem, including emergent phenomena difficult to reduce to physics and chemistry and requiring other types of explanatory accounts. Rather, we seek a full explanation of how the origin of life *might have happened* on the primitive Earth or, in other words, an experimental demonstration of the outstanding potential of

chemistry to generate life, a goal considered a Holy Grail in chemical science (Krishnamurthy 2017).

The prospect of reproducing the earliest steps of life in a laboratory is not new. Over a century ago, several pioneers of synthetic biology, such as Alfonso Herrera, John Burke, and Stéphane Leduc, tried to cross the boundaries dividing inert from living matter (Peretó and Català 2007; Peretó 2016). There is an epistemological continuity between these premature and naïve attempts to synthesize life and the ultimate objective of the scientific quest to reveal the origin of life, framed within an evolutionary and chemical context. This approach is represented by the original proposals of Aleksandr I. Oparin (1924) and John B. S. Haldane (1929), who independently argued that any proposal on the natural emergence of life would be mere speculation, unless we are able to offer empirical support for its plausibility on early Earth.

The classic research on prebiotic chemistry – the chemistry that led to life – initiated by Stanley L. Miller and Harold C. Urey in the United States in the 1950s and inspired by Oparin's heterotrophic theory (Lazcano 2010a), promoted the notion of a primitive Earth rich in organic materials that could be a source of both raw materials and food for the earliest life forms. Thus, the chemical landscape on a young abiotic Earth (generated both from endogenous sources and from extraterrestrial delivery) offered a wide range of compounds, whose accumulation in the oceans shaped the primitive soup. Did life originate from an immense chemical diversity? Or rather, were there prebiotic processes providing a fairly reduced chemical repertoire that anticipated the subset of molecules operating in biochemistry? In this chapter, I will show that although these fundamental questions are not yet resolved, they are greatly clarified by current advances in prebiotic systems chemistry – an approach dealing with complex multicomponent, interacting reactions and processes (Powner and Sutherland 2011; Ruiz-Mirazo et al. 2014).

5.1.2 IS TERRESTRIAL BIOCHEMISTRY ONE AMONG MANY?

Life is the outcome of a complex network of chemical reactions and molecular interactions. Biological complexity is organized around a small set of organic molecules – amino acids, nucleotides, lipid molecules, and a suite of metabolic intermediates – used to build polymers and supramolecular architectures – proteins, nucleic acids, membranes, ribosomes, etc. The whole system is sustained by an almost universal metabolic network (Smith and Morowitz 2016), which, by gathering matter and energy from the environment, drives the idiosyncratic and paradoxical performance of life, namely, autonomous chemical systems able to make imperfect copies of themselves and, hence, evolve (Ruiz-Mirazo et al. 2004). But, how did this peculiar chemical phenomenon begin? We do not know for sure, but let's start by quoting Richard

Dawkins (Dawkins 2009, p. 419): it must have been whatever it took to get natural selection started. Once the extraordinary unfolding of natural selection has begun, the Darwinian evolutionary theory, conveniently updated and extended, explains much of what happened along the history of life. And for natural selection, a population of entities that replicated with imperfections was needed, resulting in a variety of survival and reproductive capacities. Although the specific characteristics of these “infra-biological” or “pre-biological” entities are not yet well determined, there is a broad consensus that natural selection was operative before cells were endowed with DNA as the genetic material, during the era of the so-called RNA world (de Duve 2005b). This situation can occur in primitive cells, in which catalytic RNAs (ribozymes) facilitate processes like the synthesis of monomers for their own replication (self-replicative ribozymes) and the synthesis of membrane components (Szostak et al. 2001). It is fascinating to see how – albeit in restricted circles – the development of molecular biology in the twentieth century ran parallel to the discussion on how evolution could have occurred using RNA before DNA (Lazcano 2010a, 2012).

But before the advent of RNA, was there some other kind of selection process taking place in this immense sea of chemical possibilities, or was RNA the result of chemical determinism? Is terrestrial biochemistry just one among many? Was the use of RNA the result of a frozen accident, a matter of chance? It is reasonable to suppose that a variety of cosmic and geological processes took place on the primitive Earth, contributing to an extraordinarily diverse inventory of organic materials. When we scrutinize interstellar space, or analyze pieces of extraterrestrial matter such as meteorites or comets, we discover the astounding richness of organic cosmochemistry (see this handbook, [Section 4](#)). Likewise, when we simulate primitive atmospheric chemistry, as in the classic Miller experiments and its derivatives (see this handbook, [Chapter 5.5](#)), all the evidence points toward notable chemical wealth (Cleaves 2015). Processes of chemical selection would operate on this chemodiversity, aided by minerals and by the environmental conditions. We know very little about how the biological subset of amino acids, nitrogen bases, sugars, or lipids, all with a certain isomerism, could have been selected to ignite the earliest cellular systems.

However, the prevalent view of life emerging from a complex and diverse mixture of chemical building blocks was questioned by some evolutionary biochemists and, more recently, by Günther Wächtershäuser (Wächtershäuser 1988), Harold Morowitz (Morowitz 1992; Smith and Morowitz 2016), and Christian de Duve (de Duve 1993, 2011). With diverse emphasis and on different grounds, these scientists suggest that prebiotic chemistry was predisposed toward synthesizing a few components, which would be almost the same as those configuring the contemporary metabolic repertoire. In fact, chemical determinism in the origin of life is a central theme in de Duve's thought and is one of the questions he posed in

his posthumous book, which recounts the intellectual journey of this exceptional biologist (de Duve and Vandenhoute, Chapter 9, 2013). In short, de Duve argues that under certain environmental constraints, the outcome of chemical evolution would almost always be the same and that the specific polymers and systems that eventually turned into evolving cell populations would not have randomly emerged by chance from an immense ocean of molecular possibilities (Fry 2019a,b).

Thus, the “cosmic imperative” for life’s emergence proposed by de Duve is at the philosophical antipodes of the proposals considering the origin of life as an unlikely chance event (Fry 2000; Lazcano 2017). In his influential book *Chance and Necessity*, molecular biologist Jacques Monod accepted the almost-proven notion of an early Earth rich in organic compounds and the possible emergence of biopolymers, such as proteins and nucleic acids (Monod 1970). Yet, Monod attributed an exceedingly low chance to the emergence of the genetic code and the functional organization of a cell having the capacity to evolve by Darwinian mechanisms. He famously stated that the planet was not pregnant with life and that, as a consequence, ours was the only inhabited planet in the universe. Clearly, Monod was astounded by the advances in molecular biology in his time, showing that the intimacies of universal cell mechanisms were much more complex than expected, thus making the question of their natural emergence still more inextricable (Monod 1970). The historicity of the process of biogenesis would comprise not only contingencies of the type that Monod was conceiving (essentially, stochastic and irreversible events) but also the emergence of intermediate systems that allowed for further evolutionary transitions to take place. Nevertheless, as we will discuss in Section 5.1.4, recent discoveries in prebiotic systems chemistry indicate that the path leading from chemistry to the earliest evolving cells may be simpler than what Monod could ever have imagined (Islam and Powner 2017; Ruiz-Mirazo et al. 2017; Sutherland 2017).

5.1.3 THE THREE PILLARS OF CLASSIC PREBIOTIC CHEMISTRY

During the last six decades, many investigations in classic prebiotic chemistry have been conditioned by the search for reasonable mechanisms underlying the direct and robust synthesis of biomonomers. Miller’s spark discharge experiments elegantly showed the ease of amino acid synthesis from mixtures of simple molecules, such as H₂O, NH₃, CH₄, and H₂, purportedly representing the chemical composition of a primitive reducing atmosphere (Miller 1953). It is likely that the amino acids obtained in this kind of setting are a product of the Strecker mechanism, a well-known reaction between ammonia and *in situ* produced cyanide **1** and aldehydes (Miller 1957).

Meanwhile, the traditional approach to investigating the prebiotic synthesis of RNA precursors has researched the conjunction of nucleobases – purines are easily derived from cyanide **1** (Figure 5.1.1) oligomerization (Oró 1960) and pyrimidines can be obtained from cyanoacetylene **6** (Figure 5.1.2), for instance (Robertson and Miller 1995) – and ribose, which is just one of the myriad products of the formose reaction of formaldehyde **2a** (Figure 5.1.1) oligomerization (Breslow 1959). The three main avenues of prebiotic research during the twentieth century (Strecker-type chemistry for amino acid synthesis, cyanide chemistry for nucleobases, and the formose reaction for sugars) have been identified as the three pillars of prebiotic chemistry (Islam and Powner 2017). These so-called pillars underpin scientists’ endeavors in their quest to find prebiotically plausible pathways for monomers en route to forming the major biopolymers, *that is*, proteins and nucleic acids. Nevertheless, despite the great intellectual and scientific benefits of this classical approach, there are some caveats (see Figure 5.1.1).

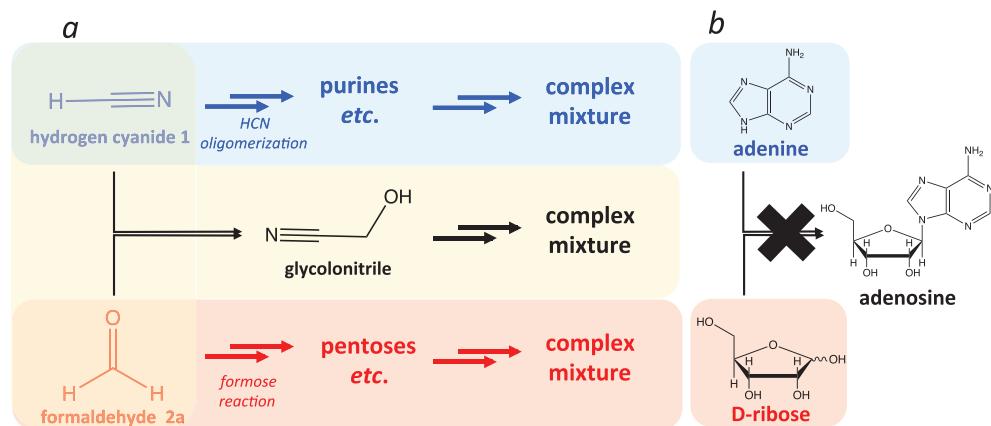

FIGURE 5.1.1 Prebiotic chemistry classical approaches. (a) Hydrogen cyanide **1** oligomerization produces purines among other compounds (blue background) and formaldehyde **2a** produces sugars (among many others, pentoses) through the formose reaction (red background); during the Miller synthesis of amino acids, the formation of glycolonitrile may impede the simultaneous synthesis of purines and pentoses (yellow background). (b) The traditional abiotic pathway to nucleosides starting from preformed nucleobases and pentoses has been proven extraordinarily difficult.

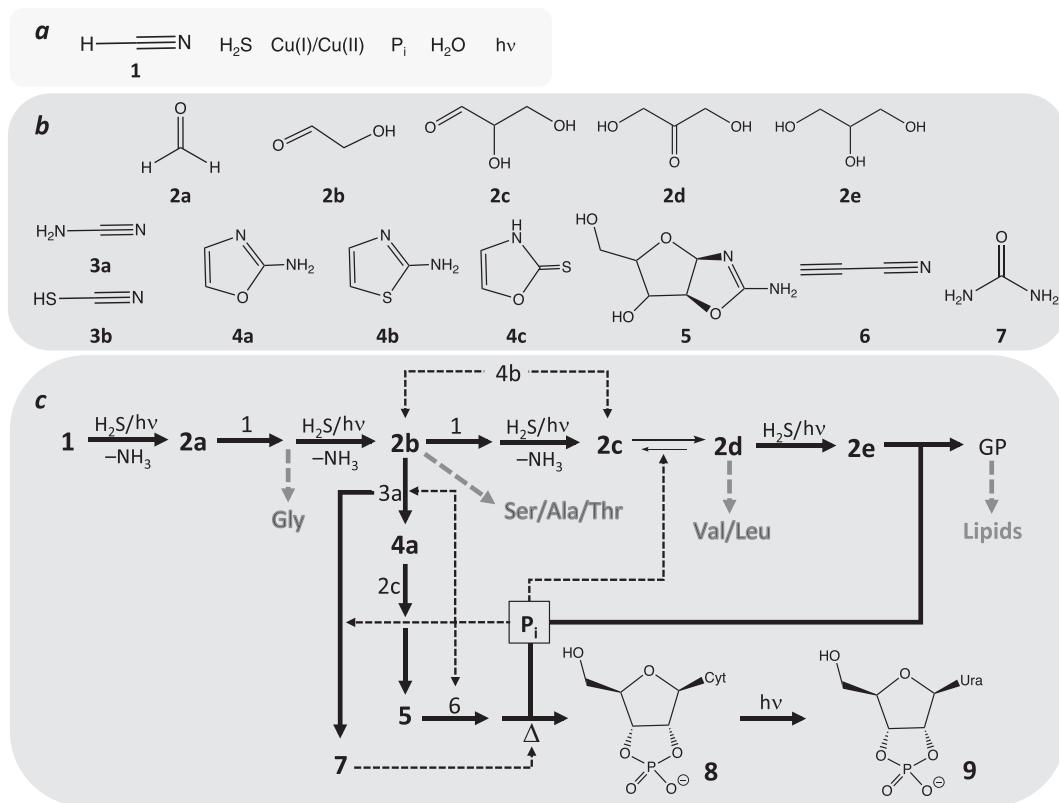

FIGURE 5.1.2 The cyanosulfidic protometabolism. (a) Feedstocks of cyanosulfidic protometabolism: hydrogen cyanide **1**, hydrogen sulfide (H_2S), copper ions, inorganic phosphate (P_i), water, and UV light (hv). (b) Some intermediates in the cyanosulfidic protometabolism: formaldehyde **2a**, glycolaldehyde **2b**, glyceraldehyde **2c**, dihydroxyacetone **2d**, glycerol **2e**, cyanamide **3a**, thiocyanic acid **3b**, 2-aminooxazole **4a**, 2-aminothiazole **4b**, 2-thioxazole **4c**, ribose aminooxazoline **5**, cyanoacetylene **6**, and urea **7**. (c) The pathway to some proteinogenic amino acids, and glycerolphosphate (GP) as precursor of lipids (gray dashed arrows), as well as cyclic ribonucleotides of cytosine **8** and uracil **9**. Black dashed arrows indicate catalytic activity.

For example, (1) sometimes, the required concentrations of reactants to produce the desired products are too high to be realistic in primitive settings; (2) there is a fundamental incompatibility between the kind of chemistry required for nucleobase and sugar syntheses – the highly favorable and rapid formation of glycolonitrile and its further oligomerization may prevent the independent oligomerization of cyanide **1** and formaldehyde **2a** within the same setting; however, a strict pH control could prevent the appearance of complex polymers (Cleaves et al. 2008) (Figure 5.1.1a); (3) even if we conceive a geochemical scenario, where both cyanide **1** and formaldehyde **2a** oligomerizations proceed, we are confronted with ongoing processes driven by thermodynamic and kinetic forces toward the generation of intractable (and uncontrollable) mixtures of products, sometimes insoluble polymers, and, consequently, the interesting molecules (nucleobases and pentoses) are actually scarce intermediates of these reactions (Figure 5.1.1a); (4) last, but not least, even assuming that pentoses and nucleobases somehow simultaneously accumulate, we know that the reaction between these two moieties required to generate a nucleoside with a suitable isomerism is one of the most elusive processes in the entire history of classic prebiotic chemistry (Figure 5.1.1b).

5.1.4 A PREFERRED ROUTE TO BIOMONOMERS?

Prebiotic systems chemistry has graphically been shown as the prebiotic rocket emerging from a historical phase of more conventional and short-range experimental flights (Lehman 2017). Recently, diverse laboratories have contributed to developing a new paradigm in prebiotic chemistry based on complex combinations that paradoxically give relatively clean products instead of intractable mixtures (Powner and Sutherland 2011; Szostak 2011; Ruiz-Mirazo et al. 2014; Islam and Powner 2017). In short, prebiotic systems chemistry exploits molecular cooperation (Lehman 2017) through the reactivity, catalytic interactions, and specific physical behavior of molecules within complex, multicomponent chemical systems. In this section, I will summarize some notable results of this new approach.

5.1.4.1 THE CYANOSULFIDIC PROTOMETABOLISM

Classical prebiotic chemistry pointed toward an apparent dead end because of the incompatibility of nitrogenous (nucleobases) and oxygenous (sugars) chemistries; however,

the results of a systems approach led by John D. Sutherland and collaborators opened up brand new avenues for the prebiotic synthesis of ribonucleotides, amino acids, and lipid precursors. The work on a proposed cyanosulfidic protometabolism (Patel et al. 2015) is a true *tour de force* in origins-of-life research, since it proposes a reaction for the synthesis of two pyrimidine ribonucleotides, the aminonitrile precursors for 12 proteinogenic amino acids, glycerolphosphate (GP, a precursor of membrane phospholipids), and (remarkably) almost nothing else. The simple starting materials of this small repertoire of organic molecules are hydrogen cyanide (HCN **1**), hydrogen sulfide (H_2S), and inorganic phosphate (H_2PO_4^- , P_i) in an aqueous solution in the presence of copper ions and ultraviolet (UV) light (Figure 5.1.2). All these ingredients can be considered prebiotically plausible.

The cyanosulfidic scheme incorporates previously successful processes, in particular the synthesis of pyrimidine ribonucleotides, based on a strategy avoiding the direct reaction between ribose and nucleobase to form a *N*-glycosidic bond (Figure 5.1.1b), through the synthesis of 2-aminooxazole **4a**, a key intermediate derived from C2 (glycolaldehyde **2b**) and C3 (glyceraldehyde **2c**) sugars (Figure 5.1.2), and containing the elusive C-N bond (asterisk in Figure 5.1.3) in its structure (Powner et al. 2009).

It is remarkable that some components of the system act as catalysts. For instance, P_i is not only a precursor for ribonucleotide and GP formation but also acts as a buffer and as a general acid-based catalyst in critical steps, such as the synthesis of 2-aminooxazole **4a** from glycolaldehyde **2b** and cyanamide **3a** or the transformation of cyanamide **3a** into urea **7**, a compound that will likewise catalyze the final step in cyclic ribonucleotide of cytosine **8** synthesis (Figure 5.1.2c). This mixture of adducts, products, and

catalyzers beautifully illustrates the prebiotic systems approach.

However, even in the case of such effective abiotic synthesis, certain selective mechanisms and sequential processes are required for the accumulation of the right ribonucleotides and amino acids. Remarkably, 2-aminothiazole **4b**, plausibly present in a cyanosulfidic environment, selectively crystallizes the required C2 and C3 sugars (**2b** and **2c** in Figure 5.1.2c) in the presence of complex mixtures of aldoses and ketoses, acting as a chemical chaperone for ribonucleotide synthesis. Furthermore, 2-aminothiazole **4b** specifically excludes the synthesis of α,α -disubstituted amino acids, favoring instead the synthesis of proteinogenic α -amino acids precursors. Thus, a common physicochemical mechanism, in which 2-aminothiazole **4b** selects the “right” precursors by chemical reaction and precipitation, would explain the prebiotic synthesis of specific biomonomers out of complex chemical mixtures (Islam et al. 2017). It is noteworthy that the role of 2-aminothiazole **4b** in this crystallization-driven selective process was deduced from a systems chemical analysis applied to cysteine (one of the proteinogenic amino acids missing in Sutherland’s cyanosulfidic scheme) (Islam et al. 2017; Islam and Powner 2017).

The original cyanosulfidic scenario (Patel et al. 2015) explains the origin of two canonical pyrimidine (cytosine **8** and uracil **9**, Figure 5.1.2) ribonucleotides. Matthew Powner and coworkers have added plausibility to the whole model by including the divergent synthesis of both pyrimidine and purine ribonucleotides (Stairs et al. 2017): 2-aminooxazole **4a** is the common precursor to pyrimidine ribonucleotides, whereas the generationally related 2-thioxoazole **4c** serves as starting material for the synthesis of 8-oxo-adanine **11** and 8-oxohypoxanthine **12** ribonucleotides (Figure 5.1.4).

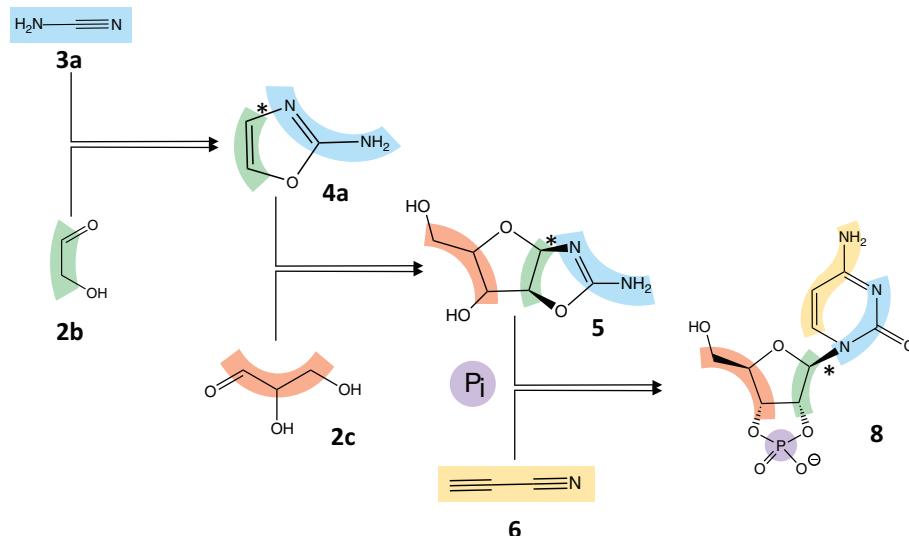

FIGURE 5.1.3 Pyrimidine ribonucleotide synthesis in a cyanosulfidic protometabolism. Asterisk (*) indicates the bond in 2-aminooxazole **4a** that will become the N-glycosidic bond in the final ribonucleotide **8**.

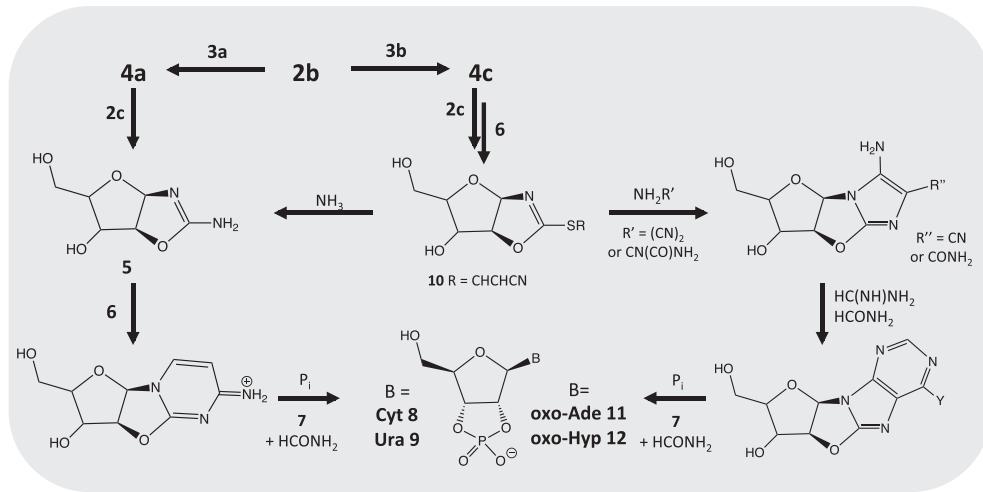

FIGURE 5.1.4 Simultaneous synthesis of purine and pyrimidine ribonucleotides in a cyanosulfidic protometabolism. Simultaneous assembly of cytidine-2',3'-cyclic phosphate **8**, uridine-2',3'-cyclic phosphate **9**, 8-oxo-adenosine-2',3'-cyclic phosphate **11**, and 8-oxo-inosine-2',3'-cyclic phosphate **12**. Divergent syntheses take place at the level of glycolaldehyde **2b** and thione **10**. For sake of simplicity, stereochemical details in the diverse compounds are omitted.

Thus, researchers have synthesized both purine and pyrimidine ribonucleotides efficiently and simultaneously under plausible prebiotic conditions for the first time. The easy synthesis of ribonucleotides based on oxo-purines would suggest that these monomers could precede the canonical ones (based on adenine and guanine) in a primitive genetic alphabet.

At the moment of preparing this chapter, the synthesis in the cyanosulfidic scenario of one important component in early protocells is missing: the amphiphilic molecules (*e.g.*, fatty acids) that would self-assemble in vesicles, generating the first compartments. Although the prebiotic presence of this kind of molecules is completely acceptable by other means, including abiotic synthesis and extraterrestrial delivery (Cleaves 2015), a continuous protometabolic source of amphiphiles is needed. It is of note that the cyanosulfidic scenario supplies both stereoisomers of GP (Figure 5.1.2c), necessary building blocks for the origin of the two phospholipid classes, namely bacterial and archaeal types of membrane lipids (Peretó et al. 2004). A further challenging issue to be addressed is the emergence of polymers from the monomers generated in the protometabolism and their functional integration with lipid vesicles into a highly organized “multiple polymer world” (Ruiz-Mirazo 2015a).

The cyanosulfidic scenario has been criticized because successful organic syntheses imply the sequential adjustment of specific laboratory conditions. Notwithstanding, all the conditions considered in the experiments, as well as the feedstocks, are prebiotically plausible, and one can imagine that all the constraints could be met over space and time on the primitive planet. In a comprehensive review, Sutherland has explained in detail the general strategy of his systems approach and the fruitful dialog between laboratory experiments and the geochemical constraints (Sutherland 2016). In

short, several plausible geochemical settings and processes, including impacts of meteorites and comets or water streams encountering a diversity of minerals, are invoked in a working model substantiated by the experimental results, and then, the refined model heuristically informs and suggests new experiments and simulations. This bidirectional conversation between prebiotic systems chemistry and geochemistry of the Archean Earth will eventually deliver a specific chemical definition of Darwin’s “so simple a beginning of life” – as he put it in the last paragraph of (Darwin 1859) – and a refined and realistic version of his metaphoric little pond.

5.1.4.2 PREBIOTIC PREFIGURATION OF METABOLISM

At first sight, we do not see any obvious correlation between the repertoire of classic prebiotic mechanisms (*e.g.*, Strecker synthesis and formose reaction) and the network of chemical transformations operative in extant enzymatic-dependent metabolic pathways. This apparent discontinuity has been compared to a dense cloud (Lazcano and Miller 1999) or an opaque barrier (Orgel 2003) separating prebiotic chemistry from biochemistry. However, looking in more detail for possible parallelisms in specific mechanisms, there are a few cases where enzymatic steps in metabolism resemble abiotic transformations. In this context, the term *chemomimetic biosynthesis* was suggested in reference to the enzymatic mechanism for riboflavin biosynthesis, which resembles the organic process taking place *in vitro* without enzymes (Eschenmoser and Loewenthal 1992). These authors perceived this case as evidence of how an enzyme could co-opt and optimize a previously existing non-enzymatic chemical transformation, suggesting certain chemical determinism and continuity with prebiotic chemistry in the origin of metabolism. But, in fact, the repertoire of possible

chemomimetic reactions in metabolism identified so far is disappointingly low (Peretó 2012 and references therein).

This lack of strict mechanistic parallelism, however, does not preclude the operation of a *principle of congruence* between a (non-enzymatic) protometabolism and a modern-like (enzymatic) metabolism, as proposed by de Duve (1993), elaborated in several works and summarized in (de Duve 2005a), with a conservation of a general outline of the mutual relationships between the main metabolic substrates and products. Therefore, it is supposed that a chemical determinism was operative in the first stages of the origin of metabolism (see also the discussions on this topic by Iris Fry, **Chapters 3.1** and **6.5** in this handbook). For de Duve, the term *protometabolism* is synonymous with prebiotic chemistry, *that is*, the early chemical processes that preceded and gave rise to the extant metabolism, and this notion has also been adopted by Sutherland and coworkers recently. In this particular sense, protometabolism was the necessary chemical landscape for the emergence of “useful” catalysts in an RNA world.

The development of these initial chemistries into something that resembles more closely a proper metabolic organization possibly involved a series of stages in which oligomerization processes ought to be included, so that functional compounds, such as peptides, oligonucleotides, amphiphiles, and so on, take the stage. Furthermore, pre-Darwinian selection processes (*e.g.*, molecular chaperones) must have started having an influence on the underlying chemistry. In other words, evolutionary dynamics will start dictating some of the changes and innovations taking place in those protobiological systems, according to the result of a complex history of interactions with similar systems and the environment at large. On these lines, it is important to notice that the replacement of a protometabolism by a modern (enzymatic) metabolism required the emergence of catalysts by a selection process based on their *usefulness* under certain conditions. For instance, in an RNA world, only the ribozymes fitting with existing substrates to be transformed into suitable products would be selected for, since an *evolving catalyst* would have a meaningful existence, as such, only if an appropriate substrate is present and ready to be transformed into a product that benefits the system as a whole. The initial suite of substrates would be the product of more primitive catalysts (mineral surfaces; metal ions; small organic molecules, such as amino acids and some cofactor precursors; short polymers, such as non-coded peptides referred to by de Duve as “multimers”; lipid vesicles; etc.) or, put in simple terms, the stable and robust outcome of a prevalent abiotic process, such as the cyanosulfidic scenario. Therefore, one could envision some initial stages in which chemical determinism was more prominent, to be later replaced, or modulated, by other processes in which evolutionary and historical aspects became increasingly influential.

From a bioenergetics perspective, de Duve’s protometabolic scenario is driven by the reactivity of the thioester bond, used before the adoption of polyphosphates and nucleotides as energy currencies (de Duve 1991). Possible traces of an ancient metabolism, independent of the use of phosphate but

enriched in reactions catalyzed by iron-sulfur clusters or thermodynamically enabled by thioesters, have been described using a systems-biology approach on a biosphere-level (or meta-metabolic) network (Goldford et al. 2017). The formation of iron-sulfur clusters under prebiotic conditions, driven by UV light, has also recently received further experimental support (Bonfio et al. 2017).

5.1.4.3 FOCUSING THE METABOLIC IMAGE

The emergence of ribozymes, as subjects of natural selection, added a new dimension to the pure chemical processes, since adaptation allowed catalysts’ optimization. Thus, the first enzymatic catalysts under natural selection (either ribozymes in an RNA world or, later on, genetically encoded protein enzymes) would play a key role in the transition from a dirty protometabolism (de Duve’s *gemisch*) to a cleaner metabolism. But, how dirty was the abiotic chemical landscape? The results of prebiotic systems chemistry (as discussed in [Section 5.1.4.1](#)) point out that certain chemical determinism would result in a more restricted abiotic repertoire than was imagined before. We now examine some empirical examples consistent with a protometabolic scenario.

Glycolaldehyde **2b** and glyceraldehyde **2c** (C2 and C3 sugars, respectively, nucleotide precursors in the cyanosulfidic protometabolism; see [Figure 5.1.2](#)) are also related to the structure of some intermediates of glycolysis, one of the most ancient metabolic pathways. Particularly, a robust and efficient synthesis of phosphoenolpyruvate **16** (PEP) from C2 **2b** and C3 **2c** sugars has been described (Coggins and Powne 2017) ([Figure 5.1.5](#)). The glycolytic intermediate PEP **16** is not only the metabolite with the highest phosphoryl transfer potential, and thus involved in the coupling between glycolysis and ATP synthesis, but also a key precursor in the metabolism of sugars and aromatic amino acids. Under plausible prebiotic conditions, other glycolytic intermediates, such as 3-phosphoglycerate **14**, 2-phosphoglycerate **15**, and pyruvate **17**, as well as serine precursor phosphoserine, are also obtained, clearly connecting the modern lower glycolysis (involving C3 intermediates) with a putative protometabolic network ([Figure 5.1.5](#)).

The oxidative decarboxylation of pyruvate C3 to acetate C2 is also observed, approaching a connection of another sub-network represented by the tricarboxylic acid (TCA) or Krebs cycle, which is through acetyl CoA **18**, or coenzyme A (CoA)-activated acetate ([Figure 5.1.5](#)), in extant metabolisms.

Incidentally, if the construction of the glycolytic pathway started from its lower segment, allowing the connection of ribonucleotide and amino acid metabolisms, and the access to other sugars, such as hexoses, was a posterior innovation, we would have a historical explanation for one of the most intriguing stoichiometric arrangements in universal metabolism: for the synthesis of C2 fragments (acetyl CoA **18**, metabolic precursor, for instance, of fatty acids and isoprenoids), C6 sugars must follow the fragmentation in C3 moieties up to pyruvate **17** that will suffer oxidative decarboxylation to acetyl CoA **18** with an

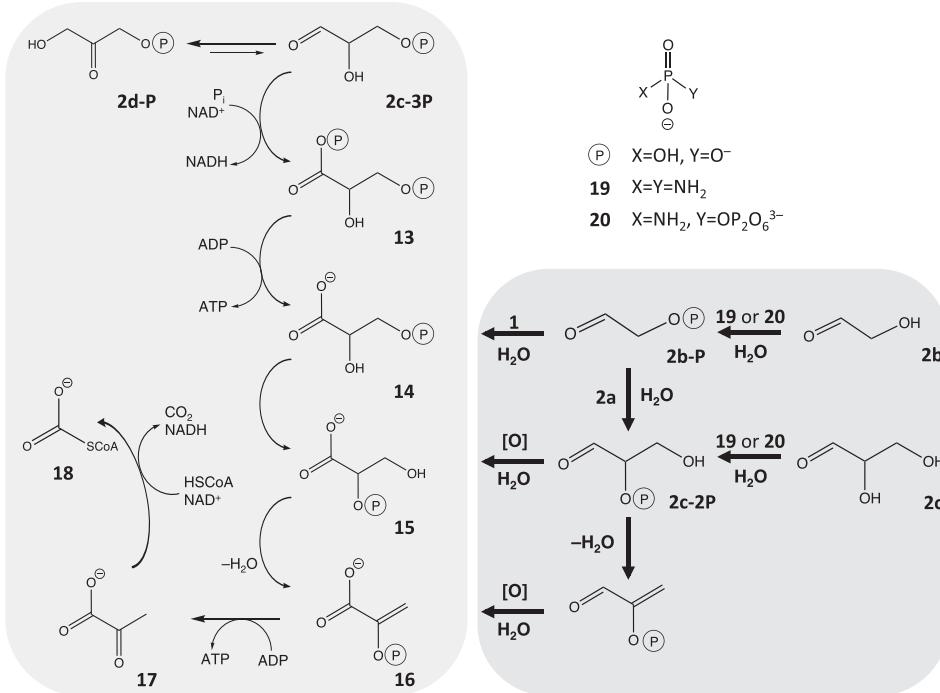

FIGURE 5.1.5 Synthesis of glycolytic intermediates in a cyanosulfidic protometabolism. A short sequence of mild and robust reactions (bold arrows, right panel) starting from glycolaldehyde **2b**, glyceraldehyde **2c**, and amidophosphates **19** or **20** produces some glycolytic intermediates such as 3-phosphoglycerate **14**, 2-phosphoglycerate **15**, and phosphoenolpyruvate **16**. Left panel shows the glycolytic pathway of enzymatic transformations from triosephosphates (dihydroxyacetonephosphate **2d-P** and glyceraldehyde-3-phosphate **2c-3P**) to pyruvate **17** and acetyl CoA **18**.

unescapable loss of 33% of carbon as CO₂ (Figure 5.1.5). In contrast, stoichiometric logic indicates that a more efficient process would fragment hexoses C6 into three C2 moieties (acetyl CoA **18**). This arrangement is absent in natural metabolic networks, because evolution had to incorporate C6 into a previous metabolic groundwork based on C3/C2 intermediates; however, this has been obtained in a remarkable example of metabolic engineering by using an artificial combination of enzymatic steps (Bogorad et al. 2013).

The preceding example, taken from synthetic organic chemistry (Coggins and Powner 2017), is complemented by the work of Markus Ralser and colleagues, who have explored the non-enzymatic conversions between the intermediate metabolites of central pathways such as glycolysis, pentose phosphate pathway (PPP) (Keller et al. 2014, 2016) and TCA cycle (Keller et al. 2017). Their strategy involves screening hundreds or thousands of possible conditions, inspired by the composition of Archaean sediments, looking for chemical transformations between intermediates. Albeit in some cases, the prebiotic plausibility of the assayed initial substrate is doubtful and the yields are very low, it is remarkable that they were able to reconstruct the basic topology of the pathways by using very simple catalysts such as Fe(II) ions and phosphate (glycolysis and PPP) or sulfate radicals (TCA cycle) at 70 °C. The aldol condensation of glyceraldehyde-3-phosphate

2c-3P and dihydroxyacetonephosphate **2d-P** (Figure 5.1.5) to generate fructose-1,6-bisphosphate – mimicking a non-enzymatic gluconeogenic reaction – has also been observed in ice (Messner et al. 2017). In addition to these indications of primitiveness of some fundamental chemistry of the central metabolic pathways, Joseph Moran and coworkers have shown that non-enzymatic catalysis by transition metals can promote sets of reactions that could be involved in primitive anabolic processes such as a reverse TCA cycle (Muchowska et al. 2017). All these experiments reinforce the notion of the establishment of networks of non-enzymatic transformations between organic molecules under plausible geochemical conditions. The topology of these networks strikingly resembles that of the metabolic core.

However interesting the research on the prebiotic plausibility of some metabolic intermediates and their non-enzymatic transformations is, we urgently need examples of sustainable non-enzymatic catalytic cycles as a model of primitive stages of metabolic cycles emergence. In that sense and following a bottom-up strategy, Springsteen et al. (2018) have described two linked protometabolic cycles that oxidize glyoxylate **19** to CO₂ and generate some intermediates shared with the metabolic TCA cycle.

The bicycle described by Ram Krishnamurthy and collaborators and shown in Figure 5.1.6a represents a simpler version of the overall metabolic process of carbon oxidation and contains some noteworthy analogies with modern

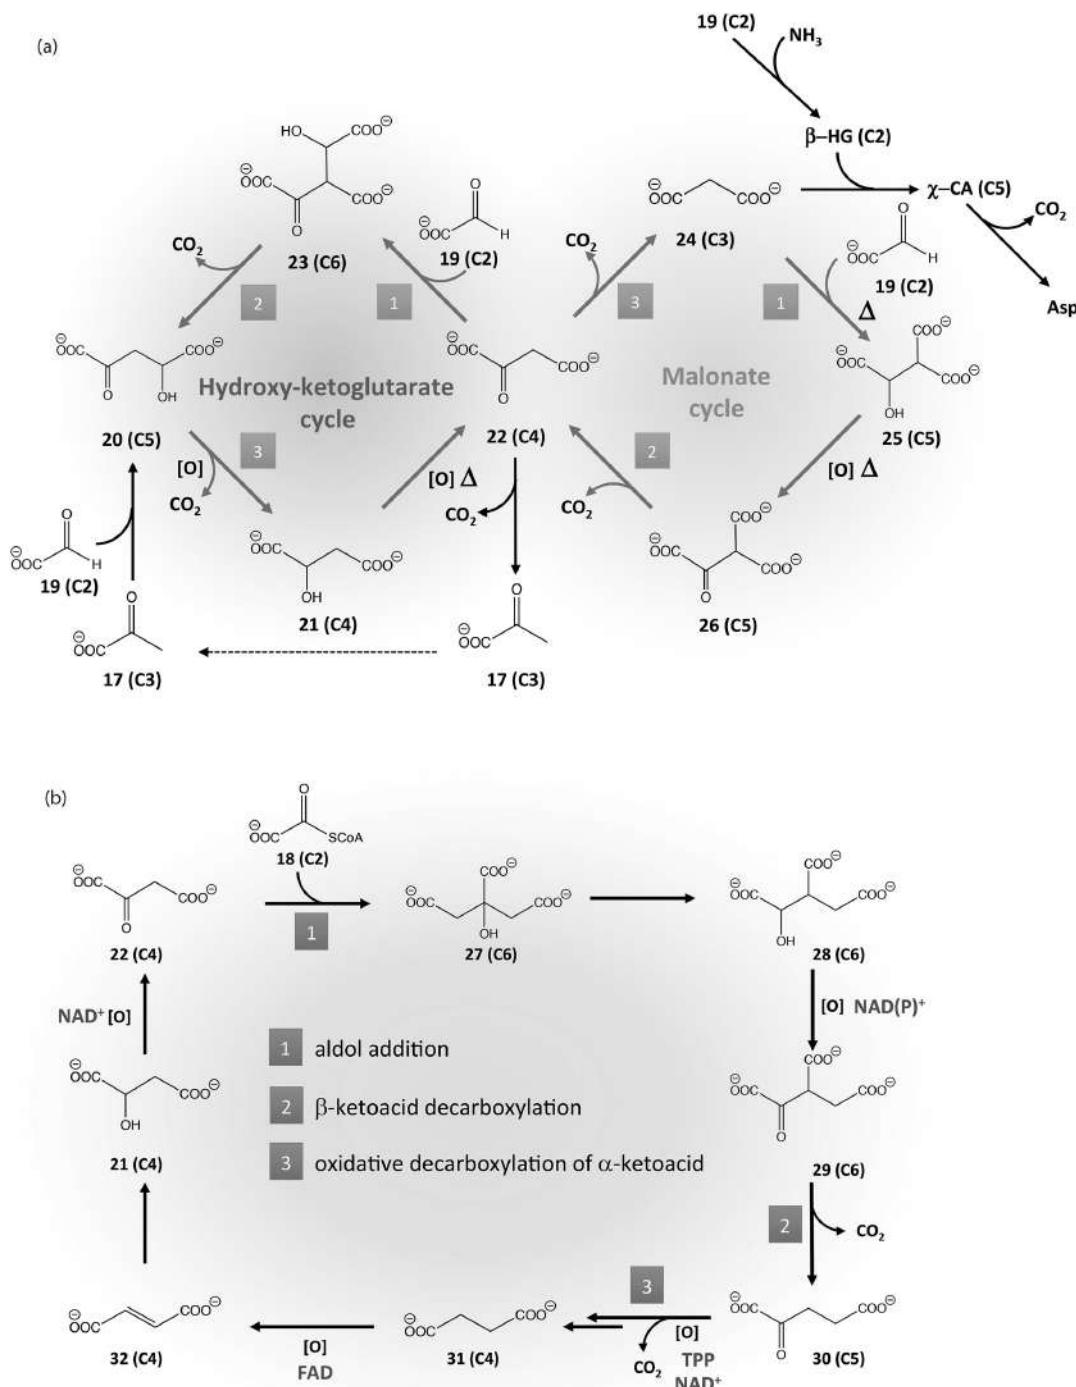

FIGURE 5.1.6 Mimicking TCA cycle, Springsteen-Krishnamurthy's bicyclic oxidizes glyoxylate to CO_2 . (a) Two concatenated abiotic catalytic cycles with oxaloacetate 22 (OAA) as common intermediate allow the complete oxidation of glyoxylate 19 under mild conditions during several hours. The 4-hydroxy-2-ketoglutarate 20 (HKG) and the malonate 24 (MLN) cycles provide a model of simpler versions of metabolic cycles. Additional intermediates involved in the HKG cycle are malate 21, OAA 22, and oxalomalate 23, whereas in the MLN cycle, in addition to OAA 22 and MLN 24, 3-carboxy-malate 25 and 3-carboxy-oxaloacetate 26 also participate. The scheme also shows the anaplerotic synthesis of HKG 20 from pyruvate 17 and glyoxylate 19 and the synthesis of aspartate (Asp) from glyoxylate 19, ammonia, and MLN 24 through the intermediates α -hydroxyglycine (α -HG) and β -carboxyaspartate (β -CA). Note that, in each cycle, the addition of glyoxylate 19 (reaction 1) and the decarboxylation of a β - and an α -ketoacid (reaction 2 and 3, respectively) follow the same order as in the modern TCA cycle, as shown in panel (b). (b) Metabolic TCA cycle allows the oxidation of acetate (activated as acetyl CoA 18) to CO_2 . After condensation of acetate to OAA 22 (reaction 1), two successive decarboxylations follow: the spontaneous decarboxylation of a β -ketoacid, oxalsuccinate 29 (reaction 2), and the decarboxylation of an α -ketoacid, α -ketoglutarate 30 (reaction 3), with the help of cofactors such as thiamine. A series of reactions synthesizes OAA 22 from succinate 31, allowing the catalytic functioning of the cycle. Other symbols: Δ , 50°C ; [O], hydrogen peroxide; and TPP, thiamine pyrophosphate.

biochemical pathways: (1) the bicycle shares three reaction types with modern TCA cycle, namely, aldol addition and decarboxylation of β - and α -ketoacids, operating in the same order over the intermediates of the cycle but without the involvement of enzymes and cofactors (in fact, it uses H_2O_2 as oxidant, instead of complex organic coenzymes) (compare panel a and b in [Figure 5.1.6](#)); (2) an anaplerotic reaction (addition of glyoxylate **19** to pyruvate **17**) allows the sustained functioning of the catalytic cycle and compensates for the spontaneous depletion of intermediates by oxaloacetate **22** (OAA) decarboxylation to pyruvate **17** or the consumption of intermediates for synthetic purposes, since (3) some intermediate skeletons may serve as a source of amino acids. Remarkably, the bicycle functions during several hours in aqueous medium under mild conditions of pH (7.0–8.5) and temperature ($\leq 50^\circ\text{C}$).

The modern TCA cycle allows the oxidation of acetate to CO_2 after addition of acetyl CoA **18** to OAA **22** and the successive decarboxylation of a β -ketoacid and an α -ketoacid with the support of sophisticated enzymes and cofactors, *that is*, NAD(P)⁺ and thiamine ([Figure 5.1.6b](#)). In contrast, the abiotic bicycle adds glyoxylate **19** to OAA **22** or to malonate **24** (MLN) and decarboxylates a β -ketoacid (oxalomalate **23** or 3-carboxy-oxaloacetate **26**) and an α -ketoacid (4-hydroxy-2-ketoglutarate **20** or OAA **22**) only with the help of H_2O_2 ([Figure 5.1.6a](#)). Furthermore, the chemistry involved in these abiotic cycles allows a net carboxylation (pyruvate **17** to OAA **22**), without requiring CO_2/ATP , as in modern metabolism, and a reductive amination (OAA **22** to aspartate), without the help of an external reductant. These notable observations offer simpler alternatives to metabolic mechanisms and represent an encouraging and plausible protometabolic model of reactions operating before the emergence of sophisticated polymeric enzymes and their cofactors and paving the road for more complex metabolic cycles.

In summary, the subset of products of cyanosulfidic protometabolism is congruent with the biomonomer spectrum, whereas geochemically plausible non-enzymatic transformations between metabolites reproduce the general topology of the central metabolism (Ralser 2014; Sutherland 2016), and extant metabolic networks may contain fossils of a phosphate-independent biochemistry (Goldford et al. 2017). It is of note that the chemosynthetic strategies observed in the scenario of the cyanosulfidic protometabolism also are comparable to those of extant pathways of the central metabolism (Sutherland 2017). Furthermore, the discovery of plausible protometabolic sustained catalytic cycles, sharing remarkable resemblances and commonalities with extant metabolic pathways, starts promising research views into the primitive stages of life evolution (Springsteen et al. 2018). Thus, today, we have more empirical reasons to conclude that de Duve's *gemisch* was perhaps less dirty than initially supposed and that, as he put it, protometabolism must have prefigured metabolism. The two are *congruent*; they followed

similar pathways (de Duve 2005a, p. 19). Prebiotic systems chemistry is opening a tunnel through Orgel's "opaque barrier."

5.1.5 THE TOTAL SYNTHESIS OF PROTOCELLS

The previously described panorama of a protometabolic landscape mostly dominated by deterministic chemical transformations that prefigured fundamental parts of extant metabolisms is still at a long distance of what we could recognize as minimal life. Evolution through transition stages involving the emergence of intermediate systems filling this gap must be invoked. Those intermediate forms of metabolism have to address problems related not only to energetics and flux of matter, from geochemical feedstocks to the own system components, but also to the emergence of functional properties such as active compartments, kinetic control, and heredity, through "major prebiotic transitions," in which all these organizational and evolutionary aspects must be integrated (Shirt-Ediss et al. 2017). Diverse theoretical efforts have tried to reduce the complexity of life to its simplest components and elementary behaviors (Letelier et al. 2011). A remarkable example is the chemoton model of Gánti (2003), based on the observation that a minimal living cell is the result of the organizational and functional coupling between three autocatalytic subsystems: (1) a self-reproductive compartment (boundary in [Figure 5.1.7](#)) (2) a self-replicative genetic polymer (template in [Figure 5.1.7](#)), and (3) a self-sustained chemical network synthesizing the necessary components for polymer replication and boundary growth out of available environmental feedstocks (metabolism in [Figure 5.1.7](#)) (Peretó 2012).

Thus, the chemoton could represent the minimal organization exhibited by the most primitive entities emerged from protometabolic networks and endowed with all the necessary components to become the subject of Darwinian evolution (de Duve 2005a, 2005b). These theoretical "minimal cells" may be considered as "protocells," provided that we give them an additional meaning of historical (emergent, intermediate) entities filling the temporal gap between protometabolism and primitive cells, similar to extant bacteria. As an example of this kind of protocell (or minimal cell), [Figure 5.1.7](#) presents a sketch of a ribocell, inspired by (Szostak et al. 2001). A more elementary use of the term "protocell" refers to any experimental or computational construct composed of a self-assembled compartment with other chemical (or biochemical) components in order to simulate or reconstruct the possible historical steps of acquisition of complexity (Ruiz-Mirazo 2015b).

Actually, the empirical exploration of the reconstruction of a simple protocell is a remarkable research program in contemporary biology (Szostak et al. 2001), with deep historical and philosophical roots (Peretó 2016), sound conceptual grounds (Letelier et al. 2011; Pascal and Pross 2017; Ruiz-Mirazo et al. 2017; Shirt-Ediss et al. 2017), and good prospects of success (Ruiz-Mirazo et al. 2014;

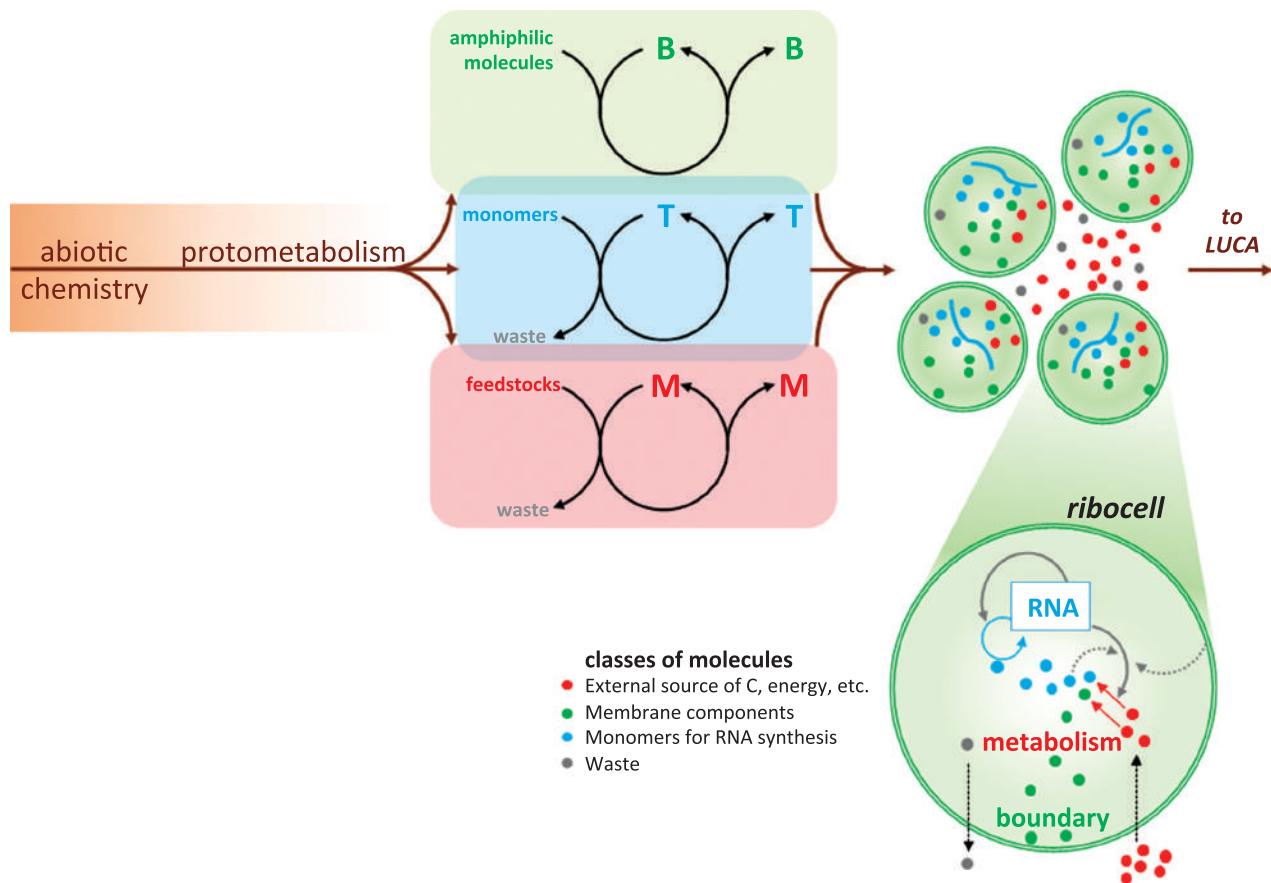

FIGURE 5.1.7 The pathway for total synthesis of a protocell. Bottom-up, constructive approaches in synthetic biology seek to combine autocatalytic cycles like self-reproductive lipid vesicles (boundaries B), self-replicative templates (T), and self-sustained sets of reactions (metabolism M) in protocellular constructs. The scheme shows, as an example, a possible ribocell with an RNA showing ribozymic activities (gray arrows) for its own replication (blue arrow), as well as the synthesis of ribonucleotide monomers for replication and membrane precursors (red arrows). Small molecules or the lipid membrane could also help ribozymes in their catalytic functions (dashed gray arrows).

de la Escosura et al. 2015). We can perceive the synthesis of a living entity from simpler, non-living components as a bottom-up strategy within the emerging discipline of synthetic biology (Porcar and Peretó 2014), also qualified as constructive biology (Kaneko 2006; Ichihashi et al. 2010; Ichihashi and Yomo 2016) or a way of knowing biology by making life (Keller 2009). This strategy has notably progressed in the field of chemistry of nucleic acid replication (*e.g.*, non-enzymatic oligomerization of RNA and ribozyme self-replication) as well as in biophysics of membranes of a simple nature (*e.g.*, fatty acid and phospholipid vesicles) (Blain and Szostak 2014; Szostak 2017). Alas, the experimental implementation of autocatalytic networks of reactions allowing the autonomy of the whole system is still in its infancy (Peretó 2012; Blain and Szostak 2014; Ruiz-Mirazo et al. 2014; Scharf et al. 2015); however, some remarkable advances in this direction have been achieved (Hardy et al. 2015).

The study of ribozyme chemistry and nucleic acid replication in the context of the RNA world model has

attracted much attention among researchers, and there was a time when some considered compartments as latecomers and referred to an acellular RNA world (Peretó 2005). Today, the general perception of the role played by early compartments is very different, and the functional significance of protocell boundaries goes beyond its task as a mere closed space (Walde et al. 2014; Hanczyc and Monnard 2017). As a remarkable example, fatty acids, used as a model of primitive amphiphilic molecules, spontaneously form vesicles that provide both a local environment for the location of hydrophobic substrates and acid-based catalysis promoting peptide synthesis (Murillo-Sánchez et al. 2016).

There are also noteworthy examples of the emergence of new properties in more integrative artificial systems, for instance, when mixing two subsystems such as template replication encapsulated in lipid vesicles or when the supramolecular system is assisted by catalytic interactions with small molecules (Blain and Szostak 2014; Ruiz-Mirazo et al. 2014; Hardy et al. 2015; Ichihashi and Yomo 2016). Although results are promising, there are still many

problems to overcome, such as the adequate permeability of the boundary for accessing feedstocks and releasing waste and the apparent incompatibility of physicochemical conditions allowing stability of lipid vesicles and efficient nucleic acid replication simultaneously. In this context, a paradigmatic case is offered by magnesium ions, required for non-enzymatic RNA replication and ribozyme polymerase at a millimolar concentration that is incompatible with fatty acid membrane stability (Szostak 2012, 2017). Chelation chemistry by small molecules (*e.g.*, citrate, albeit with a doubtful prebiotic plausibility) or by short peptides (de Duve's multimers) seems to offer some possible solutions to this critical issue (Szostak 2017). Another way to advance and overcome some of these problems is by using alternative compartmentation: instead of lipid vesicles, some laboratories assay heterogeneous systems, such as water-in-oil emulsions. Using this approach, Tetsuya Yomo and coworkers have described a simple artificial chemical system that exhibits Darwinian evolution (Ichihashi et al. 2013), a notable success of the synthetic approach.

5.1.5.1 A NOTE OF CAUTION: ORIGINS OF LIFE ≠ LAST UNIVERSAL COMMON ANCESTOR

When we refer to protocell research, we are talking about bottom-up strategies, from chemistry up to biology, in reconstructing the earliest steps, from protometabolism to fully fledged biological entities. Now, the reverse strategy is represented by comparative biochemistry of present prokaryotic biodiversity (or top-down approach), which aims to reconstruct the common ancestor or last common ancestor (LCA), also known as Last Universal Common Ancestor (LUCA) (Figures 5.1.7 and 5.1.8).

Comparative genomics and phylogenomic analysis recovers a rather metabolically complex LUCA (Becerra

et al. 2007; Weiss et al. 2016). However, top-down approaches are plagued with methodological issues, such as dealing with the effect of horizontal gene transfers and lineage-specific gene losses (Becerra et al. 2007). Even apparently straightforward questions, such as whether LUCA was endowed with an autotrophic metabolism, remain controversial (*cf.* Becerra et al. 2014; Weiss et al. 2016). Notwithstanding the obvious scientific interest of the top-down approach to the phenotypic profile of LUCA, we cannot justify extrapolating the reconstructed metabolism and putative environmental constraints to the origins of life, as presented, for instance by (Weiss et al. 2016). We certainly do not know the time it took from protometabolism and the emergence of protocells to LUCA, but the huge distance between them is evident in terms of biochemical complexity and environmental constraints (Arrhenius et al. 1999; Cornish-Bowden and Cárdenas 2017). Phylogenomic analyses cannot deliver conclusions about a period beyond the invention of the coded macromolecules used in those analyses. In other words, phylogenomic studies based on proteins cannot give direct information on stages before the emergence of the genetic code and the translation machinery. Protometabolism occurred before the earliest stages of the RNA world and, for profound reasons, will remain inaccessible to protein phylogenies. On the other hand, prebiotic systems chemistry, in intimate correlation with geo- and cosmochemistry, is the most appropriate way to project the chemical logic of protometabolism upon extant metabolic virtuosities, thus searching for the transition from chemistry to biology and revealing the very origins of biological evolution.

Finally, we should contemplate the “origin of life” not as a historical singular event but rather as a long process of expansion of increasingly complex (autonomous, evolutionary) chemical systems. Introducing an updated

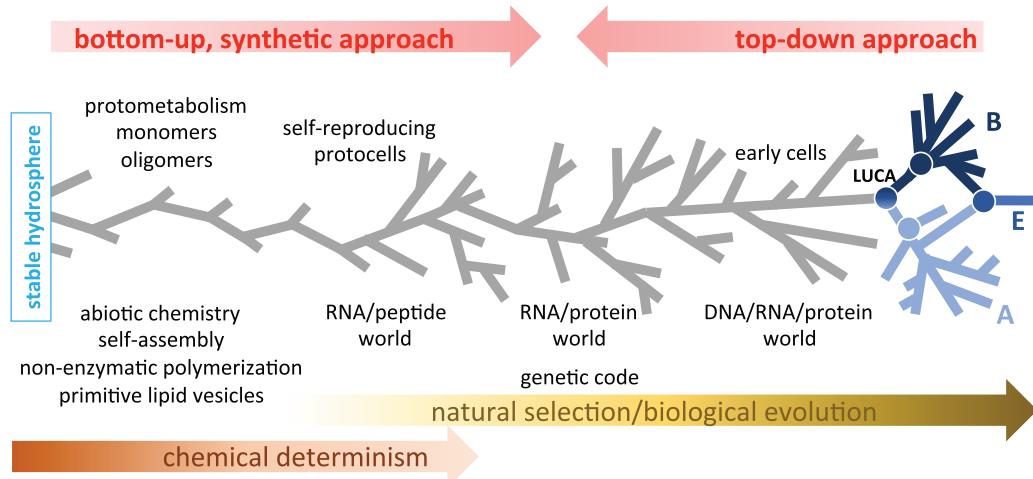

FIGURE 5.1.8 The origins of life and LUCA are not the same. The scheme illustrates some intermediate stages from protometabolism to LUCA through systems of increasing complexity, with chemical determinism playing a major role before the emergence of RNA as genetic material and catalytic player in an RNA world. Two main research approaches, from chemistry up to primitive biological entities (bottom-up) and from extant biodiversity down to early life (top-down), are indicated.

discussion on “*what is life?*” may have a heuristic effect in prebiotic systems chemistry (Ruiz-Mirazo et al. 2004), as it would illuminate our views on the intermediate stages endowed with different degrees of “aliveness” and that populate the trajectory between protometabolism and the first fully live cells – at this moment, the reader should ask him or herself where to locate this stage in [Figure 5.1.8](#) according to his or her own life definition.

5.1.6 SUMMARY AND PROSPECTS

Prebiotic systems chemistry is on the way to superseding the classical controversies surrounding the origin of life based on dichotomist alternatives, such as the early *vs.* late emergence of compartments, metabolism-first *vs.* genetics-first models, and autotrophic *vs.* heterotrophic scenarios (Peretó 2005). A more integrative approach is rapidly evolving in this field.

Experimental results in prebiotic systems chemistry suggest that protometabolism on Archaean Earth generated a small set of biomonomers that prefigured extant biochemistry. There are, nevertheless, extraordinary challenges ahead when trying to implement systems with increasing levels of complexity. For instance, we need to know more about the dynamic coupling of lipid vesicles with heterogeneous chemical mixtures of small molecules and polymers and their experimental evolution into more robust systems, aiming to simulate protocells with Darwinian behavior. The merging of systems chemistry with experimental evolution methodologies is an absolute must if we are to bridge the vast gap between protometabolism and functionally integrated protocells (Ruiz-Mirazo et al. 2017; Shirt-Ediss et al. 2017). In short, solutions hardly accessible by rational design can be found by the own system’s dynamics. In this context, merging laboratory, computational, robotics, and microfluidics technologies is compulsory to explore in depth the transition from simple chemical mixtures to systems with complex behaviors (Scharf et al. 2015; Cronin 2017), also opening up the field to chemical models that imitate biological behaviors, albeit assaying with abiological molecular components (Miljanić 2017; Taylor et al. 2017). Certain aspects, however, still require significant and persistent research efforts, which include finding the paths for the emergence of autocatalytic networks of reactions exhibiting dynamics of prebiotic relevance (Semenov et al. 2016; Wong and Huck 2017) or looking for empirical explanations for the origin of biochemical homochirality (Hein et al. 2012), one of the most colossal unknowns in origins-of-life research.

As we will never know exactly how it happened, the scientific study of the origins of life is an open and permanent debate that has maintained, maintains, and will continue to maintain the interest of many generations of scientists. This is particularly true for synthetic chemists, among others, since the field of prebiotic systems chemistry urgently needs the enthusiasm and audacity of young investigators (Wagner and Blackmond 2016; Krishnamurthy and Snieckus 2017; Tor 2017) engaged in one of the major synthetic breakthroughs:

finding a second example of life through the chemical synthesis of an artificial cell (Solé 2016).

5.2.1 INTRODUCTION

5.2.1.1 HIERARCHICAL REDUCTION IN THE RESEARCH OF ORIGINS

“Hierarchical reduction” (Pross 2012) of problem solving in the logics of the natural sciences means that, in order to fully solve a problem, which always includes the problem of finding the true origin of its processes, we need to navigate outside the field, in a domain that embraces and integrates the field, rather than being simply part of it. For example, our perceived reality has three spatial dimensions, so we can easily visualize dynamic one-dimensional (1D) and two-dimensional (2D) objects, such as vibrating violin strings and tambourine membranes, but we reach our limits when mentally picturing dynamic three-dimensional (3D) objects, such as those that we call atomic or molecular “orbitals,” and our “universe.” We then prefer to resort to holographic projections from a reduced dimensionality.

Applying this logical rule to “major transitions” in our perceived reality, that is, the large decisive steps in evolution

(Maynard Smith and Szathmáry 1995), we can state that the *origins* of the physical cosmos, biotic life, human language, and societal economy are studied best by logicians and mathematicians for physics, including cosmology; by astronomers, geologists, and chemists for biology, including astrobiology and the origin of life; by biologists for linguistics, including etymology and the origin of language; and by psychologists for economy, politics, and wars, including the origin of human trade, respectively (Figure 5.2.1). For example, a neurobiologist working on the origin of human language will *think* like a linguist in terms of expected results but *exploit* “Darwinian” algorithms to generate these results. A psychologist will *study* human behavior in a family community and *translate* its effects to societies that are at (trade) war with one another.

In this set theory of scientific relations, chemistry bears a very special role, since it operates at the border between the inanimate and the animate states of matter (outermost white border in Figure 5.2.1). Robert Pascal and Addy Pross have recently put forward that physics embraces both states of matter, “dead and alive,” only when thermodynamic (and mechanic) stability

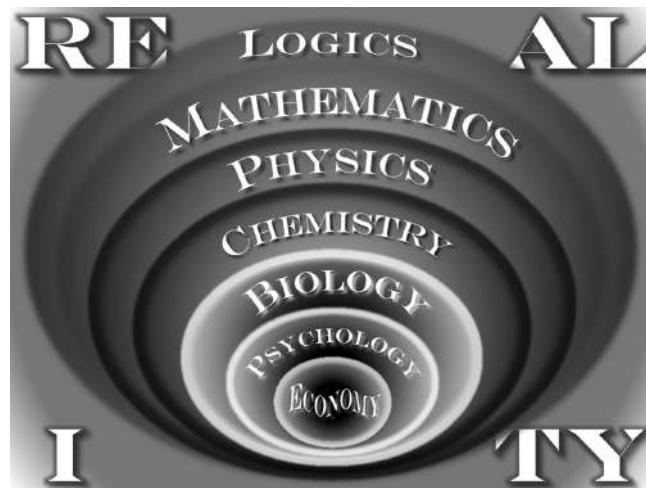

FIGURE 5.2.1 Euler diagram of the hierarchic relationship between sciences: inner \in outer zones. Relations of the inner zones are more complex, and their elements act more autonomously than those of the outer zones. The more inward bound the zone, the larger the distance from, and more complex the relationship to, the fundament of logics. Diffuse gray borders define abstract and very general elements, concepts, and rules. Dark borders delineate inanimate (“inert”, “dead”) elements observed in nature. White borders demarcate animate (“alive”) elements. Dynamic relationships (rules) within gray and dark borders are, in principle, predictable properties. Dynamic relationships within white borders are best described as a combination of properties and not exactly predictable “behavior.” First, second, and third white borders mark out elements of increasingly higher autonomy (“intelligence”).

is looked upon as one of the two fundamental ways of persisting in time, the other way being the exponential reproduction (“replication”) of individual units. A population or colony of similar reproducing units will *persist, despite the relative instability* and eventual degradation of its individual members. The most fundamental notion in physics must therefore be *persistence* rather than stability (Pascal and Pross 2015). Hence, a chemist or geochemist that aims at *understanding* the transition from one state to the other, for example, the origin of life on Earth, will have to *explore* first the “bricks” that ultimately make up a living system. Prebiotic chemistry is a very active science of prominent age; its task is to provide the bricks of life from “natural” and “plausible” chemical reaction conditions. A second step will consist of experimentally realizing abiogenesis from such or similar bricks (cf. Chapter 6.3).

5.2.1.2 SYSTEMIC MEMORY: PRINCIPLES OF COPYING AND ENCODING

The bricks that biotic nature—as we know it on Earth—uses to maintain a systemic memory throughout many generations of reproduction of individual system units, which themselves individually almost fully degrade and ultimately vanish, are composed of nucleic acids. Nucleic acids can harbor and transmit an astonishingly large number of information through more or less faithfully copying long strings termed “polymers.” In biotic nature, these strings are composed of four different (but similar) letters, that is, information-theoretical *quaternary digits* (“quits,” not Qbits) realized by the nucleotides A, G, C, and U or T. Natural *quits* are pairwise complementary to one another through the Watson-Crick rules (G-C, A-U, or A-T), which give the grounds for faithful template-directed

copying, as during cellular replication (double copying of complementary single-stranded DNA), or complement copying, as in transcription or reverse transcription, of strings of nucleic acids of virtually deliberate length. Upon translation, however, these strings of *quits*, rather than being recognized one by one, as during complement copying, can be read out by anticodons—parts of transfer RNA bound to ribosomes—as a series of *three-letter words* termed “base triplets,” that is, information-theoretical unitary blocks of 3-*quit* “quytes” (3Q), that are chained up in heterogeneously and almost deliberately long sentences termed “reading frames” (genes). The grammar and syntax (gene regulation, message editing, and epigenetics) used in these sentences are then a matter of *system unit type* and *network organization*, that is, cell (germ line or somatic), organism, species, interaction with other species, ecological niches and traits, and so on.

All known natural (biotic) genomes can be divided into a “coding fraction,” made up of the sum of all reading frames, and a “non-coding fraction” composed of all untranslated but nevertheless “permissively transcribed” regulator and not transcribed spacer nucleic acids. Known natural total genome sizes range from 600 kilobases (kb) in *Mycoplasma genitalium* through 2.9–3.4 gigabases (Gb) in chicken, mice, chimpanzees, and humans to 250 Gb in *Psilotum nudum* (skeleton fork fern). Known amounts of natural genes span between 481 in *M. genitalium* (average distance between genes $d = 1.2$ kb) through 16,736–23,493 in chicken, mice, chimpanzees, and humans ($d = 141$ –177 kb) to about 27,000–50,000 genes, many of them are gene repeats, in plants such as cress, rice, and maize ($d \approx 4$ –50 kb). Known coding fractions can thus take anything between 2% in *Homo sapiens* to 90% in *M. genitalium*.

According to Claude Shannon (Equation 5.2.1), the

$$\text{Shannon Information (SI)} = \log_b N \quad (5.2.1)$$

where b denotes digit multiplicity (the number of different digits)— $b = 2$ for *bit* (binary digit), $b = e \approx 2.718\ldots$ for *nit/nat/nepit* (natural or Neperian digit), $b = 3$ for *trit* (trinary or ternary digit), $b = 4$ for *quit* (quaternary digit), etc.—and N denotes the number of digits in a string, for example, the polynucleotide sequence length. The maximal amount of information, viz. the degree of minimal diversity, stored in the coding fraction of the *M. genitalium* genome equals $SI = \log_4(0.9 \cdot 6 \cdot 10^5) = \log_4 10 \cdot \log_{10}(0.9 \cdot 6 \cdot 10^5) \approx 1.66 \cdot 5.73 \approx 9.5$, whereas the SI stored in 2% of the human genome merely is $SI = \log_4(0.02 \cdot 3.2 \cdot 10^9) \approx 7.8$. Total genome sizes result in maximal information contents $SI = 9.6$ for *M. genitalium* and, ignoring gene repeats, $SI = 15.8$ for *H. sapiens*, which indicates that the evolution from one to the other species undeniably prevailed in the

non-coding fraction of their genomes, i.e. in their long non-coding RNA (Morillon 2018).

Biotic nucleic acids such as RNA and DNA, whether translated or not, are used in known animate systems as *quit* carriers that are relatively easy to copy through molecular templating, irrespective of whether this copying is assisted by enzymes or not. Complementary or self-complementary readouts, that is, copying and encoding rules as we know them from biotic genome replication and the universal genetic code, are reducible to the hydrogen donor-acceptor patterns that are being exposed from the so-called Watson-Crick face of the natural nucleobases of each nucleotide (Strazewski 1990; Strazewski and Tamm 1990). These patterns are not limited to the natural nucleobases. Other N -heterocycles may furnish different patterns and thus distinct pairing preferences (Krishnamurthy 2012). Therefore, from a purely chemical point of view, molecular template variants such as binary- or ternary-digit memory polymers composed of strings of subsequent *bits* or *trits*, respectively, are well imaginable (Figure 5.2.2). These *bits*

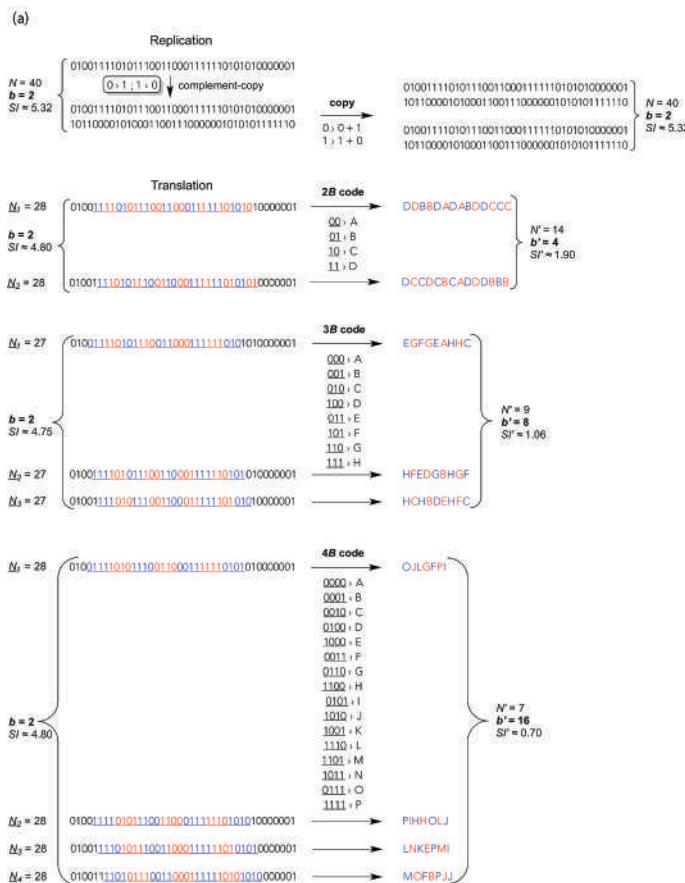

FIGURE 5.2.2 Template copying and translating an exemplary string of total $N = 40$ residues, composed of b digits, storing, according to Equation 5.2.1, a maximum amount of Shannon Information (SI). Upper part: Replication. Complement-copying rules (small frames) by virtue of a minimal requirement for self-complementary digits, that is, *bits* {0,1}, *trits* {0,1,2}, and *quits* {0,1,2,3}. Lower part: Translation of consecutive blocks ($B = \text{bytes}$, $T = \text{trytes}$, $Q = \text{quaytes}$) of two to four digits (a *bits*, b *trits*, and c *quits*). The reading frame (underlined digits) is translated into products (strings of letters) of a condensed residue number N' and higher digit multiplicity (diversity) $b' = b^{2-4}$, and thus, lower SI' . Frameshifts \underline{N}_{1-2} for two-digit blocks, \underline{N}_{1-3} for three-digit blocks, and \underline{N}_{1-4} for four-digit blocks generate alternative translation products of the same length N' , diversity b' , and SI' but different sequences. (a) Binary digit (*bit*) strings, replicated and translated from 2-bit bytes (2B), 3-bit bytes (3B), and 4-bit bytes (4B).

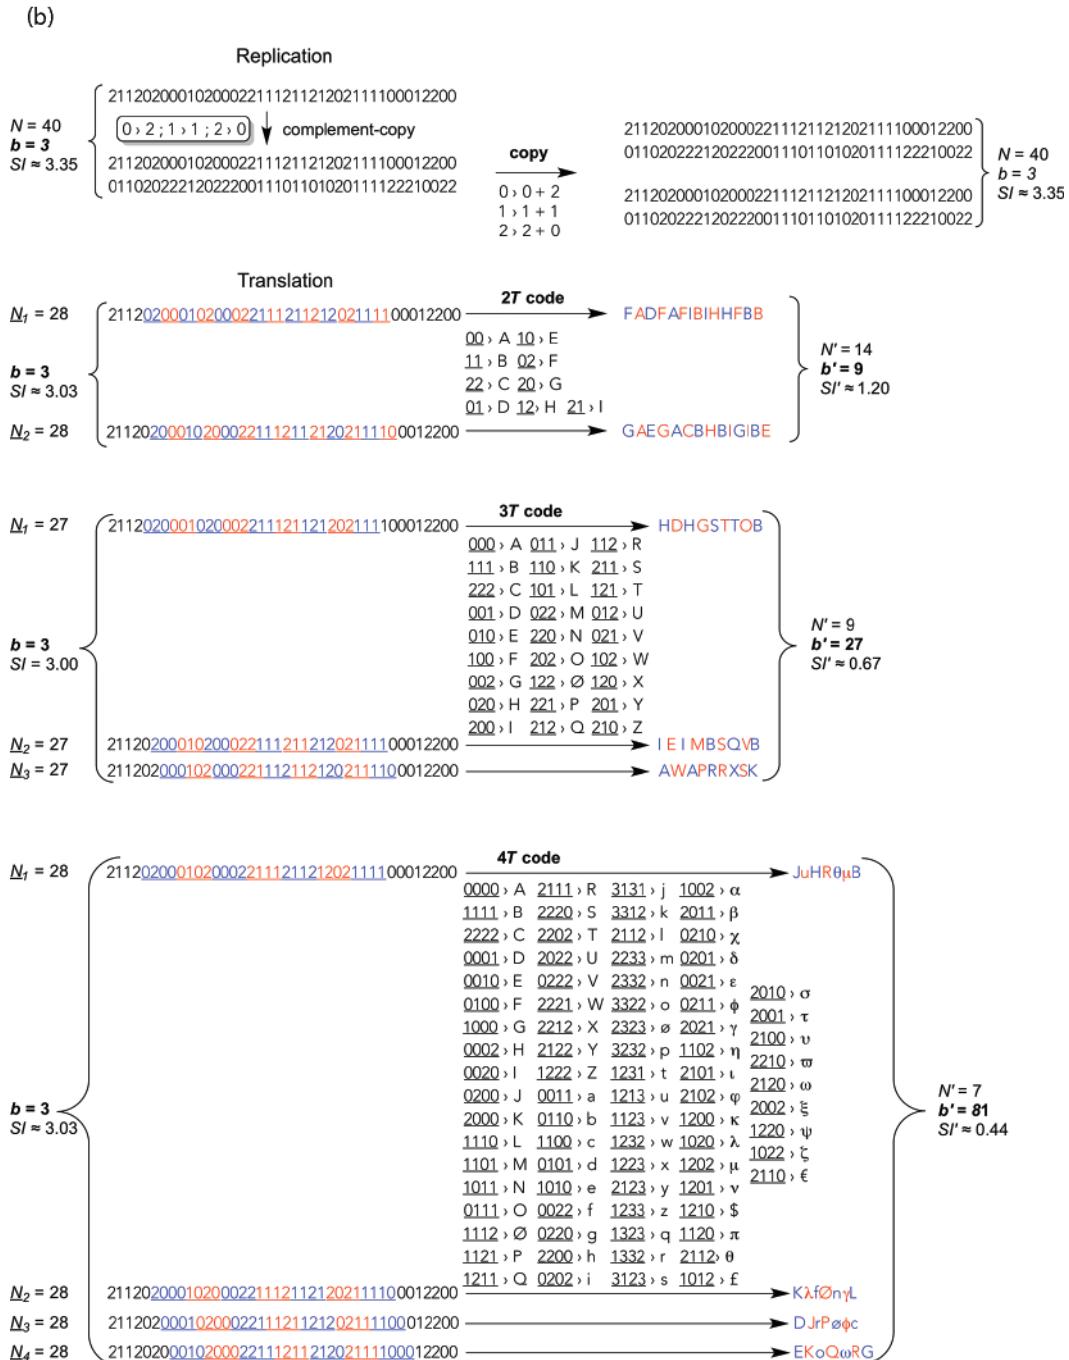

FIGURE 5.2.2 (Continued) (b) Ternary digit (*trit*) strings, replicated and translated from 2-trit trytes (2T), 3-trit trytes (3T), and 4-trit trytes (4T). For a *trit* string to bear the same *SI* as that of a *bit* string, it needs to be about 8.65-fold longer (higher *N*) than a *bit* string; for example, $\log_2 40 \approx \log_3 346$.

or *trits* could be complementary through different pairing modes. In principle, each *bit* or *trit* could be strictly self-complementary in its pairing property: 0 pairs only with 0, 1 pairs only with 1, and 2 pairs only with 2. Chemically more likely, alternative *bit* genomes could be composed of, for instance, only G and C or only A and U, where one digit (0 or 1) is complementary to the other (Figure 5.2.2a). Alternative *trit* genomes could bear two digits that are

complementary to one another (e.g., 0 pairs with 2) and a third strictly self-complementary digit (1 pairs only with 1) and thus be composed of, say, G, C, and X, the latter being a strictly self-complementary nucleotide (Figure 5.2.2b). In addition, the coding fractions of such low-digit memory polymers could be read out, for example, as 4-bit bytes (4B) or 3-trit trytes (3T). Biotic 3-quit quytes (3Q: natural base triplets) comprise $b' = b^3 = 4^3 = 64$ values, that is, offer 64

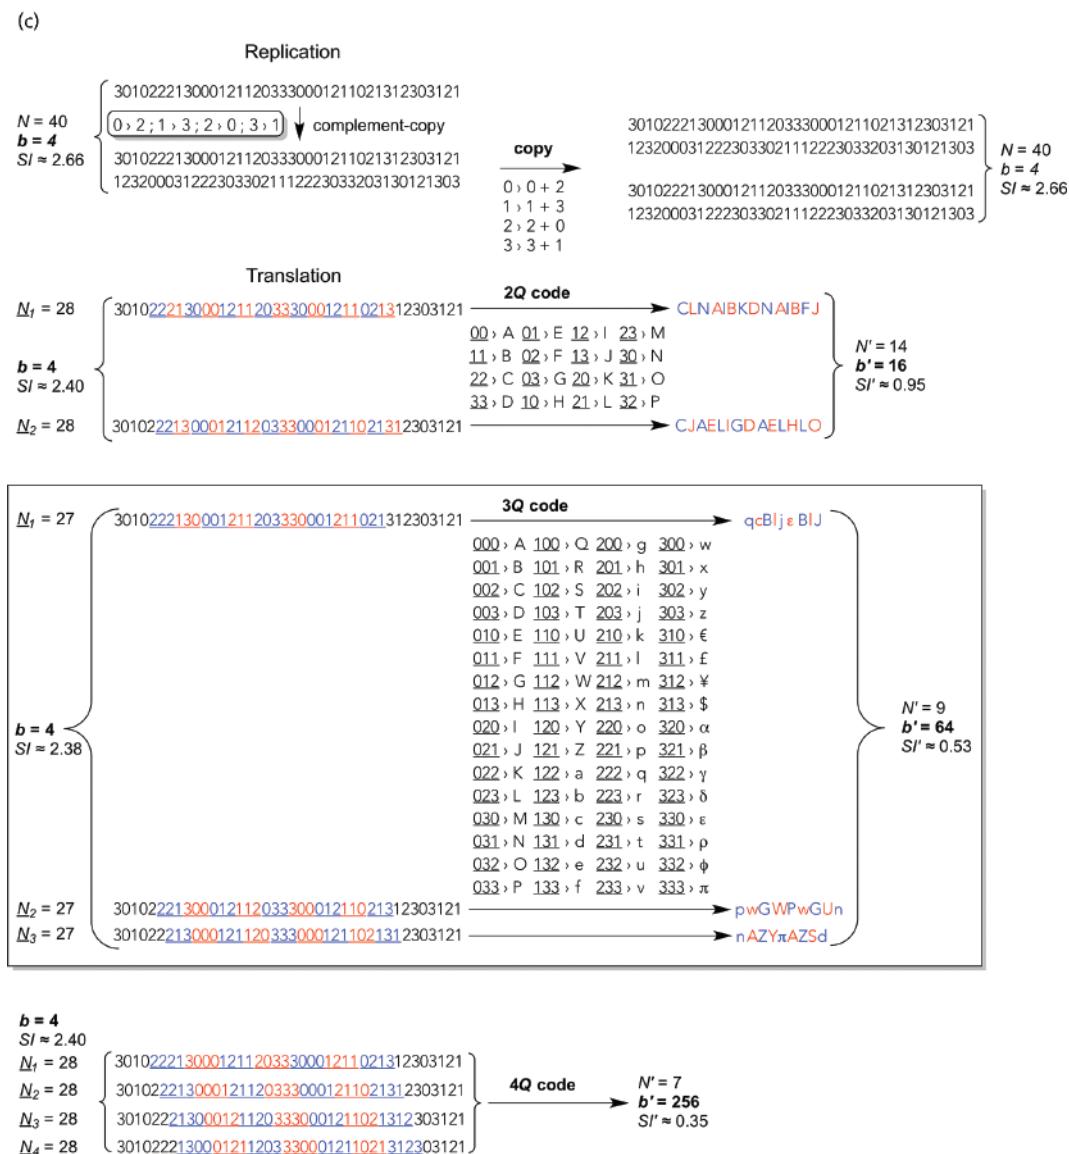

FIGURE 5.2.2 (Continued) (c) Quaternary digit (*quit*) strings, replicated and translated from 2-*quit quytes* (2Q), 3-*quit quytes* (3Q), and 4-*trit quytes* (4Q, code and translation products not shown). For a *quit* string to bear the same *SI* as that of a *bit* string, it needs to be 400-fold longer (higher *N*) than a *bit* string; for example, $\log_2 40 = \log_4 1600$. Framed: the current natural (biotic) memory systems are *quit* strings being translated from reading frames of consecutive 3Q, utilizing $b' = 64$ codons that are reduced, mainly for fidelity reasons, to $b'_{eff} = 21$ effectively translated digits, viz. 20 different proteinogenic amino acids and a stop signal (i.e., lack of amino acid).

different triplet “codons” (large frame in Figure 5.2.2c). So do 6-bit bytes of binary memory polymers ($6B: b' = 2^6 = 64$, not shown), but such long codons would necessitate hexaplet anticodons for translational readout. Shorter 5-bit bytes (5B) generate $b' = 32$ different pentaplet codons. Chemically more realistic are 4-bit bytes (4B), giving rise to $b' = 16$ different quadruplet codons, and 3-bit bytes (3B), giving merely $b' = 8$ different triplet codons (Figure 5.2.2a). In ternary-digit memory polymers, blocks of 3-trit trytes (3T) produce $b' = 3^3 = 27$ different triplet codons, whereas 4-trit trytes (4T) generate $b' = 3^4 = 81$ different quadruplet codons. The latter set of codons would suffice for an even larger than natural (biotic) diversity of translated digits b' , cf. 4T code in Figure 5.2.2b versus 3Q code in Figure 5.2.2c.

These are simply numerical-combinatorial guidelines “degenerate” (redundant) and stop codons exempt. The modern-day ribosomal translation mechanism has established a universal genetic code based on 64 different 3-*quit quytes*, that is, triplet codons that are currently occupied by merely 20 “proteinogenic” amino acids and usually 3 stop codons, unless a biocompatible “expanded alphabet” for triplet codons has been artificially introduced at selected positions by using synthetic nucleotides that offer a distinct pairing selectivity that may differ from the natural Watson-Crick rules (Picirilli et al. 1990; Strazewski and Tamm 1990; Cornish et al. 1995; Liu et al. 2003; Malyshev et al. 2014; Georgiadis et al. 2015; Winiger et al. 2016). Most of the 20 proteinogenic amino acids are coded by a set of faster and slower, thus, more and

less erroneously translated, redundant codons being read by more abundant and rarer “isoaccepting” anticodon triplets, respectively, all carrying the same amino acid.

However, these copying and encoding principles ([Figure 5.2.2](#)) show that unbranched molecular strings (1D polymers) composed of a limited number of different monomeric complementary residues (monomers), that is, strings that bear a relatively *low multiplicity* of digits (low b), are likely to be a *general feature of memory keepers* in any animate system. The lower the digit multiplicity the smaller the diversity of a given string length (N), the simpler the template, and less ambiguous to copy and replicate the string on a molecular level (Szathmáry 1992). This generates fewer errors in template-copied memory polymers and thus a higher replication error threshold for a given spreading “quasi-species” (similar genome population), and this eventually imposes a weaker selection pressure on the maximal genome length of any evolved organism (Eigen 1971; Biebricher and Eigen 2005; Kun et al. 2005).

The opposite is true when it comes to *functional translation products*; there, the higher their digit multiplicity (high b'), the *higher the diversity* (low SI') of a given resulting string length (lower N'). The high diversity is further multiplied by the number of reading frame shifts (N_b) that give rise to an encoded set of a completely different choice of translated string sequences ([Figure 5.2.2](#) bottom). This generates translated string polymers that are inherently difficult to copy through direct templating, since the complement rules—analogous to the Watson-Crick base-pairing rules—needed to be as manifold and exclusive as the digits are diverse. On the other hand, the longer the translation blocks (codons, translated words) in the messenger nucleic acids, the more compact the generated diversity of the “secondary” polymer, which allows for more diverse “molecular functions” at a given secondary string length N' . In other words, we should expect evolution from alien and very early biota to string polymers of both kinds, low-digit and high-digit variants, where the more diverse latter is encoded by the simpler former.

Alternative nucleic acids composed of fewer letters, *bits* or *trits* rather than *quits*, might be considered in extra-terrestrial biota and/or during early periods of the origin of life on Earth. They might encode a smaller or larger choice of proteinogenic amino acids—or some other molecular equivalent of a functionally more diverse polymer than nucleic acids—by translating from shorter or longer *bytes* or *trytes*, respectively, as mentioned earlier. In principle, alternative nucleic acids could also form triple complements through triple-strand formation or even higher-order supramolecular string associations. The chemical reality, as expressed in pairing/tripling/quadrupling properties of such alternative nucleic acids, would expectedly impose grave consequences on their copying and translation fidelity and thus on the number of genes and maximal genome length, all of which is out of scope of this chapter. In principle, memory strings could also be extended to higher than quaternary digit multiplicities (not to be confused with an “expanded alphabet” of triplet codons) and translated using longer than four-digit blocks (pentaplet, hexaplet, etc. codons). In the reality of macromolecules offered by nature, however, more diverse higher-digit memory polymers are likely to be copied more erroneously, since the monomers

would necessarily be more similar to one another, again limiting the replication error threshold, maximal number of genes, and total genome length. In addition, longer codons than quadruplets are at higher risk of being misread because of spontaneous frameshifting and mispairing, which would produce more erroneously assembled proteins (secondary polymers) and necessitate a more elaborate and costly error correction effort by the system. Yet, alien biota that would provide linear memory polymers that were markedly more rigid than RNA or DNA, thus perhaps less prone to frameshifting and mispairing, should not be ruled out *a priori*, not for chemical reasons. The overall energetic “cost” at the available energy influx needed to generate such polymers, to keep their replication error threshold high, and also to keep the erroneously produced secondary polymers under a liveable limit, are probably much more preventive factors than the huge choice of bricks chemistry can offer.

The prebiotic chemistry on our planet apparently produced prebiotic bricks that could condense under prebiotic reaction conditions into 1D polymers (nucleic acids) that could form double strands, at least locally in certain string zones, through the spontaneous association (hybridization) of pair-wise complementary digits, cf. complement copying in [Figure 5.2.2c](#). The digit multiplicity of the first replicating nucleic acids (*bit*, *trit*, *quit*, etc.) is unknown, although there is a consensus on *bit* polymers having preceded modern natural (biotic) nucleic acids that are generally *quit* polymers. For reasons that shall be elucidated in the sections further on, these prebiotic bricks are purine and pyrimidine ribonucleosides that, under appropriate prebiotic reaction conditions being present on this planet some 3.6 Gya, could condense with phosphate and polymerize into RNA and similar RNA-like linear polymers. At least a part of the early nucleic acid single strands could synthesize 3Q-translated secondary polymers, viz. polypeptides and proteins very early on, or else, we would hardly expect the genetic code to be universal (Theobald 2010). Apparently, on Earth, RNA proved to be the most successful “primary” 1D (memory) polymer. Not only can its monomer sequence be easily copied and faithfully reproduced, but also more faithful and streamlined information storage carriers can be derived from RNA by its deoxygenation to DNA. Most importantly, RNA, not DNA, can direct and catalyze the linking of amino acids into defined strings of polypeptides, that is, take an essential part in catalyzing the controlled dehydration of amino acids to produce amide bonds, a process termed peptidyl transfer (PT). Strong evidence suggests that uncoded PT preceded coded PT and, thus, that RNA could grow polypeptide chains from amino acids before a recognition system eventually emerged—from RNA, too—that allowed RNA-directed PT to profit from specific codon-anticodon interactions, thus, to translate genetic information ([Section 6](#)).

5.2.1.3 COPYING VERSUS COMPARTMENTATION

Long unfolded template polymers need to be soluble and disaggregated for copying. Self-folded polymer zones require the costly effort of denaturation (unfolding). From a prebiotic chemical point of view, RNA is probably ancestral to DNA, although perhaps not exclusively ([Section 5.2.2.3](#)). The molecular

reason for why, out of all previously discussed possibilities, not base-paired (dehybridized) RNA and DNA single-strands constitute the ideal systemic memory polymer is that they are periodically polyanionic and thus very well water-soluble and reasonably unfolded (because of being hydrophilic throughout) when compared with other polymers, at almost deliberate chain (string) lengths. An inevitable consequence of this physico-chemical property is that RNA and DNA are inherently difficult to compartment in “units” that separate bulk solvent from “self” content. Hans Kuhn (later with Jürg Waser), Sidney Walter Fox with Klaus Dose, and William Hargreaves with David Deamer have realized in the 1970s that semipermeable compartments are prerequisite for “biology to happen,” that is, what was called “molecular Darwinism” or “molecular evolution” to start from a prebiotic mixture of chemical substances. Kuhn, Waser, and others assumed that porous mineral (rock or clay) micro-cavities played the earliest compartmenting role for nucleic acids (Kuhn 1972; Kuhn and Waser 1981; Greenwood Hansma 2017). Kuhn postulated that, at an early stage of production of secondary polymers (polypeptides) from mineral-caged primary RNA or DNA (–) strands, that is, the pairing complements of the translated (+) strands, the translation products would rarely be soluble and catalytically functional, or not at all. Such (–)-strand polypeptides would have been made up of “gibberish” amino acid sequences that most likely misfolded and coagulated, ending up as aggregated polypeptide “coacervates” that had encapsulated the RNA or DNA from which they originated. Waste peptides of that sort might have eventually become the translated source of primitive organic compartments. Fox and Dose, on the other hand, proposed that microspheres composed of “proteinoids,” viz. untranslated insoluble polypeptide mixtures generated from heating certain amino acids, could form the first “protocellular” vesicular objects defined by semipermeable membranes (Fox and Dose 1972, 1977). Hargreaves and Deamer showed for the first time that phospholipids and “fatty” acids would aggregate under simulated prebiotic hydration conditions and form membranes that would spontaneously close to give micrometer-sized vesicles and thus define an isolated aqueous interior “lumen” that could, in principle, harbor foreign macromolecules (Hargreaves et al. 1977; Hargreaves and Deamer 1978). Membranogenic lamellar-phase bilayered amphiphiles, usually originating from hydrating lipids, are ever since the most convincing candidates for primitive dynamic protocellular compartments.

Unlike clay or volcanic mineral pores, or even (viscous) proteinoid coacervates, lamellar-phase amphiphiles can, depending on temperature and composition, adopt either a disordered liquid-like phase (2D liquid) within the bilayered lamella that make up the membranes, or they aggregate in a more ordered but soft gel phase. Both phases transform into one another non-linearly with temperature, through a phase transition involving an abrupt molecular reorganization on a supramolecular level. Spontaneously separated 2D zones of both phases, liquid disordered and gel, can co-exist in the same membrane. In addition, these membrane-bound amphiphiles are in a more or less rapid dynamic exchange with amphiphiles outside the membranes. Thus, vesicles composed of lamellar-phase amphiphiles such as fatty acids (Hargreaves and Deamer

1978), long-chain *n*-alkanoic (“fatty”) alcohols (Apel et al. 2002), and glyceryl single- and double-chain esters are able to grow in size (Bachmann et al. 1990), fuse with one another (Chen et al. 2004), divide into smaller vesicles through different mechanisms (Budin and Szostak 2011; Briers et al. 2012), spontaneously cluster into “colonies” (Carrara et al. 2012), and interact in diverse ways with the outside solution—especially when the membranes are composed of mixtures of chemically different lipids that form mobile heterogeneous-phase zones separated by temporary membrane defects (Baumgart et al. 2003). For example, the import of externally added ribose and nucleoside triphosphates (NTPs) inside vesicles composed of mixtures of single-chain amphiphiles has been achieved that way (Mansy et al. 2008).

Despite being covered with polar (phosphate, carbohydrate, and amino acid) headgroups at both the outside and inside membrane surfaces, each being about 0.7–1.0 nm deep and often carrying net negative or zwitterionic (never net positive) electric charge, all lipid vesicles bear closed hydrophobic zones between the inside and outside polar headgroups. This inner 2.5- to 3.5-nm-thick part of lipid bilayers renders the membranes virtually impermeable for large electrically charged hydrophilic molecules—the higher the electric charge density and size of the solute, the slower the membrane-crossing rate (Deamer 2017). Large charged macromolecules such as RNA and DNA are therefore lipophobic and cannot cross lipid membranes easily, irrespective of the direction, whether from the outside or inside. So, once they find themselves, for whatever reason, encapsulated in a lipid vesicle (Chen et al. 2004; Mansy et al. 2008; Kurihara et al. 2015; Engelhart et al. 2016; Tsuji et al. 2016), they shall not leak out easily, unless the membrane architecture dissolves (sometimes termed “denaturation”). Notwithstanding this intrinsic physico-chemical incompatibility between lipids and nucleic acids, self-evolvable compartments, being able to grow in size and compositional diversity, are still at the heart of every so-called Darwinian protocellular and cellular behavior (Part VII), which operates over long time periods, with competing variants of reproducing (cellular) units that harbor variants of replicating systemic memory polymers inside them (Szathmáry et al. 2005). Hence, once the prebiotic chemical pathways leading from primary chemicals to RNA and DNA are reasonably clarified and experimentally reproduced (Section 5.2.2), future research must focus on plausibly prebiotic compartmentation pathways of RNA and DNA into lipid vesicles (Section 5.2.3).

5.2.2 PREBIOTIC CHEMISTRY OF GENETIC BIOMOLECULES

5.2.2.1 BRICKS OF LIFE

The prebiotic bricks of life, as we know it, are more or less of the composite type and can be roughly divided into four chemical compound classes: (1) α -amino acids; (2) carbohydrate-type polyhydroxyaldehydes, ketones, and polyols; (3) *N*-heterocycles; and (4) long-alk(en)yl-chain fatty acids and alcohols. They should all covalently assemble (“condense”) in water, or neat, under prebiotically and geochemically plausible reaction conditions, from repeated units of similar fragments

or molecules into macromolecules that bear a resemblance to the known bio-macromolecules, the proteins (oligopeptides), the carbohydrates (oligosaccharides), the nucleic acids (oligonucleotides), and the lipid amphiphiles (phospholipids).

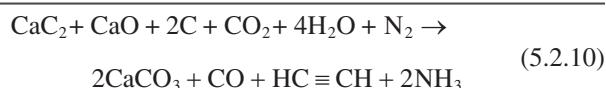

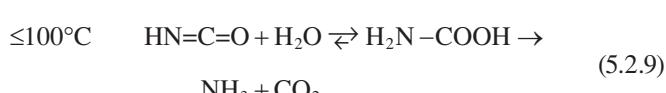

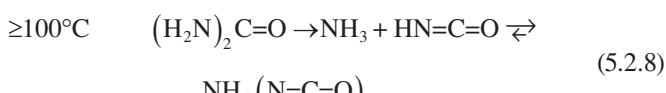

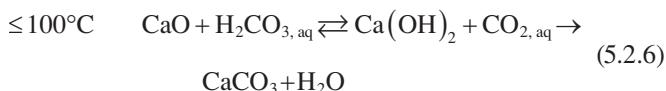

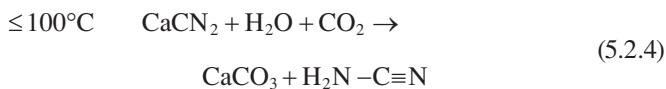

Currently and experimentally, prebiotic syntheses giving reasonable yields of α -amino acids (Miller 1953; Ritson and Sutherland 2013; Parker et al. 2014; Coggins and Pownar 2017; Islam et al. 2017) and *N*-heterocycles (Oró 1960; Oró and Kimball 1961; Sanchez et al. 1966; Saladino et al. 2001; Al-Azmi et al. 2003; Orgel 2004; Menor-Salván et al. 2009; Saladino et al. 2009; Salván and Marín-Yaseli 2013; Saladino et al. 2015) are mastered best, followed by those of lipids (Hargreaves et al. 1977; Hargreaves and Deamer 1978; Rao et al. 1982, 1987; McCollom et al. 1998; McCollom and Simoneit 1999; Deamer and Dworkin 2005; Rushdi and Simoneit 2006; Simoneit et al. 2007; Fernández-García and Pownar 2017; Fiore et al. 2017) and carbohydrates (Butlerow 1861; Kim et al. 2011; Ritson and Sutherland 2012). For too long, and unhappily at the bottom of this heap, were specific prebiotic syntheses of nucleosides and nucleotides. Nucleosides are composed of two precursor classes, one of which, the *N*-heterocycles, is particularly stable and usually readily accessed. The other compound class, prebiotic carbohydrates, is rather problematic from a stability point of view (Kim et al. 2011). The importance of finding convincing prebiotic pathways to synthesize nucleosides and nucleotides cannot be overestimated. One can almost say that the world is waiting for the answer for more than 60 years.

So, which carbon-, oxygen-, and nitrogen-containing small molecules should be considered plausibly prebiotic? Cyanamide $\text{H}_2\text{N}-\text{C}\equiv\text{N}$ has been used by many prebiotic chemists, starting in 1964 (Steinman et al. 1964), for its structural simplicity and its manifold reactivity once the conditions are appropriate (Eschenmoser 2004, Fiore and Strazewski 2016). A geochemically plausible provenance of large amounts of cyanamide on primordial Earth may have been similar to that of its industrial production. Elementary carbon was nucleosynthesized in high amounts by the young Sun. This carbon (density of C: $d_{20^\circ\text{C}} = 1.8\text{--}3.5 \text{ g/cm}^3$, $M_p > 3500^\circ\text{C}$), being markedly less volatile than dinitrogen, dioxygen, or even water, would accumulate and condense into essentially “coke” at a distance in the solar nebula, where now our planet Earth orbits, together with abundant rock-forming minerals mainly composed of the oxides and hydroxides of sodium, magnesium, aluminum, silicium, potassium, calcium, titanium and iron in smaller amounts of strontium, zirconium, barium, and others. While cooling down, the Earth’s crust separated from the bulk iron (Fe: $d_{M_p} = 6.98 \text{ g/cm}^3$, $M_p 1538^\circ\text{C}$), which eventually gravitated to form the planet’s core. Nevertheless, even today, there is carbon hidden as iron carbide Fe_7C_3 in the Earth’s core (Fe_3C : $d_{20^\circ\text{C}} = 4.93 \text{ g/cm}^3$, $M_p \sim 3140^\circ\text{C}$) (Chen et al. 2014). The atmosphere of that time was already rich in dinitrogen (almost 90%), contained perhaps 10% carbon dioxide, much lesser amounts of water vapor and carbon monoxide, and only trace amounts of noble gases, dihydrogen, dioxygen, sulfur dioxide, and ozone (trioxygen).

The majority of the oxygen atoms were immobilized in the minerals or covalently bound to hydrogen. When calcium carbonate was present on the hot planetary surface, it would

decarboxylate to give carbon dioxide and calcium oxide, viz. partly molten “quicklime” or “burnt lime” (CaO : $d_{20^\circ\text{C}} = 3.34 \text{ g/cm}^3$, $M_p > 2580^\circ\text{C}$). With passing time, the temperatures fell. Burnt lime reacted above 2000°C with coke to give carbon monoxide and calcium carbide (Equation 5.2.2). Industrial CaC_2 is produced since 1892 from the same starting materials at 2300°C in an electric arc furnace. The procedure was invented by Henri Moissan (Nobel Prize in Chemistry 1906) and by Thomas Willson (*Union Carbide*[®]). When calcium carbide rose to the planet’s surface through convection (CaC_2 : $d_{20^\circ\text{C}} = 2.22 \text{ g/cm}^3$, $M_p 2160^\circ\text{C}$, $B_{p1 \text{ atm}} 2300^\circ\text{C}$), it reacted with dinitrogen gas to give (back) coke and calcium cyanamide (Equation 5.2.3). This is an exothermic reaction, known as the Frank-Caro process for the industrial production of “nitrolime.” The reaction is conducted above 1000°C , where it is exergonic, $\Delta G_f^\circ(1273 \text{ K}) = -22.6 \pm 1.4 \text{ kJ/mol}$, and the composition of nitrolime equilibrates at around 20 wt% C, 18 wt% CaO, and 62 wt% CaCN_2 (Nagakura et al. 1998; Yamanaka et al. 2000). Calcium cyanamide on dry spots of the primordial Earth would stay as a liquid or solid reservoir (CaCN_2 : $d_{20^\circ\text{C}} = 2.29 \text{ g/cm}^3$, $M_p 1340^\circ\text{C}$). Once the temperatures fell enough for allowing liquid water to arrive and slightly acidify the crust with carbonic acid, calcium cyanamide would transform into limestone (calcium carbonate) and separate from aqueous cyanamide (Equation 5.2.4). Upon periodic night-day evaporation of water, cyanamide could crystallize ($M_p 44^\circ\text{C}$). If during that period unreacted calcium and other carbides were still penetrating the water phase, carbide would immediately eliminate acetylene gas (Equation 5.2.5). The resulting burnt lime would hydrolyze to “slaked lime” (calcium hydroxide) and, upon slow addition of carbonic acid, again transform into limestone, mostly as calcite and aragonite (Equation 5.2.6). Hence, this could have been a huge geochemical planetary prebiotic nitrogen-fixation process, resulting in virtually unlimited amounts of cyanamide. If cyanamide would co-deposit with large amounts of liquid ammonia ($B_{p1 \text{ atm}} -33^\circ\text{C}$, $M_p -77^\circ\text{C}$), solid guanidine feedstocks could form ($M_p 50^\circ\text{C}$). At elevated temperatures, dry cyanamide could be transported by sublimation or would react with itself, especially above 150°C , to give the dimer 2-cyanoguanidine ($M_p 209.5^\circ\text{C}$) and the stable cyclic trimer melamine ($M_p 345^\circ\text{C}$). In the presence of other organic compounds, higher oligomers and polymers could form (Pankratov and Chesnokova 1989). But, given an excess of liquid water, cyanamide would inevitably hydrolyze to urea (Equation 5.2.7) and, over geological timescales, to ammonium cyanate (Equation 5.2.8, Shaw and Bordeaux 1955), unstable carbamic acid (Callahan et al. 2005), and finally evaporate water, ammonia, and carbon dioxide (Equation 5.2.9). Of note, this way of generating cyanamide and urea is independent of exposing carbon monoxide and ammonia ices to galactic cosmic rays, as has been recently proposed (Förstel et al. 2016), or of heating calcium and magnesium cyanides to 400°C and 660°C , respectively (Pincass 1922; Seifer 1962a, 1962b). The overall process consists of the deposition of calcite and aragonite—“chalk” rock, that is, the main non-silicate minerals of today’s Earth crust—generated from transforming primordial hot burnt lime and calcium carbide, entropically driven by the oxidative release of elemental solid carbon as carbon monoxide and solid or liquid carbide as

acetylene gases and accompanied by the reductive hydrolysis of nitrogen gas to ammonia (Equation 5.2.10).

Carbon monoxide (CO) is the isoelectronic oxygen analogue of dinitrogen (N_2), hydrogen cyanide (HCN), and acetylene or ethyne (HCCH). Cyanamide (H_2NCN) is the isoelectronic dinitrogen analogue of carbon dioxide (CO_2) and isocyanic acid (HNCO). Guanidine [$(\text{H}_2\text{N})_2\text{CNH}$] is the isoelectronic trinitrogen analogue of urea [$(\text{H}_2\text{N})_2\text{CO}$] and carbonic acid (H_2CO_3). Electrophilic formaldehyde (H_2CO), isocyanic acid, cyanamide, and nucleophilic hydrogen cyanide, which had arrived from the solar nebula (Öberg et al. 2015) and was immobilized in cyanoferrate minerals (Sutherland 2016), as well as carbon monoxide, acetylene, guanidine, and large amounts of urea, were the geochemically metastable carbon feedstock reagents that could generate a great many of more complex organic products further down the prebiotic reaction network (examples in Figure 5.2.3). Most important for the chemistry discussed in this chapter (cf. Equations 5.2.11 and 5.2.12) are the homologation products of hydrogen cyanide (HCN)₂₋₅ up to adenine; the homologation products of cyanamide (H_2NCN)₂₋₃ up to melamine; cyanogen $\text{N}\equiv\text{C}-\text{C}\equiv\text{N}$, acetylene $\text{HC}\equiv\text{CH}$, and cyanoacetylene $\text{N}\equiv\text{C}-\text{C}\equiv\text{CH}$ and their partially oxidized, reduced, or hydrolyzed products such as glyoxal $\text{O}=\text{CH}-\text{CH=O}$, glyoxylic acid $\text{O}=\text{CH}-\text{COOH}$, acetaldehyde $\text{H}_3\text{C}-\text{CH=O}$, cyanoacetaldehyde $\text{N}\equiv\text{C}-\text{CH}_2-\text{CH=O}$, and 2-amino-2-cyanoacetamide $\text{N}\equiv\text{C}-\text{CH}(\text{NH}_2)-\text{CONH}_2$; many different aldolization products, that is, carbohydrates and their partly reduced or oxidized derivatives, including glycerol, ribose, 2-deoxyribose (Oró and Cox 1962), and pyruvic acid (Coggins and Pownall 2017); and many small

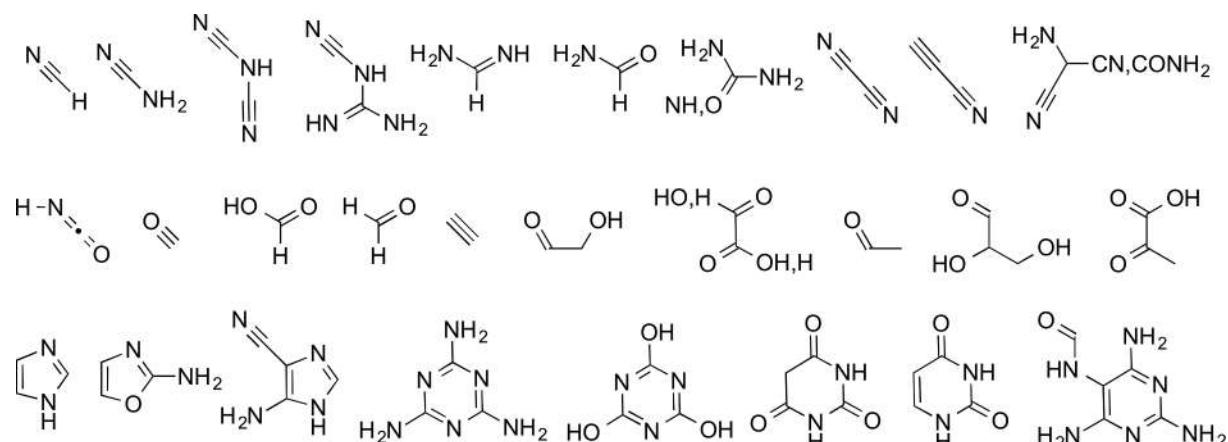

FIGURE 5.2.3 Prebiotic H-, N-, and O-containing C₁-, C₂-, and C₃-feedstock reagents, and some of their most important cyclic products. First row (from left to right): Hydrogen cyanide (hydrocyanic acid, from electric discharge on nitrogen and methane or interstellar clouds); cyanamide (stable tautomer of carbodiimide, from carbide and nitrogen, see text); dicyanamide (deamination product of 2-cyanoguanidine); 2-cyanoguanidine (dicyandiamide) = $(\text{H}_2\text{NCN})_2$; formamide; formamide; RHN = guanidine/RO = urea; cyanogen (dicyan, oxalonitrile); cyanoacetylene (2-propynenitrile, from electric discharge on nitrogen and methane); and RCN = 2-amino-2-cyanoacetamide = $(\text{HCN})_3/\text{RCOCONH}_2$ = 2-amino-2-cyanoacetamide. Second row (from left to right): Isocyanic acid (unstable deamination product of urea); carbon monoxide; formic acid; formaldehyde; acetylene (ethyne, from carbide and water); glycolaldehyde; 2x OH = oxalic acid/2x H = glyoxal; acetaldehyde (hydrolysis product of acetylene); glyceraldehyde; and pyruvic acid. Third row (from left to right): Imidazole (from formaldehyde, glyoxal and ammonia, or from photo-irradiation of cyanoacetylene and ammonia); 2-aminooxazole (from cyanamide and glycolaldehyde); 5-amino-4-cyanoimidazole (5-aminoimidazole-4-carbonitrile) = $(\text{HCN})_4$; melamine (2,4,6-triamino-s-triazine) = $(\text{H}_2\text{NCN})_3$; cyanuric acid (s-triazinetriol = major tautomer in the absence of melamine, see also Figure 5.2.4D); barbituric acid (pyrimidine-2,4,6(1H,3H,5H)-trione); uracil (pyrimidine-2,4(1H,3H)-dione, from cyanoacetylene to cyanoacetaldehyde plus urea and water); and 2,4,6-triamino-N5-formylamino-pyrimidine (from 2-malononitrile, guanidine and formamide or formic acid).

N-heterocycles, that is, imidazoles, oxazoles, pyridines, pyrimidines, purines, and pterins. The richness of this list of “bricks of life” becomes much higher when other hetero-elements, mainly sulfur and phosphorous, are included ([Section 5.2.2.3](#)).

5.2.2.2 NUCLEOSIDES

Much has been written about intuitive pathways leading from very simple organic compounds to the known nucleosides and nucleotides. For the average organic chemist who spends his or her scientific life on synthesizing molecules and, for doing so, works through the most evident “retro-syntheses,” that is, ways to cut down the target molecule into simpler starting compounds, the most intuitive means of getting nucleic acids “from scratch” should roughly follow the Equations 5.2.11 through 5.2.15:

The first two equations are based on solid experimental knowledge pioneered by Alexander/Aleksander Mikhaylovich/Mikhailovitch Butlerov/Butlerow/Boutlerow—Александр Михайлович Бутлеров—for the formose reaction (Equation 5.2.2; Boutlerow/Butlerow 1861) and, respectively (Equation 5.2.3), the works of Juan Oró (purines) and Leslie Orgel (pyrimidines) and their collaborators at the time (Oró 1960; Oró and Kimball 1961; Sanchez et al. 1966). These reactions have been exploited by several generations of chemists for many decades. A prebiotic alternative to the formose reaction has been proposed by Ramanarayanan Krishnamurthy and collaborators, according to which ketoses, rather than aldose-ketose mixtures, are produced from dihydroxyfumaric acid, but the corresponding pentulofuranosyl nucleic acids do not hydride through base pairing (Sagi et al. 2011, 2012; Stoop et al. 2013). Perhaps, the most authoritative recent essay on the problems that every chemist encounters, when trying to experimentally reconstruct the above pathways, was written by Steven Benner et al. (2012). Their arguments concentrated on the rich reaction network of the formose reaction and how this reaction would favor tetroses and pentoses over hexoses, longer -oses, branched polycarbohydrates, and intractable “tar.” By reversibly scavenging furanosidic *cis*-diols as cyclic borate esters, typical formose run-off side reactions are suppressed in the presence of plausibly prebiotic borate minerals or boric acid (Prieur 2001). To tame the formose reaction is a formidable challenge ever since Boutlerow/Butlerow (1861), who himself needed to stop the reaction by adding water and cooling down the mixture before it

turned brown. Using borates to obtain useful yields of tetroses and pentoses, among which were arabinose and ribose, is a formidable achievement (Kim et al. 2011). The same run-off side reactions—based on ever-present aldose-ketose isomerizations and collateral aldolizations of the intermediate ene-1,2-diols—could be suppressed by yet another modification. Albert Eschenmoser and collaborators obtained preferentially pentose-2,4-diphosphates over tetrose-2,4-diphosphates and hexose-2,4,6-triphosphates (72% total pentose, 36% ribose, 19% total hexose, and 4% total tetrose) when carrying out the formose reaction in the presence of 0.08 M glyceraldehyde-2-phosphate and 0.04 M formaldehyde in, albeit prebiotically questionable, 2 N NaOH (Müller et al. 1990). This kind of taming of the formose reaction was not wholly plausible in terms of pH >13, albeit locally imaginable, cf. Equation 5.2.6 at high temperature. It did set a new standard for the chemical analysis of the formose reaction mechanisms and how to interfere with the formation of carbohydrate ene-1,2-diols (Eschenmoser and Loewenthal 1992).

But there are more “demons” lurking on the pathway from formaldehyde and cyanide or cyanoacetylene to the nucleic acids. Let us go straightaway to the most difficult chemical problem, which is—once the ribose problem has been sufficiently solved and all sorts of *N*-heterocycles being more or less similar to the natural nucleobases have also been obtained—the formation of the nucleoside’s *N*-glycosidic bond. Much of the research has been carried out under simulated primitive Earth conditions. The Eo-Archean Sun 4.0–3.6 Gya was smaller and its radiation was at least 20% weaker than today, albeit with a larger fraction in the broadband ultraviolet (UV) range, but the solar wind is thought to have blown more intensely on the surface of the early Earth because of the absence of today’s atmospheric dioxygen and protective ozone gases. In the early 1960s, Cyril Ponnamperuma and collaborators reported on the prebiotic synthesis of minute amounts of adenosine from irradiating aqueous solutions of adenine and ribose and of deoxyadenosine from irradiating aqueous solutions of adenine and 2-deoxyribose, under a mercury lamp emitting narrow-band UV light of 254-nm wavelength (Ponnamperuma et al. 1963; Ponnamperuma and Kirk 1964). At this wavelength, however, the *N*-glycosidic bond of guanosine, for instance, is unstable (Crespo-Hernández and Arce 2000). γ -Photons at 0.93-nm and 1.06-nm wavelengths—the 1.33-MeV and 1.17-MeV beams generated from $^{60}\text{Co} \rightarrow ^{60}\text{Ni}$ —were shown to transform deaerated, that is, oxygen-depleted, aqueous solutions of deoxyadenosine to the corresponding 5-*N*-formylaminopyrimidine (FaPy) nucleoside, through the hydrolytic ring opening of the imidazole part of the adenine residue (Raoul et al. 1995). Pyrimidine and purine derivatives obtained in the same pot, that is, mixtures of uracil, thymine, 5-hydroxymethyluracil, cytosine, *N*-formylpurine, *N,N*-diformyladenine, and *N*-(hydroxyacetyl)- and *N*-(2,3-dihydroxypropionyl) purines and -adenines, have been reported from heating pure formamide (FA) at 160°C in the presence of TiO₂, a powdered form of the abundant mineral rutile (Saladino et al.

2003). Under the same conditions, purine and pyrimidine 2'-deoxynucleotides were shown to degrade into 8-oxopurines, dihydroxylated pyrimidines, and FaPy derivatives. In the presence of ammonia, one of FaPy's further degradation products is FA. Formamide is thought to have played, in small amounts, crucial catalytic and, in large amounts, dehydrating and solvating roles on prebiotic Earth (Saladino et al. 2009). Raffaele Saladino, Ernesto Di Mauro, and their collaborators have recently experimentally simulated the presumed conditions on an early Earth being submerged in a persistent flux of slow protons supposed to arrive from the solar wind. They obtained complex mixtures of products from the irradiation of pure FA at -30°C with a 170-MeV proton beam ($7.29 \text{ fm wavelength} = 7.29 \cdot 10^{-6} \text{ nm}$), in the presence of various catalytically active meteorite powders. Trimethylsilyl-derivatized crude reaction mixtures were analyzed by GC-MS, revealing the presence of a plethora of polyhydroxy alcohols, aldehydes, carboxylic acids, amino acids, urea, guanidine, nitriles, *N*-heterocycles, and, most notably, what appeared to be pyrimidine nucleosides and purine nucleosides in nanogram to microgram amounts per milliliter FA (Saladino et al. 2015). As eyebrow-lifting or -raising these recent results might be, still no convincing prebiotic synthesis starting from *N*-heterocycles and carbohydrates that would lead to significant amounts of reasonably enriched nucleosides or nucleotides has been demonstrated to date.

Benner et al. also proposed high-boiling ($\text{Bp}_{\text{atm}} 210^{\circ}\text{C}$) and low-melting ($\text{Mp } 2^{\circ}\text{C}-3^{\circ}\text{C}$) FA as the prebiotic salvage reagent and solvent. Hot FA is thought to promote the regioselective *N*-ribosylation of *N*-formylheterocycles, O-phosphorylation of the resulting nucleosides (Schoffstall 1976, Schoffstall et al. 1982, Furukawa et al. 2015), as well as the activation of mononucleotides through O-formylphosphate-mixed anhydrides to give nucleic acids (Benner et al. 2012). The *umpolung* from nucleophilic water to electrophilic FA as prebiotic solvent was evoked. The weak electrophilicity of FA's carbon atom—it's a carboxamide after all—versus the weak nucleophilicity of its oxygen atom—thought to generate O-formidoylphosphate (not O-formylphosphate) in supposedly FA-catalyzed phosphorylation reactions (Xu et al. 2017)—is a matter of ongoing debate and so are its long-term reactivity profile, geochemical abundance, and prebiotic role in general (Hudson et al. 2012; Pietrucci and Saitta 2015; Pino et al. 2015; Bada et al. II 2016; Šponer et al. 2016). Mechanisms involving FA as a catalyst still need experimental support.

Be it as it may, many chemists have believed for long that there should be a way of *preferentially* building the required carbon-nitrogen bond, that is, between the carbohydrate's anomeric carbon atom from the right side—the β -face of the furanose ring—and the required nitrogen atom of both the pyrimidine base (N1) and the purine base (N9). Alas! No, not spontaneously in water, not without protective groups and modern directive synthetic strategy or enzymes. Something out there steadfastly and successfully hampers this chemical challenge. For us chemists it is as if, every time when we try to *throw a dart* at the bull's eye, we find ourselves instead struggling to *catch a javelin* more or less

frontally—it is a nightmare. The trials under plausibly prebiotic reaction conditions but, without more or less harsh irradiation, have started in the early 1970s. Leslie Orgel and his collaborators at the time succeeded in adding cyanamide to a pentose (ribose and arabinose) to make the corresponding 2-aminooxazole that would react with cyanoacetylene to give, after partial hydrolysis, pyrimidine nucleosides in moderate yields and with the wrong stereoselectivity at the anomeric center for ribose (Sanchez and Orgel 1970). The Orgel group has also attempted to obtain purine nucleosides from *N*-ribosylating purines under neat conditions (Figure 5.2.4B). They obtained nucleosides in low yields and disastrous regioselectivities with respect to the purine's nitrogen atoms (Fuller et al. 1972). Orgel's approach of obtaining pyrimidine nucleosides from arabinosyl and ribosyl 2-aminooxazoles turned out to be absolutely pioneering and highly influential (see Section 5.2.2.3), but the low yields and regioselectivity problems could not be overcome until shortly. The only successful regio- and reasonably stereoselective direct ribosylation and 5-phosphoribosylation of a pyrimidine derivative were recently achieved by Nicolas Hud and collaborators (Figure 5.2.4C). Pyrimidine-2,4,6(1*H*,3*H*,5*H*)-trione, alias barbituric acid, is an oxidized form of pyrimidine-2,4(1*H*,3*H*)-dione, alias uracil (Figure 5.2.3, third row). Thanks to a favorable 6-keto to 5-en-6-ol tautomerization of barbituric acid, good yields of the corresponding C(5)-nucleoside and C(5)-nucleotide were obtained under plausibly prebiotic reaction conditions (Cafferty et al. 2016). Melamine (2,4,6-triamino-s-triazine), the cyclic trimer of cyanamide and base-pairing partner of barbituric acid and cyanuric acid—the latter locked as tautomeric s-triazinetrione when mixed with melamine (Whitesides et al. 1995, Avakyan et al. 2016)—is the other *N*-heterocycle that could be easily and selectively ribosylated and 5-phosphoribosylated under the same conditions, however, at one of the exocyclic nitrogen atoms (Figure 5.2.4D). In spite of this, there is no pyrimidine or purine that would be directly and regioselectively N1- and N9-ribosylated, respectively—for that matter, regioselectively *N*-glycosylated at any endocyclic nitrogen atom—to give the corresponding nucleoside or nucleotide, respectively, under plausibly prebiotic conditions. The “natural” *N*-heterocycles (biotic nucleobases) are simply not nucleophilic enough at their endocyclic nitrogen atoms to be efficiently *N*-glycosylated enzyme-free in water (Figure 5.2.4A and B).

Thus far, the short answer to the question: “Why did it take so long to obtain nucleosides under plausibly prebiotic conditions?” should be: “Because *separately* joining prebiotic *N*-heterocycles with prebiotic sugars was too seducing an intuition.” It was nourished by several seminal results from the past. They were recently comprehensively discussed by Sutherland (2016). This idea (Equation 5.2.13) was kept alive by our almost insurmountable confidence in what we scientists see in biotic nature. For example, knowing that pyrimidine nucleosides are biosynthesized from the natural *N*-heterocycle orotate (6-carboxyuracil, Figure 5.2.4A, $\text{R}^1 = \text{O}$, $\text{R}^2 = \text{COOH}$) and 5-phospho- α -D-ribofuranosyl-1-pyrophosphate (PRPP: the chemically activated carbohydrate, Figure 5.2.4A,

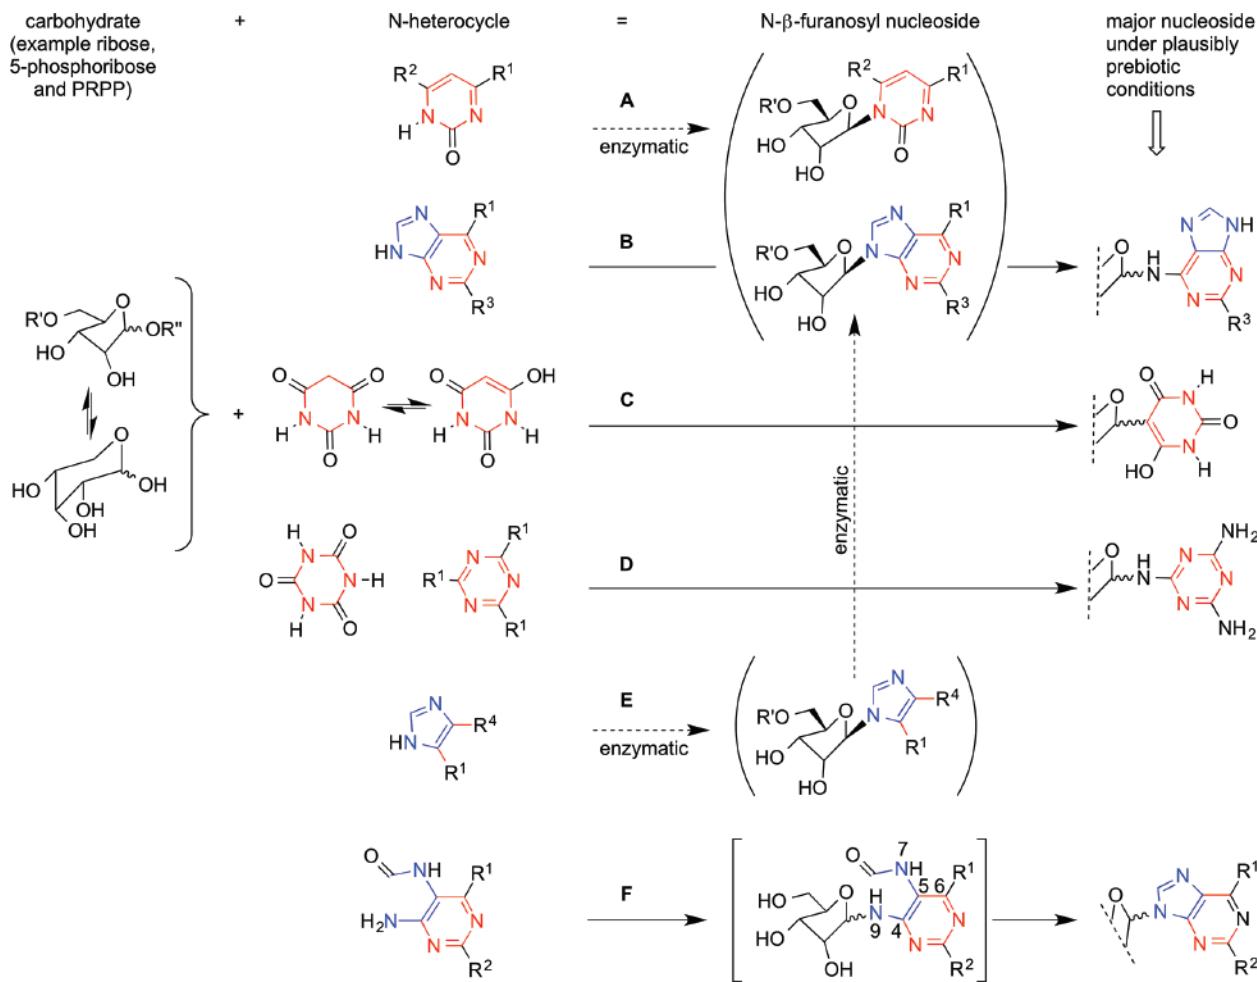

FIGURE 5.2.4 Summary of prebiotic nucleoside syntheses (continuous arrows) according to the concept carbohydrate + *N*-heterocycle = nucleoside, as in Equation 5.2.13 and enzymatic pathways (dotted arrows). First column: Any tetrose, pentose, or hexose as furanose, pyranose, or corresponding carbohydrate phosphate, for example, R' = H or phosphate, R'' = H or diphosphate. Second column: *N*-heterocycles R¹ = NH₂, OH (= rare lactim tautomer shown for depicting convenience, major tautomer = lactam), R² = H (uracil, cytosine) or COOH (orotic acid/orotate = 6-carboxyuracil), R³ = H or NH₂ (adenine, guanine, 2,6-diaminopurine), and R⁴ = H, CN, or CONH₂ (5-aminoimidazole, 5-amino-4-cyanoimidazole/5-aminoimidazole-4-carbonitrile, 5-amino-4-carboxamidoimidazole/5-aminoimidazole-4-carboxamide). Third column: desired (biotic) nucleoside: round parentheses indicate absence or very low yields in prebiotic mixtures. Fourth column: obtained major product(s). **A:** Pyrimidines do not form nucleosides under plausibly prebiotic conditions. Natural pyrimidine nucleotides are biosynthesized from orotate (R² = COOH) and PRPP (R' = phosphate, R'' = diphosphate). **B:** Purines (R¹ as for pyrimidines) do not form (endocyclic) N9-glycosylated nucleosides under plausibly prebiotic conditions. Instead, exocyclic R¹ = NH₂ is preferentially glycosylated. **C:** The enol tautomer (right) of barbituric acid (left) is readily (5-phospho)ribosylated to the corresponding C5-nucleos(t)ide. **D:** Cyanuric acid trioxo tautomer (left), forced by base pairing (not shown) with melamine, and cyanuric acid triol tautomer in aqueous solution (R¹ = OH, right). Melamine (R¹ = NH₂, right) is readily (5-phospho)ribosylated to the corresponding exocyclic N²-nucleos(t)ide. Mixtures of products from **C** and **D** form long supramolecular fibers and have been proposed as alternative genetic material (Cafferty et al. 2016). **E:** Imidazoles and carbohydrates do not form nucleosides under plausibly prebiotic conditions, but the natural purine nucleotides are biosynthesized from AIR (R¹ = NH₂, R⁴ = H) and PRPP (R' = phosphate, R'' = α-diphosphate). **F:** Purine nucleosides do form from 6-amino-5-formylaminopyrimidines and carbohydrates.

R' = PO₃²⁻, R'' = α-triphosphate), we tend to assume that a similar but prebiotic pyrimidine compound, for example, cytosine or uracil (Figure 5.2.4A, R¹ = NH₂ or O, R² = H), can be plausibly phosphoribosylated—but it can't. Purine nucleosides are biosynthesized from PRPP to give first the imidazole *N*-glycoside 5'-monophosphate 5-aminoimidazole β-D-ribonucleotide (AIR). The purine is then completed on the aminoimidazole part by stepwise building up the pyrimidine component of the purine (Figure 5.2.4E, R' = PO₃²⁻,

R¹ = NH₂, R⁴ = H). Hence, we imagine that a similar but direct prebiotic “imidazole-first” synthesis should be possible (Figure 5.2.4E, R' = H, R¹ = NH₂, R⁴ = CN or CONH₂), but it shall not, not directly at least (cf. Section 5.2.2.3), despite the fact that the well-understood HCN homologation pathway to adenine (HCN)₅ leads through 5-amino-4-cyanoimidazole (HCN)₄ (Figure 5.2.3, third row).

An answer to the “imidazole-first” purine nucleoside question was recently given by Hendrick Zipse, Thomas

Carell, and collaborators (Becker et al. 2016). They proposed a “pyrimidine-first” purine nucleoside synthesis strategy, according to which three different FaPy derivatives would be mixed with solid carbohydrates and heated under plausibly prebiotic neat conditions (100°C, 8 hours). The carbohydrate readily added regioselectively to the exocyclic free amino group next to an endocyclic N-atom of the FaPy producing a Schiff base intermediate (not shown). The subsequent ring closure of the N-glycoside generated intermediate furanosidic (Figure 5.2.4F) and pyranosidic FaPy nucleosides with varying stereoselectivities at the anomeric center. Upon addition of water and a choice of plausibly prebiotic additives, such as simple amines, basic amino acids, borax, or a carbonate-borate buffer, and heating the mixtures in a sealed tube at 100°C for 1 day to 1 week, the intermediate FaPy nucleosides ring-closed to the purine nucleosides. These researchers obtained, for the first time in considerable yields (up to 60%), prebiotic purine nucleosides with the expectedly absolute N9-regiosomeric selectivity and, especially in the presence of borax or borate, with the “correct” (biotic) β-furanosidic stereoisomeric preference. In addition, several carbohydrate variants, that is, pyranosides versus furanosides and tetrosides versus pentosides, were produced from adding dry FaPy to different carbohydrate precursor mixtures, that is, to glycolaldehyde and glyceraldehyde that were kept together beforehand for 30 minutes at ambient temperature in the presence of slaked lime (calcium hydroxide), and to ammonia, formaldehyde, and glycolaldehyde, after heating the solution without FaPy for 1 hour at 65°C, respectively, thus under prebiotic formose reaction conditions. These protocols necessitated the separation of calcium sulfate by filtration and repeated lyophilization before proceeding with the imidazole ring closure at 100°C.

This “pyrimidine-first” synthesis of purines is rooted in Wilhelm Traube’s work, *Der Aufbau der Xanthinbasen aus der Cyanessigsäure. Synthese des Hypoxanthins und Adenins*, where the first synthesis of hypoxanthine and adenine appeared in the literature (Traube 1904). The absolutely regioselective formylation of the 5-amino group of 4,5,6-triamino-2-thiopyrimidine, to become N7 in purine nucleosides, was reproduced several times since (originally in boiling formic acid, later at higher temperatures in FA) (Bendich et al. 1948; Haley and Maitland 1951; Robins et al. 1953; Trinks 1987; Koch 1992), was then proven by a crystal structure of 2,4,6-triamino-5-formylamino-pyrimidine (Koch 1992), and is now elegantly explained through an *ab initio* pK_a calculation and X-ray analysis of 4,5,6-triaminopyrimidinium chloride (Becker et al. 2016). It transpires from two dissertations from the Eschenmoser group that the key prebiotic purine (and pterine) nucleoside precursors could all be FaPy derivatives (Trinks 1987; Koch 1992). In the presence of carbohydrates, 6-amino-5-FaPys readily generate exocyclic N-Schiff bases that cyclize twice to give first FaPy nucleosides and then purine nucleosides. In the absence of carbohydrates, FaPys cyclize to purines that are not glycosylated, but the FaPys can be partly recovered in hot FA (Saladino et al. 2003).

There is no question about the possible abiotic provenance of FaPy precursors that lead to 2,6-diaminopurine nucleoside ($R^1 = R^2 = NH_2$, cf. in Figure 5.2.4F) and natural guanosine, since both FaPy precursors can be obtained under prebiotically plausible conditions from guanidine (Trinks 1987), if not urea (Koch 1992). The pyrimidine ring closes with 2-aminomalononitrile and with 2-amino-2-cyanoacetamide to form the required 2,4,6-triaminopyrimidine and 2,6-diaminopyrimidine-4-one, respectively. The C₁-precursor guanidine forms from cyanamide and ammonia and both three-carbon 2-aminonitriles are intermediate products on the HCN homologation pathway (Figure 5.2.3). The FaPy C₁-precursor for adenosine ($R^1 = NH_2$, $R^2 = H$, Figure 5.2.4F) would be formamidine, viz. the addition product of two molecules of ammonia on dehydrated formic acid. Formamidine, however, rather than ring-closing with 2-aminomalononitrile to form the obligatory 4,6-diaminopyrimidine, apparently prefers to integrate the imidazole ring of 4-aminoimidazole-5-carboxamide under similar reaction conditions (Sanchez et al. 1966; Schwartz and Hornyak-Hamor 1971; Trinks 1987; Koch 1992). So, the only known access to an FaPy precursor of adenosine is (thus far) not prebiotic, since the currently available reaction protocols proceed from malononitrile and thiourea rather than guanidine. Both molecules are plausibly prebiotic, but the reaction works only with the assistance of anhydrous alcoholate (Traube 1904). In Traube’s hands, nitrosylation of the resulting crude 4,6-diamino-2-thiopyrimidine with nitrous acid, subsequent reduction of the C5-oxime to 4,5,6-triamino-2-thiopyrimidine with hydrogen sulfide, and regioselective N⁵-formylation in hot formic acid allowed for the cyclization of this FaPy to create the adjacent imidazole ring. The resulting 2-thiadenine was oxidized and eliminated in hot 20% sulfuric acid containing 3% H₂O₂ to give adenine and H₂SO₄. This protocol was much later optimized and modified by a final reductive desulfuration over Raney-Ni (Bendich et al. 1948). An alternative reductive desulfuration of 4,5,6-triamino-2-thiopyrimidine with Raney-Ni or Ni₂B (amorphous synthetic “nickel boride”) was carried out by Clark et al. (1968).

Hence, there is still work to be done to find the missing links for fully prebiotic adenine to be generated on the “pyrimidine-first” purine nucleoside pathway. We should anyway refrain from intuitively assuming that there is only one prebiotic way to RNA, as shown in the next section.

5.2.2.3 NUCLEOTIDES

In all previously described works, other crucial prebiotic elements were missing: sulfur, thiols, and phosphorous in one of their oxidized forms. In plausibly prebiotic and geochemical environments on the young Earth, phosphate was mostly locked up in very stable and quite insoluble apatite minerals, such as hydroxylapatite Ca₅(PO₄)₃(OH). The role of phosphate for the prebiotic production of nucleosides, ribonucleotides, and other vital organophosphates—either neat in more soluble evaporite minerals or as a eutectic liquid in the presence of water, ammonium formate, and urea—is currently a hot subject in prebiotic chemistry (Burcar et al.

2016; Kim et al. 2016; Karki et al. 2017). In this handbook, **Chapters 5.7** and **5.8** are devoted to phosphorous in prebiotic chemistry, so let us concentrate here on the synthesis of nucleotides from simple building blocks and ignore for the moment the questions: how highly soluble phosphate concentrations could be achieved in truly prebiotic mixtures and how they would react with nucleosides when present.

When the old prebiotic pyrimidine synthesis work of Sanchez and Orgel 1970 was taken up by the Sutherland group and now in the presence of high concentrations of inorganic phosphate, a whole new “prebiotic universe” opened up. Said Sutherland in Venice 2005: let’s make prebiotically plausible nucleosides and nucleotides in a sequence of reactions, where *N-heterocycles are allowed to form in the presence of inorganic phosphate and sugar precursors*, instead of separately synthesizing prebiotic *N*-heterocycles and prebiotic sugars. Exploiting the homologation of HCN in concert with unsaturated or otherwise highly reactive prebiotic nitriles ([Figure 5.2.3](#)) and with the homologation of formaldehyde in “one pot,” being “geologically linked” to other “pots” (Sutherland 2016), does produce prebiotic carbohydrates, as if under classic Butlerow conditions. But, while the sugars keep their electrophilicity and α -enolisability at almost all stages of H_2CO homologation, as in a classical formose reaction, the compositional outcome of an expanded formose reaction mixture is strongly modified by the presence of nitrogen-rich intermediates. This change of outcome takes its beginning in the reaction between C-electrophilic cyanamide and the sufficiently nucleophilic α -hydroxy group of hydroxyaldehydes and ketones (carbohydrates) when anchimerically assisted by the opposite reactivity next door, viz. the nucleophilic attack of the amino group of cyanamide on the carbonyl group of the aldehyde or ketone, which in the end leads to all sorts of 2-aminooxazoles, for example, from pure glycolaldehyde to 2-aminooxazole *per se* (cf. first reaction in [Figure 5.2.5](#)).

At neutral pH, this reaction works particularly well in the presence of phosphate as a general acid-base catalyst,

and excess cyanamide is rapidly converted to urea under these conditions (see side products in the second row of Figure 5.2.5). In turn, 2-aminooxazole adds through its relatively nucleophilic C5-atom to the aldehyde function of aldoses, whereby the adjacent α -hydroxy group attacks imine-like C4, thus readily forming various bicyclic 2-aminooxazoles, technically 3a,5,6,6a-tetrahydrofuro[2,3-*d*]oxazol-2-amine derivatives (cf. second reaction in Figure 5.2.5). From pure glyceraldehyde and 2-aminooxazole, a diastereoisomeric mixture of bicyclic pentose derivatives is generated that way, where the *ribo*- and *arabino*-configurations prevail. It is of note that the natural β -anomeric pyrimidine nucleotides are derived from the corresponding *arabino*-configured bicyclic 2-aminooxazole and that the *ribo*-configured bicyclic 2-aminooxazole crystallizes in enantiomeric forms as “kryptoracemate” or “conglomerate” and hence offers a spontaneous way of separating the enantiomers. If, for some reason, a scalemic (non-racemic) mixture of *ribo*-configured bicyclic 2-aminooxazole was locally present in solution, that is, one of the enantiomers appeared enriched because of its formation from scalemic (enantioenriched) glyceraldehyde, for example, it could spontaneously crystallize virtually enantiopure and thus persist over much longer time periods than if the compound stayed in solution (Pownier et al. 2009; Patel et al. 2015; Sutherland 2016).

Mixtures of carbohydrates are, of course, more typical for a prebiotic formose reaction. A mixture of carbohydrates, including aldoses and ketoses, reacts with cyanamide to give a mixture of 2-aminooxazoles. A common short ketose, dihydroxyacetone, reacts with two cyanamides to form a C4-spiro-*bis*-(2-aminooxazole) compound, whereas with 2-aminooxazole, it forms a bicyclic C5-disubstituted 2-aminooxazole (both shown in the second row in Figure 5.2.5). Formaldehyde and glycolaldehyde react to the corresponding C5-substituted 2-aminooxazoles, none of which are useful precursors for pentofuranosyl nucleotides, albeit tetrafuranosyl nucleotides and particularly 3',2'- α -threose nucleic acids

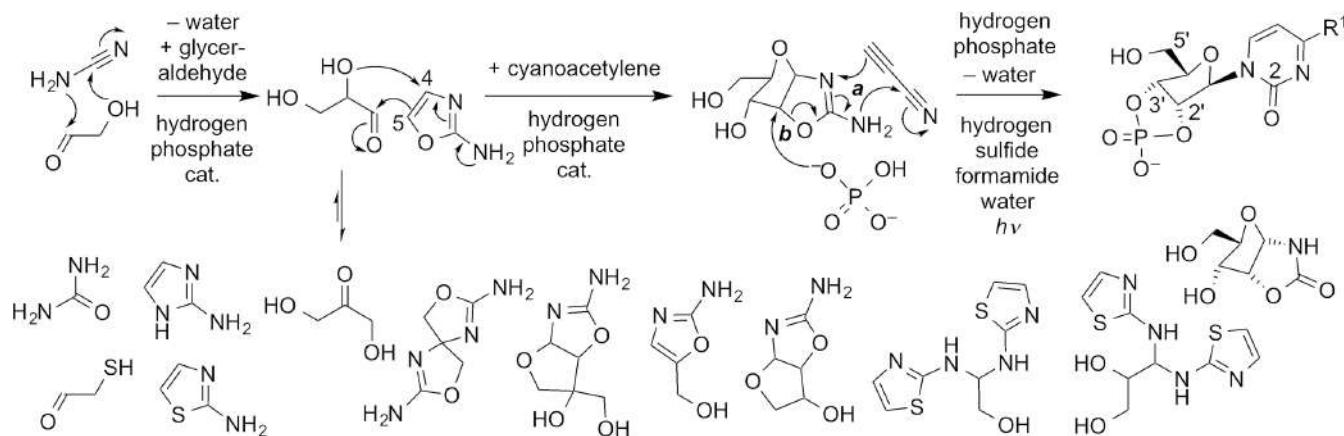

FIGURE 5.2.5 Prebiotic pyrimidine nucleoside 2',3'-cyclic phosphate synthesis. First row: Streamlined summary with pure starting materials. Second row: Identified side products when carbohydrate and other mixtures are used. $R^1 = NH_2, OH$ = rare lactim tautomer shown for depicting convenience, major tautomer = lactam. For explanations, see text.

(TNAs) might, in principle, have had an alternative functional role in alien or early biota (Eschenmoser 1999; Schöning et al. 2000; Eschenmoser 2004; Pinheiro et al. 2012; Yu et al. 2012). However, here, the problem is how to form and accumulate (enrich) useful pentofuranosyl nucleotide precursors from mixtures of carbohydrates in the presence of cyanamide. In the presence of prebiotically plausible β -mercaptoproacetaldehyde, for instance, the addition to cyanamide results in 2-aminothiazole instead of 2-aminooxazole, whereas, when phosphate and ammonium are present, 2-aminoimidazoles compete with 2-aminooxazoles (Fahrenbach et al. 2017). Interestingly, mixtures of short carbohydrates react differently with 2-aminothiazole. This *N,S*-heterocycle was found to play the role of a “chemical chaperone” in sequestering glycolaldehyde from carbohydrate mixtures through plausibly prebiotic crystallization events (Islam et al. 2017). In those mixtures, in the (temporary) absence of cyanamide, aldehyde functions are preferentially captured as their corresponding di(thiazol-2-yl)aminals (second row in Figure 5.2.5), showing that the exocyclic amino group of 2-aminothiazole is much more nucleophilic than that of 2-aminooxazole, and it outweighs the nucleophilicity of its C5, too (Powner et al. 2012). Out of the two mentioned aminals, the first shown is glycolaldehyde aminal. Both, glyceraldehyde and dihydroxyketone are shown in the first and second rows, respectively. After a prebiotically plausible physical separation of the solids from the liquids, this “prebiotic mother liquor” continues to react over longer time periods to form the homologue glyceraldehyde aminal (shown). In the absence of the former solid, this glyceraldehyde aminal accumulates through spontaneous crystallization as well. The physically separated glycolaldehyde aminal crystals can now be exposed to fresh aqueous cyanamide to form per aminal two molecules of 2-aminothiazole and one 2-aminooxazole in a quantitative yield. Furthermore, when the homologous glyceraldehyde aminal crystals are exposed to this reaction mixture, one aminal is transformed in a high yield into two 2-aminothiazoles and one bicyclic pentose 2-aminooxazole, the same as is obtained from mixing pure glyceraldehyde with hydrogen phosphate and cyanamide. Hence, the C5-atom of 2-aminooxazole preferentially reacts with aldehydes under aqueous close to neutral prebiotic reaction conditions, even in the presence of 2-aminothiazole; the latter transforms aldehydes to di(thiazol-2-yl)aminals only in the absence of 2-aminooxazole. This explains under what circumstances di(thiazol-2-yl)aminals can offer chaperone services to a formose reaction, namely, when 2-aminothiazole exposure, crystallization events, and cyanamide exposure can occur separately from one another. A subsequent solid-liquid separation (crystallization) leaves pure *ribo*-configured bicyclic 2-aminooxazole crystallized from the last liquid. All initially formed tetroses, pentoses, and hexoses do not participate in this sequential reaction-crystallization-reaction-crystallization process; they remain minor leftovers in the liquid that has separated from pure *ribo*-configured bicyclic 2-aminooxazole.

The other decisive reactivity in such mixtures is based on the readiness of 2-aminooxazoles to ring-close with

cyanoacetylene to pyrimidines (Ferris et al. 1968). Hydrogen cyanide and cyanoacetylene are the major products after the exposure of a mixture of ammonia and methane to powerful electric discharges (Sanchez et al. 1966). Best in the presence of 1 M phosphate buffer, bicyclic 2-aminooxazoles add cyanacetylene to form 2,2'-anhydropyrimidines, that is “oxygen-tethered” pyrimidine nucleosides (not shown intermediate after reaction *a*), and subsequently ring-open this tether through a stereoinversion at C2' with (hydrogen) phosphate (reaction *b*) to end up as various pyrimidine nucleoside 2',3'-cyclic phosphates (cf. third reaction in Figure 5.2.5). Of course, if pure bicyclic pentose 2-aminooxazoles are brought in contact with cyanacetylene and phosphate, they all transform into pentosyl pyrimidine nucleoside 2',3'-cyclic phosphates. If nature starts from pure crystalline, perhaps enantiopure bicyclic *ribo*-configured 2-aminooxazole, and then, the “wrong” anomeric α -configuration results (not shown). Only diastereoisomerically pure bicyclic *arabino*-configured 2-aminooxazole will generate the biotic β -furanosyl pyrimidine ribonucleoside 2',3'-cyclic phosphates, 2',3'-cCMP and 2',3'-cUMP, which can be racemic, scalemic, or enantiopure (Figure 5.2.5). In the absence of phosphate, the conversion from *ribo*- to *arabino*furanosidic tethered derivatives (not shown) requires UV light and long photoanomerization times, cleaves in parts the *N*-glycosidic bond, and also generates high amounts of the bicyclic *ribo*-configured oxazolidin-2-one, that is, hydrolyzed 2-aminooxazole (Figure 5.2.5) and correspondingly low yields of the desired β -furanosyl cytidine. Alternatively, if the starting compound was the minor, less persistent because non-crystalline bicyclic *arabino*-configured 2-aminooxazole, then satisfactory yields of both 2',3'-cCMP and, after photoanomerization, 2',3'-cUMP are generated (Powner et al. 2009). However, in the presence of aqueous FA and hydrosulfide HS⁻, being abundant only in alkaline waters as the conjugate base of plausibly prebiotic hydrogen sulfide (H₂S) ($pK_a = 7.0$), the reaction with bicyclic *ribo*-configured 2-aminooxazole involves the formation of α -configured 2-thiocytidine (α -2-thioC) by opening the tether at C2 rather than through stereoinversion at C2' (not shown). The β -furanosyl anomers of 2-thiocytidine (β -2-thioC), cytidine, 2',3'-cCMP, and 2',3'-cUMP are quite readily generated through the photoanomerization of α -2-thioC in the presence of FA and phosphate, followed by partial hydrolysis at 60°C (Xu et al. 2017). Having alleviated the anomerization problem with the help of hydrosulfide, other problems have been evoked, namely, the poor water solubility of hydrogen sulfide and low abundance of hydrosulfide at neutral pH, as well as the expected high reactivity between cyanacetylene and hydrosulfide to form the adduct (Z)-3-mercaptoproacrylonitrile HS-CH=CH-C≡N. Cyanacetylene is the key ingredient to transform bicyclic pentose 2-aminooxazoles into 2',3'-cCMP and 2',3'-cUMP. Therefore, the intermediate photoanomerization precursor 2,2'-anhydro- α -cytidine can only be generated in the absence of hydrosulfide from pure crystalline, perhaps enantiopure bicyclic *ribo*-configured 2-aminooxazole (reaction *a* in Figure 5.2.5). Once FA and hydrosulfide arrive after that, the ring opening and the smooth photoanomerization can

take place. But what happens when cyanoacetylene meets hydrosulfide and bicyclic *ribo*-configured 2-aminooxazole? And what if, instead of hydrosulfide, “hydrated SO₂” viz. highly water-soluble bisulfite HSO₃⁻ ($pK_a = 7.2$), was more easily available on the early Earth?

Before we dive into subsequent investigations, let us reflect for a moment upon the pyrimidine chemistry thus far. What we learn from the previously described experiments is that short prebiotic carbohydrates act as efficient scavengers of intermediate *N*-heterocycles before these intermediates continue to react downhill to give stable dead-end products such as cytosine and uracil. It turns out that *ribo*- and *arabinofuranosyl* scaffolds can hold this promise best. They are ideally configured for the formation of cyclic nucleoside phosphates, thus providing a prebiotic reservoir of, in principle, sufficient free enthalpy for the spontaneous polymerization to RNA, *vide infra* (Figure 5.2.7). The same argument holds the other way around: few nitrogen-containing organic key compounds that result from prebiotic high-energy reaction conditions act as efficient scavengers of intermediate short carbohydrates before these intermediates continue to react downhill to give intractable dead-end products that taste like caramel, sweet as it is, and eventually look like tar. For this mutual reaction interference between carbohydrates and *N*-heterocycles to be efficient and productive, two more elements have been identified: phosphorous and sulfur. The phosphate anion catalyzes important reactions between small acyclic molecules as general acid-base reactions at close to neutral pH, and both thiols and phosphate act as nucleophiles on different carbon atoms of nucleotide key precursors. Phosphate prefers to attack carbohydrate residues, whereas thiols favorably interfere with unsaturated parts of organic compounds. The sunny side of the thus-far described systems chemistry experiments: The farther from chemical equilibrium chemists work, the more complex the chemical mixtures can be, which, despite this complexity, generate clear-cut results, that is, few major products. One way of avoiding thermodynamic overall equilibrium is to work with spatio-temporal separations. Prebiotically plausible sequential reaction, crystallization, and re-solubilization/reaction events help generating the virtually enantiopure pyrimidine nucleoside key precursor from scalemic carbohydrate mixtures. Another important result is the successful experimental bifurcation or divergence of the prebiotic pathway from carbohydrates and organic nitriles to the amino acids and to the nucleotides (Ksander et al. 1987; Eschenmoser 2004; Ritson and Sutherland 2013; Patel et al. 2015; Coggins and Powner 2016; Sutherland 2016; Islam et al. 2017). The downside thus far is that there is apparently no viable *direct* way in sight that would lead from 2-aminooxazoles to the purine nucleotides.

One of several possible “small bricks of life” that contains more than merely nitrogen and oxygen “hetero-elements” has led to a remarkable conclusion for a possible divergent pathway that might lead to pyrimidine and purine nucleotides. The plausibly prebiotic combination of hydrogen cyanide and sulfur results in the quantitative formation of thiocyanic acid HS-C≡N (Bartlett and Skoog 1958), the mono-sulfur analogue of cyanamide. Therefore, thiocyanic acid is regarded as a plausibly

prebiotic compound (Chyba and Sagan 1992; Thaddeus 2006; Ritson and Sutherland 2013). Thiocyanic acid reacts with glyceraldehyde in a different way from that of cyanamide, thus generating crystalline 2-thioxazole, not 2-aminothiazole, in high yields (first reaction in Figure 5.2.6). Unlike the reaction to 2-aminooxazole, there is no need for phosphate to buffer this reaction. Analogously to the bicyclic 2-aminooxazoles, similar pentose preferences are observed for the reaction of 2-thioxazole, or its *NH* tautomer, with glyceraldehyde to form bicyclic oxazolidinone-2-thiones, from which the *arabino*-configured diastereoisomer crystallizes (second reaction in Figure 5.2.6). The aminolysis of *S*-benzylated bicyclic pentose oxazolidinone-2-thiones derived from xylose, ribose, arabinose, and fructose with anthranilic acid (*ortho*-aminobenzoic acid) was pioneered by Patrick Rollin and collaborators, who were the first to synthesize quinazolinedione nucleosides from *D*-arabinose, albeit not in a plausibly prebiotic context (Girniene et al. 2001, 2004). Matthew Powner and collaborators took up this route and discovered that, while *S*-benzyl or *S*-methyl derivatives were unsuitable for an efficient aminolysis by ammonia, the plausibly prebiotic *S*-cyanovinyl residue could be readily formed and subsequently displaced with ammonia, 2-aminomalononitrile, or 2-amino-2-cyanoacetamide ($pK_{a, \text{ammonium}} \approx 9.2, 6.5, \text{ and } 3.4$, respectively). The reactivity of bicyclic oxazolidinone-2-thiones is not the same as that of bicyclic 2-aminooxazoles (compare the second reaction in Figures 5.2.5 and 5.2.6). The superior and softer nucleophilicity of sulfur, when compared with nitrogen, favors conjugate attack on cyanoacetylene, forming an intermediate bicyclic pentose 2-*S*-cyanovinyloxazolidine-2-sulfide adduct (oxazolidine-2-thioacrylonitrile, not shown), thus offering (*Z*)-3-mercaptopropanonitrile HS-CH=CH-C≡N as an excellent leaving group. This constitutes the bifurcation point on the divergent pathway to pyrimidine nucleotides upon exposure to ammonia (left downward reaction in Figure 5.2.6) and to oxypurine nucleotides upon exposure to the other bricks of life (Figure 5.2.3), viz. 2-aminomalononitrile or 2-amino-2-cyanoacetamide (third reaction in Figure 5.2.6). The crude aminolysis yields, as determined by proton NMR spectroscopy, were roughly 20%–45%, along with lower amounts of pentose oxazolidine-2-thione from the reaction with aqueous ammonia and both pentose oxazolidine-2-thione and pentose oxazolidine-2-one (second row in Figure 5.2.5) roughly 1:1 from displacements by 2-aminomalononitrile or 2-amino-2-cyanoacetamide. The latter two aminolytic products are tricyclic pentosyl “oxygen-tethered” aminocyanato- and aminocarboxamidoimidazoles. All *arabino*-configured bicyclic and tricyclic pentose derivatives, that is, the oxazolidine-2-thione, oxazolidine-2-thioacrylonitrile and both cyano- and acetamidoimidazoles, are crystalline. This opens a plausibly prebiotic pathway to an “imidazole-first” synthesis for N9-β-ribosylfuranosyl-8-oxopurine nucleotides (Stairs et al. 2017).

The *dot on the i* was put by ring-closing the pyrimidine residue of the above tricyclic imidazoles in adding formamidine in FA at 100°C to form tetracyclic pentosyl “oxygen-tethered” 2',8-anhydropurine nucleosides in up to 60% yield (right downward reaction in Figure 5.2.6). This tether was opened during prebiotic phosphorylation in urea at 140°C, where

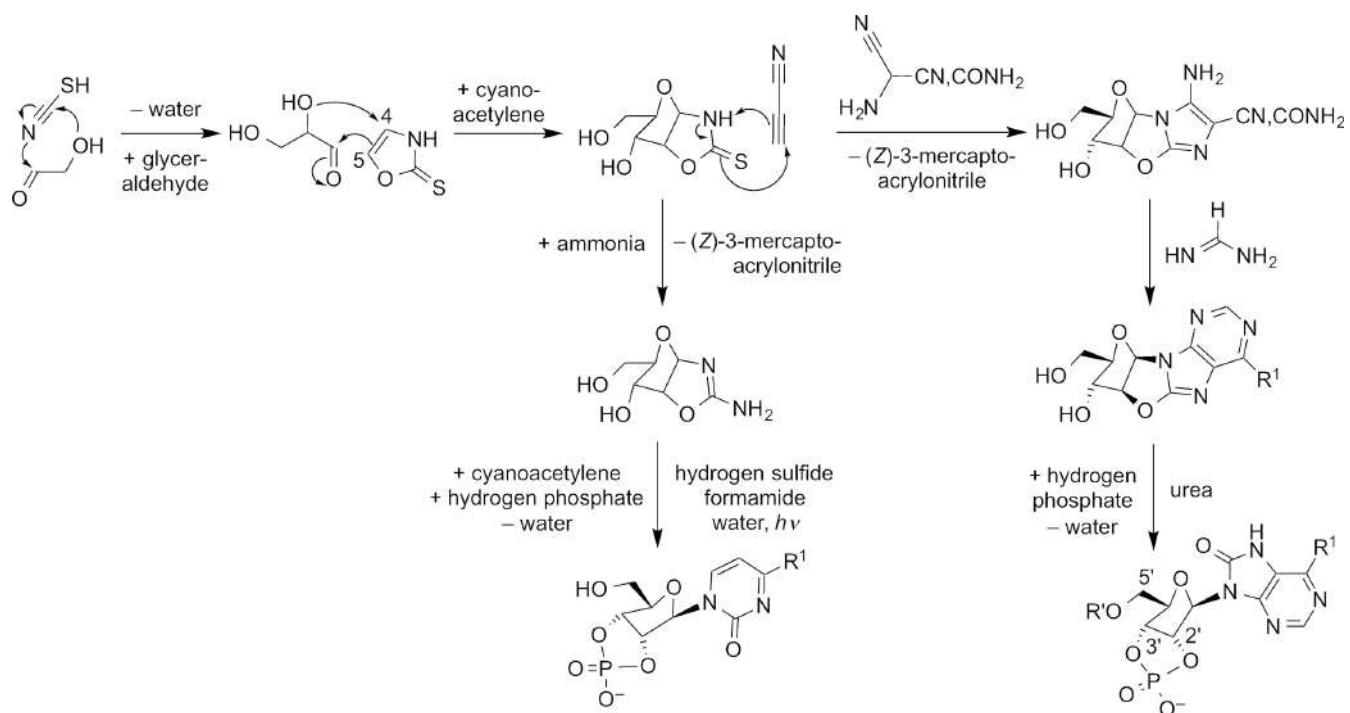

FIGURE 5.2.6 Divergent prebiotic pyrimidine nucleoside and oxopurine nucleoside 2',3'-cyclic phosphate synthesis. The bent arrows of the first reaction are a strong oversimplification and meant only to illuminate the overall constitutional outcome of a multi-step reaction mechanism. Most probably, the reaction sequence involves the initial attack of sulfur on the aldehyde group to form a hemithioacetal, which gives anchimeric assistance to the nucleophilic attack of the α -hydroxy group on the nitrile carbon atom. A first reasonably stable intermediate is expected to be 2-imino-1,3-oxathiolan-4-ol. This intermediate can reversibly dehydrate to 1,3-oxathiol-2-imine, but the first formed C-S bond can also ring-open again to generate O-(2-oxoethyl) carbamothioate $O=CHCH_2OC(=S)NH_2$, which, upon rotation and nitrogen attack on the aldehyde, can ring-close and dehydrate to the aromatic 2-thioxazole, thence, its NH tautomer (shown). $R^1 = NH_2$, OH = rare lactim tautomer shown for depicting convenience, major tautomer = lactam, $R' = H$ or phosphate. For explanations, see text.

8-oxopurine nucleoside 2',3'-cyclic phosphates are the major products. In mixtures containing both bicyclic pentosyl oxazolidine-2-thiones and pentosyl 2-aminooxazoles, the former can be quantitatively and chemoselectively re-cyanovinylated at the sulfur in the presence of the latter or with excess cyanoacetylene, thus concomitant synthesis of anhydropurine nucleoside and anhydropurine nucleoside precursors can be achieved with remarkable efficiency. This is where the field presently stands (September 2017).

This newest work is highly complementary to the prebiotic syntheses of pyrimidine nucleotides (Figure 5.2.5), as well as to the “pyrimidine-first” purine nucleoside synthesis that thus far lacks prebiotic access to adenosine (Figure 5.2.4F). The complementarity of this “imidazole-first” 8-oxopurine nucleoside synthesis can be tracked down to the different reactivities of formamidine versus guanidine or urea (Figure 5.2.3). Formamidine, the diamide of formic acid HCOOH, furnishes the C2 atom of adenosine and inosine. Guanidine, the triamide of carbonic acid H_2CO_3 , serves to create the same C2 atom in guanosine and 2,6-diaminopurine nucleosides. Formamidine is more nucleophilic than guanidine, albeit its conjugate acid is expected to be less resonance-stabilized, and thus, formamidine is somewhat less basic. Formamidine reacts with 2-aminomalononitrile to the corresponding 5-amino-1*H*-imidazole-4-carbonitrile,

not 4,5,6-triaminopyrimidine (cf. Section 5.2.2.2). But when an imidazole is already present, as in the tricyclic oxygen-tethered pentose imidazoles (Figure 5.2.6), then formamidine reacts at high temperatures, thus ring-closing to the imidazole-annealed pyrimidine, whereas guanidine apparently does not. If it did after all, oxygen-tethered 8-oxoguanosine nucleosides were in prebiotic reach on an “imidazole-first” pathway. It is intriguing to see how this strategy of avoiding the separate synthesis of carbohydrates and *N*-heterocycles (Equation 5.2.13) navigates through a chemical space where the oxidation states of the obtained purine nucleotides do not correspond (yet) to the biotic variants. All biotic pyrimidine nucleotides bear the same oxidation state at the corresponding carbon atoms—in particular, that of C2 is the same as that of urea, guanidine, cyanamide, carbonic acid, and carbon dioxide, or, for that matter, of thiocyanic acid. Hence, many (all biotic) pyrimidines can, in principle, be built up from these bricks, with no need for prebiotic redox reactions. All biotic purine nucleotides bear the same oxidation state at C8, being the same as in formic acid, FA, and formamidine but different from 8-oxopurines. C8 in pentosyl 8-oxopurines is provided from thiocyanic acid, that is, an isoelectronic sulfur-nitrogen equivalent of CO_2 . In contrast, the oxidation state of C2 varies in biotic purine nucleosides; it is either reduced, as in adenosine and inosine,

or oxidized, as in guanosine and 2,6-diaminopurine nucleoside. Therefore, the prebiotic pathway(s) to the biotic purine nucleosides must either involve a prebiotic redox reaction, or else, of course, two chemically different pathways are taken for one and the other, as described in this chapter. Prebiotic redox reactions have been relatively recently worked out for the divergent prebiotic synthesis of carbohydrates, and thus also nucleotides, and α -amino acids from formaldehyde and hydrogen cyanide through a so-called “cyanosulfidic chemistry out of the blue” (Sutherland 2016). Photoreductions from UV light at 254 nm intended to mimic the effect of the early Earth’s Sun light (Ranjan and Sasselov 2016), using cuprous cyanide (CuCN) and sodium hydrosulfide (NaHS) or hydrogen sulfide (H_2S) (Ritson and Sutherland 2013; Patel et al. 2015; Sutherland 2016; Ritson et al. 2016). Organic nitriles, formed, for example, from prebiotic HCN homologation, are usually quite inert, but, upon photoirradiation in the presence of Cu(I) and HS^- , they thiolyze to thioamides ($\text{R}-\text{CSNH}_2$) that are chemoselectively reduced to the imines that rapidly hydrolyze to the aldehydes. Prebiotic Strecker reactions (Miller 1953; Parker et al. 2014) furnish α -aminonitriles that equilibrate with α -hydroxynitriles (“cyanhydrines”). Cyanhydrines are thus mildly reduced to the corresponding α -hydroxyaldehydes, that is, to short carbohydrates. Given the importance of the sequential addition, exclusive presence, and separate prebiotic access of reactive nitriles, such as cyanamide, cyanoacetylene, and 2-amino malononitrile, from that of organothiols or -thiones, such as β -mercaptoacetaldehyde and pentose oxazole-2-thiones, this calls for testing plausibly prebiotic photoreduction conditions (Ranjan and Sasselov 2016) on mixtures containing 8-oxopurine nucleosides or, even more so, on mixtures of

both tetracyclic pentosyl oxygen-tethered 2',8-anhydropurine nucleosides and 8-oxopurine nucleosides. Which carbon atom is more easily reduced, tethered, or untethered C2? If the tethered C2, then we shall encounter a stereochemical problem at C2' of the crystalline *arabino*-configured 2',8-anhydropurine nucleoside. Besides, are there ways of photooxidizing C8 of the above nucleosides, perhaps through a prebiotic dismutation between C2 and C8? These questions remain elusive. If 8-oxopurine nucleosides won’t react to the biotic purine nucleosides, then the polymerization and base-pairing properties of 8-oxopurine nucleotides (OP) need much deeper and more systematic investigation. Perhaps, indeed, 1D polymers containing OP, C, and G (or U) could have been early *trit* (or *quit*) memory polymers.

5.2.2.4 NUCLEIC ACIDS

The repeated and sequential dehydration of nucleotides to generate polymeric chains of nucleic acids (Equation 5.2.15) under plausibly prebiotic conditions is still an open question, although several methods are being discussed and investigated since long. Two general routes differ in the kind of nucleotides with which to begin the polymerization, either from acyclic 5'-phosphates, such as the biotic nucleoside monophosphates (NMPs), or from the 3',5'-cyclic nucleoside phosphates and 2',3'-cyclic nucleoside phosphates. From a purely thermodynamic point of view, the former needs strong chemical activation by an *umpolung* reagent that can transform a dianionic foremost nucleophilic phosphate residue into an electrophile, where the phosphorous atom can be attacked in water by a moderately nucleophilic hydroxy group of another NMP. The NMP pathway is the biotic buildup of nucleic acids and promotes step-wise chain growth in the 5' \rightarrow 3'-direction

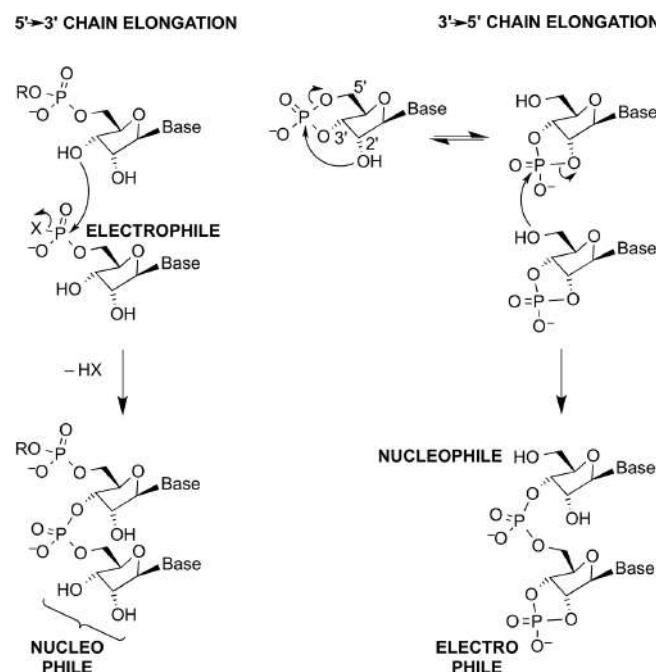

FIGURE 5.2.7 Principal pathways for RNA chain growth. R = negative charge or 5'-pRNA, X = leaving group (nucleofuge). For explanations, see text.

(Figure 5.2.7 left). The latter cyclic phosphates should be able to profit from their strained-ring tension energy and a diminished negative (maximally single) charge for a hydroxy group attack by another nucleotide monomer, without the absolute requirement for an additional activator X. With both an electrophilic site and a nucleophilic site present in each oligo- and polymer molecule, multiple ligations at both the termini and step-wise chain growth in the 3'→5'-direction are possible (Figure 5.2.7 right).

While the mere principles of RNA chain growth from the nucleotides seem straightforward and clear-cut, the chemical reality is far from simple (Costanzo et al. 2011, 2012; Burcar et al. 2013). The problems can be divided into three classes, where one is purely chemical. Hydroxy groups are poor nucleophiles and compete with a huge excess of water molecules, which are also poor nucleophiles; they also compete with anionic phosphate groups, which are stronger nucleophiles, especially the dianionic terminal phosphates (Liu et al. 2016). When an inactivated nucleophilic phosphate group attacks an activated electrophilic phosphate group, hydrolytically labile organic “pyrophosphates” (phosphoric acid anhydrides) are generated; these eventually hydrolyze back to the starting materials. Biotic nature uses NTPs as monomers, where X leaves as inorganic pyrophosphate $P_2O_7^{4-}$ (Figure 5.2.7 left). Pyrophosphate is a good leaving group once it is tightly complexed, that is, when it “clamps” one or two divalent metal ions, such as magnesium and manganese, that are best provided enzymatically and ideally positioned by the polymerase (Wu et al. 2017). The required concentration of magnesium ions without enzyme is much too high to be useful for RNA polymerization. Nucleotide polymerizations are endergonic processes, that is, energy-consuming “uphill” reactions, so the reversed reaction, the magnesium-catalyzed RNA strand cleavage, is usually favored over the forward reaction. What other plausibly prebiotic activator might have been taken over by biotic pyrophosphate?

Many different charge-neutral leaving groups have been explored ever since imidazole was proposed as nucleofuge X and phosphorimidazolides as the corresponding P-electrophiles (Weimann et al. 1968). Most often, an electrophilic dehydrating agent, such as cyanamide, cyanoimidazole, or a carbodiimide, would be combined with charge-neutral, somewhat-labile 5'-mononucleotidic acids (better than with 5'-mononucleotides) and a nitrogenous nucleophile as the ultimate leaving group. The longest homopolynucleotides have been obtained from separately (non-prebiotically) prepared adenosine-5'-phosphorimidazolide, when the polymerization was carried out in the presence of montmorillonite clay (Ferris and Ertem 1993; Ferris et al. 1996; Ferris 2002). The chain lengths are much shorter from mixed nucleoside-5'-phosphorimidazolides, despite optimized conditions and the use of acid-treated montmorillonite (Coari et al. 2017). The clay-catalyzed reactions of mixtures of separately or *in situ* prepared nucleoside-5'-phosphorimidazolides showed that the extent of polymerization was greatest in the presence of adenylate. The pyrimidine nucleotides generally were less reactive than

the purine nucleotides, and heteropolymers containing both pyrimidines and purines tended to favor those with higher purine content. When activated adenylate was present, it tended to dominate the polymerization products. Polymerizations in the absence of solid catalysts, for example, mixed ribonucleoside-5'-phosphorimidazolides that have been achieved in ice eutectic phases, show a greatly diminished preference for purines (Monnard et al. 2003).

Many alternative non-anionic prebiotic X groups, which have been tested for enzyme-free and ribozyme-free polymerizations, can be found among the biotic bricks in Figure 5.2.3. But the favorite prebiotic “pet nucleofuge” remains imidazole, albeit often as a derivative at the C2 position, that is, an imidazole, where the hydrogen between the endocyclic nitrogen atoms has been replaced by something else, for example, by a C2-alkyl or C2-amino group (Wu and Orgel 1992; Li et al. 2017). It is of note that enzyme-free primer extensions from separately prepared ribonucleoside-5'-phospho-(2-aminoimidazolides), that is, using plausibly prebiotic 2-aminoimidazole as the leaving group (Fahrenbach et al. 2017), show a greatly enhanced reaction rate with templated nucleotidic hydroxy groups when compared with other C2-imidazole derivatives. Another important discovery was the enhanced reactivity of 5'-nucleotides, when activated in the presence of possibly prebiotic N-alkyl derivatives of imidazole (derivatives at the N1-position), owing to the *in situ* activation of NMPs as N1-alkylimidazolium-N3-phosphoramidates, rather than phosphorimidazolides, which allows for more efficient chain extensions with all four NMPs (Röthlingshöfer and Richert 2010; Kervio et al. 2014; Jauker et al. 2015a). These rate enhancements are explained by the positively charged X group, making the activated monomers zwitterionic, rather than monoanionic, at neutral pH, and thus, making them more electrophilic.

For the biomimetic RNA 5'→3'-chain extension pathway, 5'-NMPs need to be generated from the nucleosides under plausibly prebiotic phosphorylation conditions. Two different tendencies are reported in the recent literature. On the one hand, prebiotic nucleoside phosphorylations from ammonium dihydrogen phosphate and urea, either neat or in FA and in the absence or presence of triols such as glycerol and cytidine, generate, over several days at 140°C, stable majority amounts of 2',3'-cyclic nucleoside phosphates and varying lower amounts of 2',3'-cyclic 5'-nucleoside diphosphates (Stairs et al. 2017). This confirms that the 2',3'-cyclic nucleoside phosphates are irreversibly formed even at these elevated temperatures and over prolonged time periods, while 5'-phosphates that form first, and much lower amounts of 3',5'-cyclic esters (Schoffstall 1976; Schoffstall et al. 1982; Furukawa et al. 2015), may be reversibly transported to other hydroxy groups. On the other hand, phosphorylations at 65°C and 85°C in urea-ammonium formate-water eutectic liquids containing FA generate about twice the amount of 5'-NMPs with respect to 2',3'-cyclic nucleoside phosphates (Burcar et al. 2016), and geochemical phosphorylations at 85°C in the presence of borate minerals suppress 2',3'-cyclic nucleoside phosphates almost completely,

through the reversible formation of 2',3'-cyclic nucleoside borates that are transformed into 5'-NMPs in 13%–33% yields (Kim et al. 2016). Generally, prebiotic nucleoside phosphorylations are not very efficient; they usually generate 10%–30% nucleotides, and molar yields above 45% are the far-out exception. Low steady-state activated NMP concentrations and/or high competitive inhibition from the unreactive non-activated NMPs and nucleosides thus limit enzyme-free step-wise RNA or DNA growth in the 5'→3'-direction to usually one-digit or maximally low two-digit nucleotide lengths. The literature is, let's say, rich in enzyme-free template-directed nucleotide chain elongation experiments, and to summarize, adequately all results are out of scope of this chapter. Excellent reviews on the topic have been published recently (Fernández-García et al. 2017; Karki et al. 2017). What should be pointed out here is that this problem class of weak chemical reactivity of nucleosides in water, for both phosphorylations and phosphodiester syntheses, may be linked to the second and third problem classes and hopefully then be solved. They are rooted in the difficulty to take over RNA and DNA *de novo* synthesis by template-directed RNA extension, alias primer extension, and hence, to achieve step-wise sequence copying from sufficiently stable complementary base-paired parts. Of course, first, we do need RNA or DNA strings of a certain (unknown) minimal chain length before useful RNA and DNA sequences can be copied and translated, as depicted in Figure 5.2.2. *De novo* chain synthesis and extension could indeed occur at quite high temperatures and would not much depend on the identity of the *N*-heterocycles being attached to the carbohydrates through the *N*-glycosidic bond. However, the temperatures must have dropped very significantly before template-directed RNA extensions could have set in (Monnard et al. 2003; Attwater et al. 2010; Attwater et al. 2013); or else, the solvent viscosity must have been at least locally remarkably higher on the prebiotic Earth, possibly generated by periodic water evaporation (He et al. 2017). Hence, what might have been a stockable monomer reservoir of nonetheless conveniently spring-loaded mononucleotides for *de novo* nucleic acid synthesis—the 2',3'-cyclic nucleoside phosphates—must have become useless for primer extensions. Yet, the ultimate reason for RNA to be ever present in all known forms of life is their ability to synthesize proteins, a function for which RNA needs to be folded (transfer RNA, ribosomal RNA). In contrast, in order to be copied by template primer extension, unfolded RNA is prerequisite—so how do we join these two loose ends?

The second problem class is the huge numbers of isomers that can be formed once prebiotic monomer polymerization begins. The greatest concerns are all linked to the required efficiency of template-directed nucleotide copying:

1. The effects of different nucleic acid backbones that have been generated from prebiotically available monomers, for example, mixtures of tetrose-, pentose-, and hexose nucleotides; mixtures of furanosyl and pyranosyl nucleotides; and mixtures of deoxyribonucleotides and ribonucleotides in the same polymer.

2. The effects of huge numbers of diastereoisomers that have been generated from racemic or scalemic mixtures of monomers, most notably, D-ribonucleotides and L-ribonucleotides, but also from α- and β-anomeric nucleotides in the same polymer.
3. The ultimately required preponderance of 3'-5'-linkages over 2'-5'-linkages in RNA, once the first and second concerns are resolved.

The literature is rich in proposed solutions, but experimentally, much more needs to be done. There are indeed prebiotic pathways that generate, for example, 3'-5'-linkages rather than 2'-5'-linkages in dinucleotides, or separate enantiomeric monomers through spontaneous enantiomorphous crystallization. But it is an entirely different problem to master astronomically huge numbers of isomers in polymers with concepts that are viable for small molecules. To cut a long and sometimes debatable story short, it seems that all these concerns could be solved by the same physically fundamental notion or law of persistence (Pascal and Pross 2015). The concept is convincing; the sloppy version sounds like: Over long time periods, everything lasts as long as something longer-lasting takes over. If not under non-equilibrium conditions and in a world where animate matter has emerged and evolved at astonishing rates, this statement sounds almost trivial. Still, a polymer of the nucleic acid kind will always be susceptible to ever-grinding hydrolysis, besides photolysis, thermolysis, and radiolysis. What transpires from recent experimental works is that, for nucleic acid polymers to persist longer in a plausibly prebiotic environment, the polymer needs to be homogeneously built. It seems that nucleic acid polymers that are not composed of identical repeat units won't last as long. The polymers that are best protected from hydrolysis are those that fold best upon themselves or hybridize best with their complements. However, for template-directed copying of nucleotide strands, the hybridized, that is, the base-paired, parts need to be separated from one another—the more stable the base pair is, the more energy-costly the strand separation becomes. A delicate balance between base-pairing stability and dehybridization effort was possibly a driving force for maintaining both prebiotic DNA and RNA at early stages of biotic evolution (Rajamani et al. 2010; Leu et al. 2011; Chen and Nowak 2012; Kumar 2016). Polymers that do bear the odd foreign monomer, anomer, isomer, and internucleotide linkage can nevertheless be functional to a certain more or less limited degree, but those that have a totally homogenous backbone will persist over the longest time periods. This can be shown by theory, but to unambiguously demonstrate it by systematic experimentation is one of the most tedious works that needs to be carried out and on by chemists (Joshi et al. 2013; Engelhart et al. 2013; Szabat et al. 2016; Gavette et al. 2016).

The third problem class is one of amplification efficiency. How can a system produce relatively huge amounts of DNA or RNA, all having the virtually identical nucleotide sequence to, at first, one single DNA or RNA molecule? Again, it is out of scope of this chapter to discuss this deeply (see Chapters 5.5 and 5.6 and Part VI of this handbook). It is obviously a

dynamical problem: How to copy enzyme-free a nucleotide polymer sequence and thus ultimately generate two identical nucleic acid molecules from one, where now, both mother and daughter molecules are copied again to produce not fewer than four identical molecules, and so forth? This is synonymous to how to obtain an exponential growth of “population” size from a self-copying or else-copied starting molecule. The problem in a real chemical, if not prebiotic, environment is one that is probably best circumscribed by “strand inhibition,” although there is much more to it than just this. Let us ignore here huge amounts of highly challenging scientific work over several decades and state that it has become obvious that the only way to master this problem class is to work far from thermodynamic equilibrium. In other words, spatio-temporal separations must gain crucial importance in future experiments. Reaction conditions must be tested where compound mixtures are periodically furnished with fresh chemical activation energy, monomers, dehydration or coupling agents, and additives and where the reaction products should be more or less rapidly and efficiently separated from the starting molecules (Chapter 6.3, Strazewski 2015b). Regarding the chemistry of enzyme-free nucleic acid copying, amplification, and ultimately gene replication, the best solution thus far was pioneered by Günter von Kiedrowski and collaborators (Luther et al. 1998). The core concept was taken up and modified by Clemens Richert and collaborators, albeit for a different reason than exponential growth rates (Deck et al. 2011). Both explored the immobilization of a first polymer molecule on an insoluble surface (microscale beads), made the immobilized hybridized polymer grow in chain length, provoked the detachment of the products, in order to move away the starting molecules from the daughter molecules, and then cycled the procedure several times. This guarantees for efficient and truly exponential growth in the number of copied molecules of considerable nucleotide length and accessible sequence diversity.

And here comes the “chemical devil” back again: Enzyme-free template-directed DNA or RNA copying has been best achieved with chemical tricks being, at first sight at least, incompatible with a prebiotic scenario. The most helpful trick for growing long chains efficiently was to use synthetic monomers bearing significantly stronger nucleophilic groups than the natural carbohydrate-derived hydroxy groups (Mansy et al. 2008). 3'-Amino-3'-deoxynucleotides react much faster with 5'-activated monomers; the hydrolytic competition in the absence of enzymes won't win under such conditions and copied nucleic acid-like polymers result. But “amino sugars” (aminodeoxysaccharides), irrespective of the nitrogen's position in the carbohydrate other than anomeric, are not the usual outcome of an enzyme-free formose reaction in the presence of ammonia or other amines. The biotic nucleic acids bear phosphodiester—not phosphoramidate—linkages. This difficulty becomes even more apparent in experiments where foreign primary amino groups are present in NMP coupling reactions. When amino acids and NMPs are mixed and a dehydrating water-soluble coupling reagent, plausibly prebiotic or not, starts polymerization reactions, one of the easiest detectable product molecules is indeed a

phosphoramidate, one that results from the rapid capture of an amino acid by a 5'-nucleoside phosphate (Jauker et al. 2015b; Griesser et al. 2017). What happens next is moderately rapid peptide chain growth on an NMP scaffold. *N*-terminal 5'-phosphoramidate-linked peptido-NMPs with impressive peptide lengths are detected. The apparition of peptido-RNA, that is, slow RNA-chain growth, can be detected in strongly diminishing amounts up to five or so nucleotides. It is obvious that, under identical reaction conditions, amino acids condense to peptides much faster than NMPs condense to RNA, irrespective of the 2'/3'-5' homogeneity of internucleotide linkages. One way to slow down amino acid-to-peptide couplings, or, for that matter, reactions with any amines, with respect to NMP-phosphodiester couplings could be to lower the pH down to values where amino groups are abundantly protonated and thus their nucleophilicity suppressed, whereas hydroxy groups would still keep their reactivity. But this does not seem to be a robust prebiotic situation, and other problems, such as solubility and aggregation, would have to be traded off in exchange. Again, we hit the problem of minimal interference of the scientist. Nucleic acid chains can be grown, even in a template-directed manner, up to impressive nucleotide lengths, with sufficient coupling rates for all four biotic *quits* and, when appropriately separated from the products through immobilization, probably with exponential amplification rates. However, these longer oligo- or polynucleotides can only form in the absence of amino groups, such as the amines that were needed to build up the nucleotides from simple bricks (cf. first row in Figure 5.2.3), or the amino acids from prebiotic Strecker reactions. Yet, the most important and never-ending activity of biotic RNA, even while the cells are dividing into two, is to synthesize proteins. Amino acids and nucleotides have been a nice pair ever since Methusalem. So, how do these two loose ends meet? Somehow, the comparably ready-to-couple amino acids must have accumulated under prebiotic and activating (coupling) conditions and grown peptide chains apart from the much slower nucleotides. The need for the compartmentation and isolation of nucleotides and nucleic acids from the environment becomes more and more obvious.

5.2.3 COMPARTMENTATION OF NUCLEIC ACIDS

5.2.3.1 SELF-EVOLVABLE SURFACES

The reaction between a given number of molecules in a given volume of liquid can gain a factor of 1000 or more in catalytic efficiency—regardless of product inhibition and the catalytic turnover numbers—when all the molecules are somehow attached to a minimal surface that holds this volume without decreasing their mobility on that surface (2D mobility). When all these surface-bound molecules are lined up on a string instead, on which they can move only back and forth (1D mobility), the effective molarity could gain another factor 1000. The strongest power of catalysis, that is, the acceleration of a reaction rate $v = k \Pi[\text{educts}]$, is

not necessarily due to the change of the effective reaction rate constant k by increasing $k_{\text{cat}} \gg k$ through an appropriate complexation of a rate-limiting transition state on the reaction pathway. Such complexations, of course, are the usual way in which enzymatic reactions occur. There are also other more refined mechanisms, such as lifting the ground-state energy of the catalyst-substrate complex with respect to the uncomplexed specimens and/or catalyzing the rate-limiting elementary step through vibrational preferences and precise atomic orientation in “near-attack-conformation” complexes (Bruice 2002; Schowen 2003; Hur and Bruice 2003; Sadiq and Coveney 2015). But creating “entropy traps” (Westheimer 1962; Page and Jencks 1971), thus, enhancing the entropic component of the “effective molarity” (Kirby 1980; Mandolini 1986; Chi et al. 1995; Cacciapaglia et al. 2004; Hunter and Anderson 2009; Sinclair et al. 2009) of the starting compounds II[educts] through confinement (Lopez-Fontal et al. 2016, 2018), for example, by their more or less specific concentration on a surface, will do a good job, not negligible at all and plausibly prebiotic too (Strazewski 2009). How deep into biotic systems this effect may reach can be seen in the modern-day ribosomal biosynthesis of proteins by aminoacyl-transfer RNAs. In addition to being severely demobilized in cellular zones of locally ultra-high viscosity *in vivo*, these universal amino acid carriers can, only partly and highly reversibly of course, line up on messenger RNAs, viz. molecular 1D strings, and thus have an enhanced effective molarity. Ribosomes line up on the same messenger RNAs and form polysomes. The prokaryotic *in vivo* translation rate, that is, protein synthesis in terms of numbers of peptide bonds formed per second and ribosome that constantly select their “cognate” anticodons (correct for each codon) from a choice of 40 different comparably large, about 76 nucleotides long slowly diffusing aminoacyl-transfer RNAs, is synchronized with its *in vivo* transcription rate, that is, the chain growth rate of the corresponding messenger RNAs, where the RNA polymerase selects at each template deoxyribonucleotide position the complementary ribonucleotide from a mere choice of four different fast-diffusing NTPs per codon. Most bacteria synthesize that way on the average one peptide bond per synthesis of one codon, or, the other way around, they extend the messenger RNA on the DNA template by about three nucleotides during the time of synthesis of one peptide bond. Both processes, transcription and translation, profit from reducing the dimensionality of at least parts of the starting material, although all cellular single-stranded DNAs (ssDNAs) and much of the messenger RNAs (mRNAs) are floating in the cytoplasm. Polysomes can interact with membrane surfaces and thus concentrate close to the membranes of organelles or the endoplasmic reticulum, where the nascent peptides cross the membrane through the ribosomal nascent peptide tunnel and the ribosome-bound transmembrane proteins and fold into their native conformation on the other side of the membrane. Hence, like for the sepharose or magnetic bead-bound DNA polymers that were immobilized to alleviate strand inhibition (Luther et al. 1998) or inactivated NMP

inhibition (Deck et al. 2011), biotic nature has chosen to synthesize proteins close to and interacting with membrane surfaces. This “choice” could only emerge from self-evolving primitive systems; therefore, it should not astonish if prebiotic nature already has taken advantage of enhancing the effective molarity of nucleotides and explored lipid membranes as self-evolving compartments, not only for isolated polymerization processes (Ross and Deamer 2016) but also to reduce their dimensionality through membrane-bound macromolecular interactions. Today, an estimated 20%–30% of all proteins are membrane proteins.

5.2.3.2 TRAPPING, ANCHORING, AND GROWTH OF NUCLEIC ACIDS IN VESICLES

The question of how RNA could be spontaneously compartmented in lipid vesicles, without designing elaborate chemical scaffolds on purpose, is being approached in three ways. A *rudimentary strategy* has been used by Hanczyc et al. and was deeper explored by David Deamer and collaborators. It consists of beginning with initially premixed lipids and nucleic acids, or their precursor NMPs, which become trapped within vesicles as they form. When pentadecaadenylate A₁₅ was adsorbed to montmorillonite clay particles and added to myristoleate micelles made from Z-tetradec-9-enoic acid at pH 8.5, the covered particles were trapped in the aqueous interior of the resulting giant vesicles and A₁₅ also became compartmented (Hanczyc et al. 2003). Deamer took a step backward and argued that it should be possible to drive phosphodiester bond formation in the absence of activated substrates by producing conditions in which water can be removed from the reactants. Upon hydration of dry lipid films, these amphiphiles draw water molecules away from bulk water to tightly hydrate the polar headgroups of nascent lipid membranes. In addition, Deamer evoked the lamellarity of dry lipid films (Walde 2006) that would produce large numbers of sheet-type surfaces, within which NMPs, when present, would be co-oriented in a liquid crystalline-like fashion and therefore their effective molecularity would be advantageously enhanced for condensation reactions (Rajamani et al. 2008; Olasagasti et al. 2011; Deamer 2012; Black et al. 2013; Mungi and Rajamani 2015). Indeed, long RNA-like polymers were detected when dry phospholipid films were cycled through repeated hydration-evaporation cycles in the presence of NMPs. In a typical reaction, the reactants were exposed to one to seven cycles of wetting and drying. A stream of carbon dioxide or nitrogen gas was used to dry the samples while they were exposed to varying experimental parameters, including temperature (60–90°C), time (30–120 min), lipid composition, and mole ratio of mononucleotide to lipid. After each drying cycle, the samples were dispersed in 1 mM HCl and allowed to rehydrate for 15–20 min. During this time, lipid vesicles reformed and components underwent mixing, and the mixtures were then exposed to a further dehydration cycle. The starting pH was 6.8, and this decreased to 2.2 at the end of seven cycles. Later, other amphiphiles and nucleotide components were explored, and it was shown, for example, that AMP and UMP performed far better than GMP or CMP for solubility reasons and confirmed that the pH needed to be

dangerously acidic for the formation of polymeric chains to be efficient. More detailed later analyses have shown that large parts of the polymers contained, in fact, many “abasic sites,” that is, positions where the nucleobases eliminated off from the polymer due to low pH, and that the chains were polynucleosides rather than polynucleotides (ethers not phosphodiesters). This, of course, sets early limits to a prebiotic lamellar dehydration and orientation-driven RNA synthesis. In any case, nucleotide trapping in nascent lipid vesicles may be effective when possible, but it is a quite crude and unselective process. What is missing in this approach is the evolvability of such a chemical system. *A priori*, there seems nothing particularly evolvable when nucleotides and nucleic acids are being trapped within nascent lipid vesicles, as if by force. The transformation from this first unselective compartmentation and subsequent self-evolvable fundamental “function” of compartmented RNA are not evident at all. Of course, once the DNA and dNTPs or RNA and NTPs are inside with the help of synthetic additives and by directive means, compartmented nucleic acids unfold astonishing properties during growth and division of the phospholipid vesicles (Nourian et al. 2012; Kurihara et al. 2015; Tsuji et al. 2016).

A *discriminatory strategy* is to directly select RNA sequences that bear a significant affinity to lipid membranes, despite the usual lipophobicity of ordinary RNA. Mike Yarus and collaborators impressively demonstrated that it is possible to select *in vitro* from “random pools” RNA molecules that do interact firmly with phospholipid vesicles (Khvorova et al. 1999; Vlassov et al. 2001; Vlassov and Yarus 2002; Janas and Yarus 2003; Vlassov 2005; Janas et al. 2006, 2012). Particular RNA loop structures and lipid membrane defects are important components for RNA-lipid interactions. The best binding RNAs were finicky hetero-trimers, that is, specifically folded RNA that would only anchor to phospholipid membranes when two distinctly different RNAs complexed with one another in a molar 2:1 ratio. Once anchored to membranes, the RNA aggregates oligomerized further, yielding larger, irregular rope-like structures that preferred the edges of altered lipid patches. These properties could be interpreted in terms of RNA-RNA kissing-loop interactions, and the RNA effects on membranes were explained in terms of an RNA preference for irregular lipid conformations. Structure-dependent RNA binding appeared for rafted liquid-ordered domains. Binding to more highly ordered gel-phase membranes was stronger, but much less RNA secondary structure-dependent. All modes of RNA-membrane association seem to be electrostatic and headgroup-directed and require divalent cations. Such unexpected RNA-lipid membrane interactions are fascinating and could have played a role in prebiotic environments, but, usually, these RNAs are so extremely rare that they appear untraceable in random pools of RNA. It seems that nature could profit from the variety of natural RNA pools for a spontaneous compartmentation but only if such RNA could find a way to cross the membranes and get inside.

A *mediator strategy* proposes an acquired further attraction between RNA and lipids, viz. with the help of a mediator compound bearing intermediate properties that will smoothen the mechanism of compartmentation of largely lipophobic

nucleic acids and thus may increase the selectivity for particularly useful RNA, or DNA if present (Bada 2013; Gavette et al. 2016; Kumar 2016), to be compartmented but to a much less restrictive degree than RNA in the absence of the mediator (Vlassov 2005; Strazewski 2007, 2009, 2014, 2015a). For reasons that are described and elaborated in Chapter 6.3, the mediators could be prebiotic lipophilic peptides. Upon addition of chemical activators and amino acids inside lipid vesicles, such peptides are expected to grow in length, variety, and eventually competence of broad catalytic specificities (Jensen 1976; Szilágyi et al. 2012). One such catalysis could be the acceleration of the PT reaction between aminoacyl-RNA and peptidyl-RNA, taking place in a lipid bilayer, that is, being anchored to the surface from the inside of lipid vesicles. The other vital catalysis is a template-dependent RNA polymerization reaction. This approach should allow for the evolution of translation and, from there, to protein-assisted RNA or DNA replication. This hypothesis is testable. First experimental examinations have been carried out and published. We found that a hydrophobic peptide served as an efficient anchoring device for a lipophobic RNA hairpin. Just how well the lipophilicity of this peptide compensated for the lipophobicity of the RNA was an unexpected outcome of this study (Le Chevalier Isaad et al. 2014; Strazewski 2015a).

5.2.4 SUMMARY

In this chapter, the transdisciplinary field of astrobiology focuses on the organic chemist’s crucial role in finding answers to questions about the origin of life through scientific experimentation on a molecular level. Organic chemistry has a particular responsibility, because it operates very close to the animated, living state of matter. A characteristic feature of all known life-forms is the ability to maintain a systemic memory in the *gestalt* of nucleic acids throughout successive generations. The principles of replication and translation are analyzed for more general cases than what is known from biology. Another characteristic feature of life is its cellular, compartmented composition. The requirement for the spontaneous compartmentation of nucleic acids is discussed. The most important molecules that are needed for a spontaneous and plausibly prebiotic assembly of nucleosides, nucleotides, and nucleic acids are presented, with a special focus on ribonucleosides and RNA. Experimental results from the past 10 years are discussed in greater detail. The chapter ends with an overview on the kinetic effect of reduced dimensionality and a short update on the spontaneous and plausibly prebiotic interactions of nucleotides and nucleic acids with lipid vesicles.

ACKNOWLEDGMENTS

I thank Michele Fiore (Lyon) for his enthusiasm in finding literature references that were destined for other articles but have found their way into this chapter. I thank my wife Marzena for her patience and smiling attitude, even though we still do not understand how I could invest so many months in writing without being paid for it.

5.3.1 INTRODUCTION

Impact cratering was the primal force in the early history of our planet, before the onset of plate tectonics. It has shaped the surface architecture, composition, and rheology of the lithosphere and enhanced the emergence of life. The explorations of the Earth, Moon, Mercury, and Mars allow reasonable inferences about the physical conditions of prebiotic Earth. During the Hadean and early Archean Eons, impacts and collisions were the dominant geodynamic processes that played a

key role in the crustal, tectonic, thermal, magmatic, and environmental evolutions of young Earth. For its first half-billion years, the Hadean Earth was violent and desolate, enduring the punishing rain of extraterrestrial impacts, which scorched the globe and widely reprocessed the crustal surface through mixing and burial by impact-generated melt (Marchi et al. 2014). It was a hot molten globe with an atmosphere filled with water vapor, carbon dioxide, nitrogen, hydrogen sulfide, sulfur dioxide, and other noxious gases. This first stage of Earth's history included the initial accretion, core/mantle

differentiation, the development of a magma ocean, and an undifferentiated mafic crust (Hawkesworth et al. 2016).

Following the Hadean, the second stage in Earth's evolution occurred during the Eoarchean Eon in a pre-plate tectonic regime (Tang et al. 2016). It was marked by elevated mantle temperatures compared to the present day, which resulted in a lithosphere weakened by the emplacement of melts. This inhibited subduction and hence plate tectonics, and magmatism was driven by impact-induced mantle upwellings that percolated the lithosphere. The crust was at least 15–20 km thick during this period; remelting could take place by meteorite impact, and the resultant magmas represented the high silica component that characterizes the Archean crust (Grieve et al. 2006; Hawkesworth et al. 2016). Although few grains of detrital zircons from the Jack Hills of western Australia are known to be Hadean (~4.4 Ga) (Harrison et al. 2008; Wilde et al. 2001), the oldest rock formations exposed on the surface of the Earth are exclusively Archean. It is in the Archean that the first earthly ecosystems are found, with their clues to life's earliest days on the planet.

During the Eoarchean (~4 Ga), the pummeling continued, but the Earth became more tranquil, as the frequency of impacts slowed down. Earth cooled, clouds formed, and torrential rain submerged the lowlands to form global oceans, and as the crust began to harden, it was followed by erosion and sediment recycling. Shortly after Earth began to cool, the planet's first outer layer, the lithosphere, was a single, solid, deformable shell, lacking any plate tectonic activity (Stern 2005; Tang et al. 2016). It was a one-plate world. The Archean Eon witnessed the production of early continental crust and global oceans, the emergence of life, and fundamental changes to the atmosphere. Around 4 billion years ago, the primordial oceans covered more than 95% of the Earth's surface surrounding the emerging protocontinents (Mojzsis and Harrison 2000). The focus of this study is to determine the likely site of life's beginnings on young Earth—the crucible of life—and to reconstruct its environment during the Eoarchean to Paleoarchean Eons (~4–3.2 Ga).

The early terrestrial planets and moons in the inner solar system experienced a cataclysm known as the Late Heavy Bombardment (LHB), about ~4.1–3.8 Ga, when a disproportionately large number of asteroids collided and crashed onto these rocky planets. The early Earth was bombarded by projectiles at the same time that large impact basins were forming on the Moon and Mercury. Earth, being a bigger target with a stronger gravitational pull, would have suffered hundreds of blows from terrestrial objects of that size. Although these early craters on Earth are no longer visible, the Earth was actually rocked by 15–20 times more impacts than our Moon! (Kring 2000; Marchi et al. 2014). The impacting objects were mostly asteroids from the asteroid belt located between the orbits of Mars and Jupiter. Comets that reside in a huge cloud at the outer reaches of the solar system appear to have comprised a small fraction of the projectiles. Impact events on the Eoarchean crust may have produced thousands of craters on early Earth, resembling the surfaces of the Moon and Mercury. But unlike our planetary neighbors, the crater

basins on early Earth were filled with water and cosmic building blocks, and there developed a complex system of subsurface hydrothermal vents that were the fundamental crucibles that led to the origin of life.

Impacts on a water-rich planet such as Earth or even Mars can generate hydrothermal activity—specifically, underwater areas boiling with heat and spewing chemicals. Over 20,000 hydrothermal crater lakes (with diameters ranging from 5 km to >1000 km) dotted the Eoarchean crust, inadvertently becoming the perfect crucibles for the prebiotic chemistry of early life (Chatterjee 2015, 2016, in press; Cockell 2006; Kring 2000; Marchi et al. 2014; Osiniski et al. 2013). Unlike the Moon and Mercury, physical evidence of Earth's early bombardments has been erased by weathering and plate tectonics over the eons.

Large meteorite impacts trigger widespread catastrophe, killing life on a global scale; this happened during the extinction of the dinosaurs 66 million years ago at the Cretaceous-Paleogene boundary (Alvarez et al. 1980). But contradistinct, comets and asteroids—the very objects impacting the inner planets and moons—contain the building blocks of life (Chyba and Sagan 1992). These impacts delivered the cosmic, organic compounds to Earth and were very likely a boon to early life on the planet: instead of wiping it out or preventing it from originating, they may have helped kick-start life. Like the cosmic dance of *Shiva*, impacts not only deliver death but also foster life. Perhaps, the bulk of the organic molecules necessary for life's origins was brought by meteorite impacts on the young Earth. Similarly, impacts may have created vast underground habitats. Impact-generated crater lakes on the Eoarchean crust may have created novel and protective habitats from meteoritic assaults, where the building blocks of life could be concentrated, integrated, selected, encapsulated, polymerized, and organized into successively more complex and information-rich molecules through symbiosis, leading to the emergence of the first cells. These crater lakes may have provided protective sanctuaries for the emerging thermophiles during the ongoing bombardments (Chatterjee 2015, 2016; Cockell 2006; Cockell and Lee 2002; Osiniski et al. 2013).

The continuous impacts of meteorites, and their cosmic composition, strongly support the conclusions that the building blocks began to accumulate in the oceans and the lakes, where the hydrothermal energy could drive the synthesis of ever more complex organic compounds. This period of LHB overlaps with the evidence of the earliest life on Earth, thus hinting at some causal connection between impacts and the origin of life. It's becoming apparent in recent years that most of the biosphere was brought to the primitive Earth by an intense bombardment of meteorites (Delsemme 1998). This included atmosphere, hydrosphere, and those volatile carbon compounds needed for the emergence of life. Prebiotic molecules, delivered by the meteorites, would have provided the "seed" for the origin of the Earth's first life.

The Eoarchean crust is the most valuable archive for unravelling the mystery of the origin of life. A symbiotic view of the geochemical origin of life has been presented in previous publications (Chatterjee 2015, 2016, in press). In this view, life arose through five hierarchical stages of increasing molecular

complexity: cosmic, geologic, chemical, information, and biological. The main thrust of this article is to elaborate the first two stages—cosmic and geologic—determining the role of impacts for biogenesis and exploring the likely site of life's origin on young Earth.

5.3.2 DELIVERY OF THE BUILDING BLOCKS OF LIFE

Biological evolution was preceded by a long phase of geochemical evolution, during which the precursors of life molecules accumulated on young Earth and began to interact. One of the intriguing questions associated with the origin of life is related to the original source of these chemical building blocks: Were they created by chemical reactions of primordial atmospheric and crustal ingredients on the young Earth, or did they, perhaps, hitch a ride on meteorites that germinated our and other planets in our solar system with the same biomolecules? Many terrestrial formation models suggest Earth would have formed extremely poor volatiles and was deficient in the organic compounds necessary for life synthesis (Delsemme 2001). Surprisingly, the chemical makeup of life is much closer to the chemistry of meteorites and stardust than it is to that of our rocky planet during this early history. Comets and carbonaceous asteroids are rich in organic molecules, which are required for the emergence of life on early Earth. Recent research in space exploration and astrobiology provides strong evidence that meteorite impacts may have sparked life on early Earth. Life's biochemical building blocks can form in the freezing, harsh, zero-gravity environment of deep space, bolstering the odds that meteorite strikes triggered life (Bernstein et al. 1999; Chatterjee 2016; Chyba and Sagan 1992; Cockell 2006; Deamer et al. 2002; Kring 2000; Osinski et al. 2013). Unlike space, the early Earth's high gravity and hot temperature were not conducive to create these building blocks.

One of the most exciting possible sources of these raw materials may have been the asteroids and comets that bombarded Earth during its first billion years. Consequently, while life itself likely arose on Earth, the building blocks of life may well have had an extraterrestrial origin. Perhaps, the important raw material needed to build life came from space and was delivered by meteorites. Many of these complex biomolecules such as lipid membranes, amino acids, nucleotides, phosphorous, and sugars have been detected in meteorites (Bernstein et al. 1999). Moreover, these building blocks of life are abundant in interstellar space. The astrobiological origin of these building blocks occurred in an unusual interstellar, freezing, zero-gravity environment during the explosion of a nearby star (Boss and Keiser 2010). Complex organic molecules, precursors to life, have been detected everywhere in space, in comets, in carbonaceous asteroids, and in interstellar dust. The NASA STARDUST mission detected these building blocks in interstellar dust particles (Materese et al. 2013).

In interstellar space, far from the Sun, temperatures are freezing, leading to abundant ice and other frozen gases such

as methane, ammonia, carbon dioxide, carbon monoxide, and even ethyl alcohol. Through the heavy meteorite bombardment, the volatiles on Earth arrived from this distant reservoir in the outer solar system. New experiments simulating conditions in deep space reveal that the complex building blocks could have been created in icy interplanetary dust and then carried to Earth, jump-starting life. Interstellar ice simulation experiments at the NASA Ames Research Center in a cryogenic laboratory at 40 K (-233°C) have shown that the ultraviolet (UV) radiation processing of presolar ices leads to more complex organic compounds. All the major building blocks of life, including ribose and related sugars, were synthesized via irradiation of interstellar ice analogs (silicate minerals coated with simple molecules such as H_2O , CO , CO_2 , NH_3 , and CH_3OH) (Deamer et al. 2002; Meinert et al. 2016; Sandford et al. 2014). Ribose is the central molecular subunit of RNA, and its prebiotic origin in interstellar environments is significant. These experimental findings support the identification of organic molecules in comet samples taken in situ by the Philae Lander part of the cometary Rosetta Mission (Meierhenrich 2015). In another laboratory simulation of interstellar ices, the building blocks of comets, that is, a frozen mixture of water, methanol, ammonia, and carbon monoxide, were subjected to UV radiation (Dworkin et al. 2001). This combination yielded organic compounds that formed bubbles when immersed in water. These bubbles are reminiscent of cell membranes that enclose and concentrate the chemistry of life, separating it from the outside world. Many of the organic compounds formed in these experiments are also present in meteorites, cometary and asteroidal dusts, some of which are necessary to the origin of life. These experiments suggest that the building blocks of life may have begun in a rather unusual freezing environment of interstellar space during the planetary formation and that they were delivered to early Earth in the suitable environments provided by meteorites. In space, when atoms are locked in ice, this bond-breaking process can make molecular fragments recombine into unusually complex structures, which would not be possible if these fragments were free to drift apart. Everywhere in space, complex organic compounds are forming on these ice grains, especially in UV-rich regions around young suns (Bernstein et al. 1999). Much of the organic compounds found on early Earth had an interstellar heritage. Carbon-based compounds are being synthesized everywhere in the Milky Way, including diffuse interstellar clouds, giant molecular clouds, and protoplanetary disks, in which new solar systems are formed. Meteorites and interstellar dusts provide a record of the chemical processes that occurred before life began on Earth; they are like manna from heaven, triggering and accelerating biosynthesis on Earth. Most of the material of biospheres—as our bodies—is stardust, a gift from the meteorites.

There is a paradigm shift in the origin of life research from the Miller-type experiment that demonstrated that several organic compounds could be formed spontaneously by simulating the condition of Earth's early atmosphere (Miller 1953) to cosmic building blocks. Experiments by NASA suggest that the building blocks of life originated in an unusual,

extreme environment of cold temperature in an interstellar medium with very low density, which was missing in early Earth. This may explain why the Miller-type experiment in laboratory failed to produce similar diverse arrays of building blocks. Finding these biomolecules in an interstellar gas cloud means that important building blocks of life such as membrane-forming molecules, amino acids, nucleobases, sugars, phosphorous, and other organic compounds—the crucial components of cells—were seeded on the primordial Earth via carbonaceous chondrites, comets, and interstellar dusts (Bernstein et al. 1999; Chyba and Sagan 1992). These prebiotic organic compounds were delivered to early Earth by the impacting meteorites that contained the building blocks of life. Moreover, cosmic dusts or micrometeorites (<2 mm) delivered some of these biomolecules to early Earth. They contain organic compounds—such as polycyclic aromatic hydrocarbons, aliphatic chains, and amino acids—some of which were used by life synthesis. They represent the largest mass flux of extraterrestrial material (30,000 tons per year), raining down on Earth daily, carpeting the land and water surface with fine dust (Motrajit et al. 2006). Though these building blocks from space were also delivered to other planets in the solar system, our Goldilocks planet appears to have been the only habitable environment, ready to jump-start biosynthesis.

Carbonaceous chondrites, comets, and micrometeorites in interstellar clouds are extremely rich in the biogenic compounds, those volatile elements like carbon and nitrogen that are essential to organic life. Carbonaceous chondrites are primitive stony asteroids that contain a rich diversity of organic molecules, including those relevant to biogenesis, such as sugars, carboxylic acids, aldehydes, ketones, nucleobases, amino acids, and membrane-forming lipids (Deamer 2011). These asteroids experienced liquid water for the first 10,000 years of their history, during which time their amino acids were synthesized. Yet, there is no evidence for peptides or nucleic acids in these asteroids, and in general, it appears that prebiotic synthesis in these objects did not proceed beyond monomers. In complete contrast, starting with these cosmic monomers, prebiotic chemistry proceeded much further on Earth, leading first to polymers and then to the first cells. Can these molecules survive the catastrophic impacts during the collision with Earth? Obviously, they did. Carbonaceous chondrites collected across the planet still, to this day, contain those essential building blocks, clearly demonstrating that the hitchhiking organic molecules withstood the extreme pressures and temperatures of fiery crashes onto Earth's surface; they remained intact and survived despite the tremendous shock wave and other violent conditions (Callahan et al. 2011).

Among the most celebrated carbonaceous chondrites is the Murchison meteorite that fell to Earth near Murchison, Victoria, in Australia in 1969. Some of the building blocks detected in the Murchison meteorite are essential components of living cells. These include pyrimidine and purine nucleobases, sugars, and phosphates for making nucleic acids, amino acids, and peptides for synthesizing proteins, membrane-forming compounds such as long-chain monocarboxylic

acids, and carbohydrates (Callahan et al. 2011; Damer and Deamer 2015; Deamer 2011; Pizzarello and Cronin 2000). Carbonaceous chondrites recovered from Antarctica contain numerous indigenous organic compounds, nucleobases, and amino acids (Burton et al. 2013). Carbon-rich asteroids may have been important sources for the organic compounds required for the emergence of life. Impacts may have increased the diversity of complex prebiotic chemical species through shock metamorphism. The carbonaceous asteroids were important contributors to life's building blocks on early Earth (Bernstein et al. 1999; Chyba and Sagan 1992).

Unlike asteroids, comets are cosmic snowballs of frozen gases, rock, and dust. Like asteroids, they are leftovers from the dawn of the solar system around 4.6 billion years ago and consist mostly of ice coated with dark organic matter. The study of the chemical composition of comets provides key information about the raw materials of organic compounds present in interstellar space, which are of prebiotic interest. Comets contain prodigious quantities of organic compounds, including amino acids, adenine, ketones, quinones, carboxylic acids, hydrogen cyanide, polycyclic amino aromatic hydrocarbons, thioformaldehyde, acetaldehyde, sugars, cyanogens, cyanide, methanol, and ethanol (Bernstein et al. 1999). HCN is a key molecule in the prebiotic synthesis of amino acids, nucleobases, and sugars. The numerous complex organic molecules such as ethyl alcohol and sugar have been detected in comet C/2014 Q2 (Lovejoy) (Biver et al. 2015). Recently, the Rosetta mission of the European Space Agency (ESA) craft Philae Lander already has detected water and organic molecules on the surface of 67P/Churyumov–Gerasimenko, a 4-km-wide comet; this may shed new light on the composition of Earth's building blocks (Goesmann et al. 2015). Sixteen organic compounds were identified, divided into six classes of organic molecules (alcohols, carbonyls, amines, nitriles, amides, and isocyanates). Of these, four organic compounds were detected for the first time on a comet (methyl isocyanates, acetone, propionaldehyde, and acetamide). The presence of complex organic compounds in comets and asteroids implies that the early solar system fostered the formation of prebiotic material in noticeable concentrations. There is thus ample evidence that a number of biogenic compounds can form spontaneously in interstellar space and on comets and carbonaceous asteroids. Hence, the origin of life as an extraordinary event is the product of two worlds: interstellar space and Earth. The building blocks of life came from interstellar space via meteorites (exogenous delivery), but first life was synthesized and evolved in the womb of our planet (endogenous production) (Chyba and Sagan 1992).

Meteorites were much more numerous in the LHB period, about ~4.1–3.8 Ga, than they are today, and they were correspondingly more likely to collide with early Earth. These collisions would have seeded our planet with organic compounds from the very beginning. Organic compounds are also found in interplanetary dust particles, which still rain down on Earth. Meteorite impacts played two distinct roles in biogenesis: the delivery of key ingredients of life and the

creation of hydrothermal impact crater lakes for prebiotic synthesis (Chatterjee 2015, 2016; Chyba and Sagan 1992; Cockell 2006; Kring 2000; Osiniski et al. 2013). These post-impact crater lakes became the incubators for biogenesis and early life.

Large impacts created tremendous shock waves and other violent conditions, causing volcanic activity in a water-rich geological system on early Earth environments and vaporizing oceans as they hit (Sleep et al. 1989; Zahnle et al. 2007). Smaller ones would have survived the impact, bringing with them prebiotic molecules. Comets would have been ideal packages for delivering terrestrial volatiles, including some important precursors for prebiotic synthesis. Because of the icy cushion of comets, the building blocks of life would have remained intact upon impact, while others fused with other chemicals to form more complex organic compounds (Delsemme 2001). There might well have been multiple delivery systems of organic compounds over the millions of years of the Eoarchean—by comets, asteroids, and interstellar dusts. These cosmic ingredients were then mixed with various biomolecules produced in the hydrothermal crater basin to form the primordial soup (Chyba and Sagan 1992; Damer and Deamer 2015). The initial stages in the origin of life required a continuous source of organic molecules, both cosmic and terrestrial, to act as precursors to the biopolymers (Deamer 2011). Today, a constant rain of interplanetary dust particles delivers the same kind of organic compounds that might have contributed to the formation of the primordial soup on early Earth (Delsemme 1998, 2001).

It is fascinating to consider that most of the building blocks that led to the first life on Earth may well have been of extraterrestrial origin. Most likely, such cosmic biomolecules provided the crucial ingredients of life, but the “cooking” was done entirely in the hot crucibles on early Earth. Of these myriads of cosmic ingredients percolating in the prebiotic soup, a few organic compounds would be selected through the hydrothermal vents for making more complex biomolecules and polymers, leading to the assembly of cell components; the rest would be discarded. The picture that emerges suggests that most of the molecular components we see in living cells were available in prebiotic conditions. Slowly, over millions of years, organized systems of contained reactions have gained the ability to grow and may self-replicate. Life began when a system of encapsulated polymers initiated symbiosis and was then able to capture energy and nutrients from the environment and use that energy to grow and reproduce (Chatterjee 2016; Deamer 2011). Life arose rapidly during the early Eoarchean Eon, in the narrow window of some 100 million years.

5.3.3 LIQUID WATER FROM STONE: THE MOLECULE OF LIFE

Liquid water is essential for the kind of delicate chemistry that makes life possible. A bacterial cell is 70% water by weight, which serves as life’s solvent. Liquid water is a

universal solvent, a mediator of life’s chemical reactions for transporting and mixing organic molecules. Water provides the matrix and universal medium for life. Water is a small, highly polar molecule. As a result, it is the ideal solvent for the chemistries of life—dissolving many molecules and transporting them to reaction sites, while preserving their integrity. Ice or water vapor will not accomplish the same function. Ice is fairly common in the universe, found everywhere, from vast interstellar clouds to many planets and moons. In contrast, liquid water is rare in the universe. Thus, the origin of life hinges greatly around the source and availability of water on the early Earth. Water is kept in the liquid form on Earth by the precise combination of atmospheric pressure and internal heat. From the geologic record, it appears that Earth was a watery planet about 4 billion years ago, or even earlier (Mojzsis et al. 2001).

Astronomers know that interstellar water is abundantly available to young planetary systems, and our young Earth collected plenty of it. Despite the abundance of water on Earth, there is a great deal of controversy about the origin of water on our planet: whether water was present at the formation of the planet through the degassing of volcanoes, or whether it arrived later, perhaps by asteroids or comets. The composition of the ocean offers some clues to its origin. Evidence is mounting that the planet’s water arrived early during the LHB, or even earlier, aboard meteorites. Delsemme (2001) championed the view that water was brought to primitive Earth by an intense bombardment of comets. New analysis of the isotopic ratio of hydrogen of the carbonaceous chondrites suggests that the water did not originate in the comets in the outer solar system, but in asteroid belts, between Mars and Jupiter. The deuterium-to-hydrogen (D/H) ratio in ocean water, approximately 150 ppm, is similar to the average of carbonaceous chondrites, which suggests that the principal sources of water might be delivered by carbonaceous chondrite-like sources, not from icy comets (Sarafian et al. 2014). Water vapor streaming off the comet contains a higher percent of deuterium than what the water on Earth has (Alexander et al. 2012). Most likely, carbonaceous asteroids were the dominant sources of Earth’s volatiles, as well as the preferred vehicle for the arrival of water on early Earth. This view of an asteroidal origin of water has been reinforced by the recent study of the D/H ratio of the comet 67P/Churyumov-Gerasimenko, which negates the cometary origin of water on Earth (Altweig et al. 2014).

5.3.4 PALEOECOLOGY OF LIFE’S BEGINNINGS: CLUES FROM HYPERTHERMOPHILIC MICROBES

The geologic site of life’s beginnings is one of the key tenets to discovering where and how life originated. The habitats of hyperthermophiles (superheat-loving microbes), which are the most primitive living organisms, may shed new light on the oldest ecosystems on our planet—the crucible of life. Discovered in 1977, submarine hydrothermal vents astounded many scientists when it was discovered that the

hyperthermophilic bacteria and archaea thrive in these deep, dark, anaerobic, hostile, and volcanic environments. They developed the unusual ability to utilize the chemical nutrients that rise from the hot vent fluids interfacing with cooler seawater as a source of energy (McCollom and Shock 1997). Today, hyperthermophiles are found in geothermally heated subterranean rocks such as the boiling hot springs of the Yellowstone National Park, hydrothermal impact crater lakes, and submarine hydrothermal vents along the mid-ocean ridge. They grow optimally above 80°C and exhibit an upper temperature border of growth up to 113°C. Hyperthermophiles have certain heat-stable enzymes (that are very important in biotechnology) and unusual rigid membranes that are specially geared to working in high temperatures. Based on their growth requirements, hyperthermophiles were probably the most primitive living organisms that could have existed on early Earth about 4 billion years ago (Stetter 2006).

Because of their antiquity, hyperthermophiles may provide clue to the paleoecology and ancestry of life's beginnings. Darwin's doctrine of common descent proclaims that all life on Earth arose from a common ancestor, which is the central pillar of modern evolutionary biology (Darwin 1859). Trace back the separate lines of descent of all organisms that ever lived, and they will converge to a single point of origin—the beginning of life. Nothing concrete could be said about the nature of this ancestor initially, but it was intuitively assumed to be simple, bacteria-like organism.

Molecular phylogeny provides compelling evidence for Darwin's theory of universal common ancestor. Based on the pioneering work of Carl Woese, the conserved molecule such as 16S ribosomal RNA (rRNA) is widely used as a powerful tool for determining microbial relationships (Woese 1987, 1994; Woese et al. 1990); molecular phylogeny suggests that all living organisms cluster into three domains—bacteria, archaea, and the eukarya within the “universal tree.” Moreover, these domains are descended from a single ancestral form, the last universal common ancestor (LUCA). This venerable ancestor was a single-cell, possibly a hyperthermophilic, microbe and is estimated to have lived some 4 billion years ago. The deepest and shortest phylogenetic branches are represented by Aquificales and Thermotogales within the bacteria and the Nanoarchaeota, Pyrodictiaceae, and Methanopyraceae within the archaea (Stetter 2006). At present, about 90 species of hyperthermophilic bacteria and archaea are known, which had been isolated from different terrestrial and marine thermal areas of the world. The LUCA is genetically closest to the base of the tree of life. The roots of the 16S rRNA tree in the domains of bacteria and Archaea are all populated by hyperthermophiles, suggesting that the emergence of life may have occurred in hydrothermal systems. If so, examining the environment and geochemistry of hydrothermal systems should provide a glimpse of the oldest ecology of our planet.

Hyperthermophiles are now regarded as the most “slowly evolving” of all extant life, the first to have diverged from the LUCA. New studies suggest that the LUCA itself was a hyperthermophilic chemoautotroph (Akanuma et al. 2013; Ciccarelli

et al. 2006; Gaucher et al. 2003, 2008; Weiss et al. 2016). This view is supported by recent analyses of resurrected proteins that predicted the hyperthermophilic adaptation of the LUCA, favoring the view that hydrothermal systems may have been the crucible of life for early biosphere evolution (Gaucher et al. 2003; Nisbet and Sleep 2001; Pace 1997; Theobald 2010). The LUCA's genes pointed to an organism that lived in deep, hot, oxygen-free, mineral-rich hydrothermal vent environments. The distribution of hyperthermophiles at the roots of the tree suggests that hydrothermal systems may have been the site for life's beginnings. Most evidence suggests that the LUCA stored genetic information by using DNA, built proteins, and used ATP as its currency for energy. The LUCA was a single-cell microbe with a few hundred genes that fed on hydrogen gas and lived in a world devoid of oxygen, bolstering strong suspicions that early life on Earth may have evolved under hyperthermophilic conditions in and around hydrothermal vents.

Current theories on the possible geologic sites for biogenesis range from frozen oceans (Bada and Lazcano 2002) to various hydrothermal systems, including tidal pools and hot springs (Deamer 2011), hydrothermal impact crater lakes (Chatterjee 2016; Cockell 2006; Osinski et al. 2013), and submarine hydrothermal vents (Baross and Hoffman 1985; Martin and Russell 2007; Wachterhäuser 1993), to name a few. However, hydrothermal vents stand out among the possible environments for life's origin, holding particular promise for understanding the transition from geochemistry to biochemistry.

Several environmental and geochemical features of early Earth favor the supposition that hydrothermal vents were the likely site for life's beginnings—the long-sought incubators. These include the following: (1) the hyperthermophiles, the most primitive organisms known, which presently inhabit such environments, are phylogenetically close to the LUCA (Gaucher et al. 2003, 2008); (2) subterranean hydrothermal vents were likely the only protected environment that would have shielded prebiotic synthesis and early life from large asteroid impacts, which vaporized the ocean's surface and annihilated the ecosystems (Sleep et al. 1989); (3) hydrothermal vents harbor reactive geochemical environments with far-from-equilibrium conditions, being rich in gradients of redox, pH, and temperature, and facilitate prebiotic synthesis (Sousa et al. 2013); (4) the paleoenvironment of early Earth was extremely hot, battered by meteorites that could trigger hydrothermal systems (Marchi et al. 2014); the obvious implication is that the first life evolved in our planet under hyperthermophilic conditions, presumably when the Earth was much hotter than it is at present; (5) mixing of hydrothermal fluids and water at the basin floor combines with slow reaction kinetics for oxidation/reduction reactions, providing a chemosynthetic source for metabolic energy and ATP for hyperthermophiles (Holm 1972); and (6) the earliest fossil evidence supports a hot start to the origin of life. The paleoenvironment of the oldest sedimentary rocks containing evidence of early life (~4 Ga) suggests that hydrothermal settings may have hosted the hyperthermophilic microbes, the oldest

life-forms (Dodd et al. 2017; Furnes et al. 2004; Hofmann 2011; Nisbet and Sleep 2001).

Once hyperthermophilic life emerged, it adapted to increasingly cooler environments, as represented in the fossil records, leading to thermophilic anoxygenic photosynthetic bacteria and finally to mesophilic cyanobacteria near the surface of the water in the 10°C–40°C temperature range, where the abundant free energy of sunlight could be directly harvested.

5.3.5 EVOLUTION OF THE EOARCHEAN CONTINENTAL CRUST

Today, the high-standing continental crust covers nearly a third of the Earth's surface. It is buoyant—being less dense than the crust under the surrounding oceans; this explains why most of the continents are not submerged. The origin of the Eoarchean continental crust is one of the key objectives to understanding the provenance of life's origin. There is little consensus with regard to processes by which Archean continental cratons formed, but the impact model can provide insight and a viable mechanism into how and when it was formed.

Proterozoic continental crust grew mainly along subduction zones, when one tectonic plate subducts beneath another into the Earth's mantle and causes magma to rise to the surface. Recent study suggests that plate tectonics began during Mesoarchean through the Neoarchean time, as indicated by a drastic change of crustal composition. The Archean crust evolved from a highly mafic bulk composition before ~3 Ga to a felsic bulk composition by 2.5 Ga. This upper-crust transition from mafic to felsic marks the onset of plate tectonics at ~3 Ga (Stern 2005; Tang et al. 2016). With the onset of Proterozoic Eon (~2.5 Ga), the crust had already assumed much of its present makeup, and modern plate tectonic cycling began. Sizable later additions to the continental crust occurred throughout the Proterozoic.

However, there was no plate tectonic regime during the early Archean time; Earth was a one-plate planet. In the Eoarchean Eon, Earth's first stable continents did not form by subduction or plate tectonics. At that time, the oceanic crust was hotter, thicker, and more buoyant and was unable to be subducted. On the other hand, the profound change in crustal composition of the continental crust 4 billion years ago appears to be linked to a novel kind of tectonic regime. In the absence of plate tectonics, we need an alternative geodynamic model to explain the origin of the Eoarchean continental crust.

The origin of the Earth's fundamental crustal dichotomy of low-density continental and high-density oceanic crust before the onset of plate tectonics remains obscure. However, cratering was still a very significant mechanism of crustal modification during the LHB (Marchi et al. 2014). Impact cratering was the major geodynamic force during the Eoarchean and Paleoarchean times that must have created small clusters of granitic protocontinents by mantle upwelling (Glikson 2010; Grieve et al. 2006). These protocontinents were like small

islands surrounded by vast oceans. It has become widely recognized that impact cratering is a ubiquitous geological process that affects all planetary bodies with solid surfaces (Kring 2000; Melosh 1989). The surface of the Moon attests to the importance of large-scale impacts in its crustal evolution. Studies of these craters indicate the largest and most violent among them were produced during the Eoarchean. Archean cratons consist of crustal granite-greenstone terrains. It is evident that if an LHB occurred on the Moon, the Earth must have been subjected to an impact flux at least as intense as that recorded on the Moon. So far, no unequivocal record of LHB on the early Earth has been found because of recycling and resurfacing of Archean crust by erosion and plate tectonics, but inferences of contemporary impact cratering events from the records of the Moon and Mercury are strong and convincing. Impactors that bombarded the Earth, Moon, and Mercury during the LHB were dominated by asteroids. The oldest known impact structure from the Archean is the Maniitsoq crater (~3 Ga) of the greenstone belt in West Greenland (Garde et al. 2012). Most impact structures are known from the Paleoproterozoic, such as the Suavjärvi crater in Russia (~2.4 Ga), the Vredefort dome (~2 Ga) of South Africa, and the Sudbury basin (~1.8 Ga) of Canada (Cockell and Lee 2002).

Bolide impact events were both larger and more frequent during the LHB than they are today. The terrestrial effect of the LHB lasted through the Archean Eon. The bolide impact hypothesis for the origin of Archean cratons requires a large bolide to pierce the thin Archean lithosphere and cause massive melting in the sublithospheric mantle (Hansen 2015). Grieve et al. (2006) calculated that early large impact events could lead to the formation of a felsic crust on the early Earth to form protocontinents. They found that on Earth, impact melt volumes exceed transient crater diameters greater than 500 km. The bolide, which penetrates the crust, also triggers a mantle response that, in turn, affects the surface, creating a plume. The impact would create massive partial melting of the sublithospheric mantle, at which point the region of excavated and thinned felsic crust shortens and thickens to form protocontinents (Hansen 2007, 2015). Thus, the initial basaltic Hadean crust would have reprocessed to produce pockets of felsic crust by crustal fractionation in the early Archean time through the impacting process.

Eoarchean rocks are known from the oldest granite gneisses, called the greenstone belts, including the Nuvvuagittuq craton of Canada, the Isua craton of Greenland, the Kaapvaal craton in South Africa, and the Pilbara craton in Australia. They are composed of volcanic and hydrothermal sedimentary rocks intruded by granitoids. Archean cratons represent the remnants and relics of the highly eroded giant Archean hydrothermal crater lakes, as the cross-section morphology of the greenstone belts suggests (Chatterjee 2015, 2016). In these basins, the oldest fossils of hyperthermophilic life have been detected in the hydrothermal chert beds in the younger sequences. These four major Eoarchean greenstone belts were the nuclei of the emerging protocontinents and are valuable archives for understanding the paleoecology of the

earliest life. Of these, the Nuvvuagittuq craton of Canada and the Isua craton of Greenland were located in the northern hemisphere and were proximate geographically, if not sutured together. Similarly, the Kaapvaal craton of South Africa and the Pilbara craton in Australia were positioned in the southern hemisphere and would be clustered into one supercontinent Vaalbara (Zegers et al. 1998). General similarities and correlation of the greenstone rocks between the Kaapvaal craton and the Pilbara craton by using various constraints such as lithostratigraphy, geochronology, structures, paleomagnetism, impact ejecta layers, and microfossils suggest that they were once part of a larger Vaalbara supercontinent as far back as 3.6 Ga. In Vaalbara, the Pilbara craton is juxtaposed next to the southwestern margin of the present-day Kaapvaal craton.

The greenstone gneisses were a product of the deformation of the original granitic rock, combined with layered intrusions, and provide a rare and useful reference model for early Eoarchean history. They represent the relics of the felsic protocontinents. Sediments in early Archean greenstones are largely cherts and volcanic sediments erupted in shallow water in hydrothermal vent settings (De Wit and Ashwal 1997). The newly formed crust of the greenstone belts of young Earth was presumably saturated with thousands of impact craters resembling the surfaces of the Moon and Mercury. The pockmarked surfaces of the Eoarchean crust were completely erased and resurfaced by weathering and plate tectonics over the eons.

The protocontinents of the greenstone belts in the Nuvvuagittuq craton of Canada, the Isua craton of Greenland, the Kaapvaal craton of South Africa, and the Pilbara craton in western Australia were the target of frequent impacts during the LHB, creating thousands of terrestrial impact crater lakes, the ideal crucibles for life synthesis. Meteorite impacts gave ancient Earth thousands of hydrothermal crater lakes that may have become the incubators for prebiotic chemistry and the emergence of life. Thus, the impacts during the LHB created not only the continental crust but also the innumerable hydrothermal crater lakes, where first biosynthesis began.

5.3.6 CRUCIBLES FOR LIFE'S BEGINNINGS

Today, Earth is teeming with life, but when it formed from the spinning disk, it was a hot, violent, and sterile planet for the first half-billion years. We know from the fossil record that life began nearly 4 billion years ago, but there is still intense debate about where on the Earth life began. During the last three decades, the discovery of hyperthermophiles living at high temperature and under extreme pressure in submarine hydrothermal vents and thriving on a chemical soup rich in hydrogen, carbon dioxide, and sulfur has inspired the imagination and hinted at novel scenarios for life's origin. The theory of deep-sea hydrothermal vents as a possible site for life's beginning was appealing, because simple metabolic reactions emerged near ancient seafloor hot springs, enabling the leap from a non-living to a living world (Sousa et al. 2013; Wachterhäuser 1993).

To test this hypothesis, one must first reconstruct the paleoenvironment on the young planet back when life emerged.

During this catastrophic time of the LHB, the giant meteorites that pelted the planet vaporized the ocean surface when they contacted water and created innumerable crater basins when they struck land (Sleep et al. 1989; Zahnle et al. 2007). Since water is so vital for life, we can say that life emerged in a watery environment in our young planet. But the ocean was not conducive to the conditions for biosynthesis. There was only one place for the refuge and nourishment of the building blocks and early life—subsurface hydrothermal vent systems. Such vents are attractive sites for the origin of life, owing to the protection they would have afforded against the bombardment of comets and asteroids (Sleep et al. 1989).

The hot-start hypothesis is supported by several lines of evidence, as discussed earlier. Among various hydrothermal settings for the incubators of life, three possible locations have been proposed: (1) submarine hydrothermal vents, (2) hot springs and tidal pools, and (3) subsurface hydrothermal crater lakes. Hydrothermal systems can develop anywhere on the crust where water coexists with a magmatic heat source. All these hydrothermal sites are geochemically reactive habitats, where microbial life thrives today around the superheated water that supports diverse chemosynthetic ecosystems (Wiegel and Adams 1998). Variations in the temperature and density of fluids drive the convective circulation in the crust, producing large-scale transfers of energy and material. Hydrothermal systems revealed vast and previously unknown domains of microbial habitats on the Earth. The geothermal vents harbor rich ecosystems, the energy source of which stems from chemicals and volcanism, not from sunlight. In these extreme environments, the microbial and geothermal interactions are tightly interconnected, providing many of the basic constituents for the primordial synthesis of organic molecules and for the evolution of fundamental metabolic processes of some modern prokaryotic chemoautotrophs. The biochemistry of these hyperthermophiles might, in turn, provide clues about the kinds of reaction that initiated the chemistry of life. Hydrothermal systems have prevailed throughout geologic history, and ancient hydrothermal deposits could provide clues to understanding Earth's earliest biosphere. Modern hydrothermal systems support a wide range of microbial habitats and provide good comparisons for paleontological interpretation of ancient hydrothermal systems.

There is a great deal of controversies about the likely site for life's beginnings among three kinds of hydrothermal settings: submarine hydrothermal vents, hot springs and tidal pools, and hydrothermal crater lakes. Here, we evaluate these three hydrothermal sites.

5.3.6.1 SUBMARINE HYDROTHERMAL VENTS

Discovery of hydrothermal vents, and their associated life-forms, on the deep ocean floor has opened up the possibility that life emerged at the ocean depths. The mid-ocean ridges are pockmarked with hot springs—the hydrothermal vents. Hot chemical-rich water is welling up below from the sea floor and pumping out through cracks of the ridges. These hydrothermal vents are densely populated by strange animals.

The chemicals found in these vents and the energy they could provide could have fueled many of the chemical reactions necessary for the emergence of life. This novel habitat is too dark at the ocean floor for photosynthesis to occur, so organisms survive by chemosynthesis, whereby energy is derived from chemical reactions. The cosmic building blocks, along with spewing gases from the hydrothermal vents, entered into a complex series of far-from-equilibrium chemical reactions in an extremely hot, dark, and highly reducing environment. Submarine hydrothermal vents are generally considered the likely habitat for the origin and early evolution of life (Baross and Hoffman 1985; Martin et al. 2008; Sousa et al. 2013; Wachterhäuser 1993). Like hot springs and geyser on land, hydrothermal vents form in volcanically active areas—often on mid-ocean ridges. To maintain life, the hydrothermal system must be open, accepting energetic input constantly or periodically in a non-equilibrium state.

Two types of submarine hydrothermal vents—acidic black smokers and the alkaline Lost City—have been considered as possible cradles of early life. Black smokers are deep, hot, energy-rich extreme environments of submarine hydrothermal vents at the ocean floor (Baross and Hoffman 1985; Nisbet and Sleep 2001; von Damm 1990; Wachterhäuser 1993). At the mid-ocean ridges where tectonic plates are spreading apart and magma wells up to the surface, intense geothermal heating generates hot springs on the sea floor. Seawater seeps through the cracks, dissolving metals and minerals, as it becomes superheated from the upwelling magma and erupts as a geyser from a hydrothermal vent. During the cycling of seawater along the axis of the vent, geothermal energy is transferred into chemical energy in the form of reduced inorganic compounds. The spewing water of these black smokers, which can reach temperatures of 400°C, contains chemicals and minerals that precipitate on contact with cold seawater, forming a black chimney around the vent. High temperature and acidic (pH 2–3) fluids characterize these black smokers. The vent spewing reduced gases (H_2S , H_2 , CH_4 , CO_2 , and NH_3) dissolved in hydrothermal fluids facilitate chemosynthetic reaction for microbes, a highly efficient microbial utilization of geothermal energy. Here, the hyperthermophiles flourish and form the base of the food chain. These heat-loving microbes support diverse organisms, including fish, clams, giant worm tubes, limpets, and shrimps.

Although black smokers provide perfect conditions for primitive hyperthermophilic life, the most basic problem of high-temperature and low-pH living is molecular stability during the emergence of life. Under both regimes, the bonds that hold together vital cell components, such as nucleic acids, proteins, and membranes, face the danger of being torn apart as quickly as they are produced during prebiotic stage, to prevent further biogenesis. However, once these hyperthermophiles appeared, they developed a high degree of thermostability because of their special high-temperature enzymes and tough membranes (Alberts et al. 2000). This thermal paradox suggests that the crucible of life was less heat-intense than the black smokers. Black smokers are not only very hot and acidic, but they are also short-lived, lasting only a few

decades (Sousa et al. 2013). The origin of life is most fruitfully approached as a long process during which the capacity to evolve facilitates itself in a step-by-step fashion rather than as a series of low-probability events.

An alternative view is that life might have originated in alkaline, off-ridge submarine hydrothermal vents. These giant white carbonate chimneys called the Lost City develop from exothermic reaction of seawater with minerals such as olivine as a result of serpentinization and release white carbonate minerals (Kelley et al. 2005; Martin and Russell 2007; Martin et al. 2008; Sousa et al. 2013). Unlike black smokers that reside directly on the seafloor spreading zone, Lost City is located several kilometers away from the mid-ocean ridge; it is highly alkaline (pH 9–11) and has a relatively cooler temperature (40°C–90°C) than that of the black smokers. The vent fluids of the Lost City system are very different from those of the black smokers. Lost City vents release methane, ammonia, hydrogen, as well as calcium and traces of acetate, molybdenum, and tungsten into the surrounding water; they do not produce significant amounts of carbon dioxide, hydrogen sulfides, or metals, which are major outputs of black smokers. The Lost City system may have been active for 120,000 years (Sousa et al. 2013), longer than the black smokers. The denizens of the Lost City are hyperthermophilic bacteria, methane-cycling archaea, and other micro- and macro-organisms.

The Lost City remains an attractive hypothesis to explain the energy flow across the rock walls before the inception of cell membranes. These vents have resulted in two chemical imbalances with the invention of cellular pumps. First, when the hydrogen-rich alkaline water from the vents met the acidic ocean water, a natural proton gradient or chemiosmotic coupling could have been generated within the pores of rocks, which could have been used as energy source. Second, an electron transfer could have occurred when the hydrogen and methane-rich vent fluid met the carbon-dioxide-rich ocean water, generating an electrical gradient. Combined with the natural proton gradient from the vent, the porous alkaline rocks were the ideal place for metabolism to begin. Once life had harnessed chemical energy of the alkaline vent water, it started making complex molecules such as RNA. Eventually, it created its own membrane and became a true cell and escaped from the porous rock into the open water (Lane and Martin 2012; Martin and Russell 2007).

However, the Lost City hypothesis faces several challenges. First, the Lost City fluid does not contain an abundant supply of catalytic metals (iron, copper, manganese, zinc, nickel, etc.), which are needed for polymerization of biomolecules. Second, the oldest ecosystems on Earth, as preserved in Eoarchean greenstone belts in Canada, Greenland, Australia, and South Africa, do not show any evidence of the Lost City environments. Third, the first cells probably developed in zinc-rich environments; the cytoplasm is rich in potassium, zinc, manganese, and phosphate ions, which are not widespread in the Lost City environments (Mulkidjanian et al. 2012). Fourth, nucleic acids such as RNA are unstable in highly alkaline pH, raising the possibility that RNA must

have arisen in neutral or mildly acidic environment. This observation clearly contradicts the hypothesis that RNA evolved in the vicinity of alkaline (pH 9–11) hydrothermal vents (Bernhardt and Tate 2012).

Supports of the submarine vent hypothesis are waning in recent years (Deamer 2011; Hazen 2005). Both submarine hydrothermal vent theories—the black smokers and the Lost City—suffer from the “concentration problem” of organic compounds. The cosmic ingredients would be dispersed and diluted rather than concentrated in the vastness of the Eoarchean global ocean, before they can assemble into the complex molecules of life. A sufficient concentration of reactants is difficult to imagine in the open oceans. A protective barrier of the cradle of life is needed for prebiotic synthesis. One crucial precondition for the origin of life is that comparatively simple biomolecules must have had the opportunities to form more complex molecules by segregation and concentration of chemical compounds. In open oceans, cosmic and terrestrial chemicals could not have mixed, concentrated, selected, or organized into more complex molecules, thus inhibiting prebiotic synthesis. Moreover, at deep sea, wet and dry cycles of condensation reactions mediated by sunlight for polymerization of nucleic acids and proteins would not be available (Deamer 2011).

The presence of the submarine hydrothermal vents as a likely incubator is difficult to explain in one-plate Eoarchean Earth. How did the submarine hydrothermal vents such as the black smokers or the Lost City originate without plate tectonics? Today, they occur along or near the axis of the spreading ridge. But if the plate tectonics did not start before 3 Ga (Tang et al. 2016), there was no spreading ridge in the oceans; we have to seek alternative hydrothermal systems on land, not in ocean.

Mulkidjanian and co-workers, working on the chemical makeup of living cells, have discovered that the chemistry of modern cells provides important clues to the original environment in which life evolved (Mulkidjanian et al. 2012). It turns out that all cells contain a lot of phosphate, potassium, and other metals—but hardly any sodium. In contrast, seawater is rich in sodium but deficient in potassium and phosphates. The composition of the living cell does not match that of the ocean water. On the other hand, the inorganic chemistry of cell protoplasm mirrors the environment of freshwater ponds and lakes. These authors concluded that first life began on land, not in sea. Once life does evolve, then both black smokers and the Lost City provide ready habitats for hyperthermophiles; but these environments are not supportive of prebiotic synthesis.

An alternative theory for the terrestrial geothermal sites of life’s origin includes hot springs and tidal pools (Deamer 2011) and hydrothermal crater lakes (Chatterjee 2016; Cockell 2006; Farmer 2000; Osiniski et al. 2013). These hydrothermal sites are conceptually similar to the central idea of Darwin’s “warm little pond” that life on Earth originated on land.

5.3.6.2 DARWIN’S “WARM LITTLE POND”

Darwin, primarily concerned with the evolution of complex life-forms from simpler ones, said little about the ultimate origin of life. Such ancient origins, he believed, were lost in the

mists of time. His evolutionary theory was not about the start of life but about the processes that gave rise to biodiversity—the tree of life (Darwin 1859). Darwin was reluctant to publish his views on life’s origin. However, in a private letter in 1871 to his young botanist friend Joseph Hooker, Darwin speculated that life could have sprung from a “warm little pond” rich in nutrients:

“It is often said that all the conditions for the first production of a living organism are now present, which could ever have been present. But if (and oh what a big if) we could conceive in some warm little pond, with all sorts of ammonia and phosphoric salts, light, heat, electricity, etc., present, that a protein compound was chemically formed ready to undergo still more complex changes, at the present day such matter would be instantly devoured or absorbed, which would not have been the case before living creatures were formed.”

Despite Darwin’s early musing of the “warm little pond” for life synthesis, the marine-origin theory for life dominated the field for many decades, in part as a reaction to Alexander Oparin’s landmark work. Oparin suggested that primordial soup was synthesized as a result of the combination of reducing atmospheric gases and some form of energy (lightning or UV rays), which would concentrate in the oceans to form amino acids and other building blocks and then combine to more complex molecules and finally to the first cells (Oparin 1924). For more than nine decades, the ocean origin was the favorite explanation, which was reinforced by the discovery of the submarine hydrothermal vents in the 1970s as the likely incubators.

Recent studies suggest that life on Earth really did start on land in a “warm little pond” and not in the oceans—just as Darwin speculated more than 140 years ago. Mulkidjanian and co-workers (2012) suggested that modern cells may reflect the chemical condition in which the first cells emerged. In all living cells, the cytoplasm is rich in potassium, zinc, manganese, and phosphate ions, which are not widespread in marine environments, and it has lower amounts of sodium ions than outside. Such conditions are found only where hot hydrothermal fluid brings the ions to the surface—places such as geysers, fumaroles, crater basins, and other geothermal fields. The chemistry of modern cellular fluid mimics the original environment in which life first evolved. Since oceans and cellular fluid are chemically dissimilar, these authors claim that it is unlikely that life evolved there. Contradistinct, the chemical nature of volcanic pools, or “warm little ponds,” more closely resembles the cell’s cytoplasm composition. For cells to synthesize proteins, their molecular machines need a lot of potassium. Life cannot live without synthesizing proteins, so it must maintain high potassium levels. But in ancient seawater—as well as in our modern ocean—sodium outnumbers potassium 40 to 1. The high K^+/Na^+ ratio and relatively high concentrations of Zn, Mn, and the phosphorous compounds of living cells support the geothermal terrestrial origin of life. Mulkidjanian and his colleagues concluded that terrestrial springs, such as those in Yellowstone Park, are much better environments for the first origin of life. This

finding challenges the widespread view that life originated in the submarine hydrothermal vents (Baross and Hoffmann 1985; Martin et al. 2008), positing instead terrestrial sites such as “comet pond” (Clark 1998) or “fluctuating hydrothermal pools,” where evaporation and replenishment by variable hot springs and precipitation occur (Damer and Deamer 2015), or hydrothermal crater lakes (Chatterjee 2015, 2016; Cockell 2006; Osiniski et al. 2013).

If all the impacting meteorites were small, the environment of early Earth might have approximated the “warm little pond.” However, the evidence preserved in the densely packed craters of the lunar highlands suggests otherwise. The environment of the early Earth appears to be far more extreme and inhospitable during the LHB than the benign picture conjured up by the “warm little pond.” Nonetheless, the “warm little pond” has literal relevance in understanding the alternative land-based environment for the origin of life.

Using the cratering history of early Earth, hydrothermal crater lakes would be ubiquitous and numerous on the Eoarchean crust and appear to be the ideal crucibles for life’s origin. They share all the necessary chemical components of the cellular fluid, first proposed by Mulkidjianian and co-workers for the terrestrial origin of life (Mulkidjianian et al. 2012). The paleoecology of the earliest fossils favors deep and large hydrothermal crater lakes as the likely crucible, rather than small surface hot springs (Dodd et al. 2017; Hofmann 2011; Knauth and Lowe 2003). Unlike the submarine hydrothermal vents, terrestrial geothermal fields such as crater lakes are conducive to condensation reactions for polymerization of nucleic acids and proteins and enable the involvement of solar light as an additional energy source (Chatterjee 2016; Cockell 2006; Deamer 2011; Osiniski et al. 2013). The mineral substrates at the crater floor, such as clays and pyrites, were excellent catalysts and helped in the polymerization of nucleic acids and proteins, respectively (Chatterjee 2016; Hazen 2005). Moreover, subsurface hydrothermal vents at the crater floor provided an escape network for emerging life from the continual bolide bombardment. Once life originated at hydrothermal crater lakes, it subsequently invaded the oceans.

5.3.6.3 POST-IMPACT CRATER LAKES WITH HYDROTHERMAL SYSTEMS

It has been suggested in recent years that post-impact crater lakes with hydrothermal systems may have provided habitats for the origin and evolution of early life on Earth (Chatterjee 2015, 2016, in press; Cockell 2006; Mulkidjianian et al. 2012; Osiniski et al. 2013). We propose that life originated in a neutral pH milieu of terrestrial, hydrothermal crater lakes, where the building blocks of life, derived from meteorite impacts, began to concentrate. In addition, continuous infall of micrometeorites containing building the blocks of life, as well as iron, manganese, and silicates, formed a blanket around the lifeless surface of newly formed crater lakes and began to interact with biomolecules at the basins. Most micrometeorites were compositionally similar to carbonaceous chondrites (Greshake et al. 1988). Inside the crater basin, the

hydrothermal vent provided a continuous stream of chemical compounds and energy, which were mixed with cosmic ingredients by convection current to form sticky, brownish, primordial prebiotic soup. Hydrothermal crater vents provided the selection, concentration, and organization of specific organic molecules into successively more-information-rich biopolymers and finally into the first cells (Chatterjee in press). The transition from chemistry to biology inside the hydrothermal crater lakes occurred around 4 billion years ago.

These crater lakes possess all the advantages of deep-sea hydrothermal vents that have been previously proposed for life synthesis, such as a prolonged circulation of heated water for mixing and concentration of the prebiotic soup, various chemicals and ATP for chemosynthesis, abundant catalytic surfaces of mineral substrates with nanopores and pockets for polymerization, and nutrients for primitive life (Chatterjee 2016; Hazen 2005; Huber and Wachterhäuser 1988; Wacey et al. 2011; Wachterhäuser 1993; Wiegel and Adams 1998). In addition, in these sequestered, hydrothermal crater lakes, cosmic and terrestrial chemicals were mixed, concentrated, and linked together to grow into larger and more complex ones by convective currents; the hydrothermal chemistry was powered by solar, tidal, and chemical energies, including ATP. The convective current in the crater basins caused the water and cosmic ingredients to move constantly, creating a thick primordial soup rich in organic molecules, which ultimately led to the first organisms in a step-by-step process of molecular symbiosis (Chatterjee 2015, 2016, in press). Hydrothermal impact crater lakes were the perfect crucibles for the concentration and cooking of these cosmic and terrestrial ingredients, where life began to brew and synthesize. Because of their abundance in the Eoarchean crust, they probably provided the ideal habitats for the origin and evolution of life on early Earth and possibly on other planets such as Mars (Farmer 2000; Osiniski et al. 2013).

One advantage of the multiple and interconnected networks of crater basins for biogenesis may be the close spatial proximity of different reaction sites to create more complex molecules in a feedback loop (Figure 5.3.1). Crater basins provide additional geochemical and environmental advantages over the earlier proposed submarine vents (Chatterjee 2016):

1. The continental excavation by impacts, forming the crater lakes, exposed a variety of rock types, including sialic, mafic, and ultramafic, which provided a dynamic fluid that mixed with variable temperatures, magmas, and pH conditions (Figure 5.3.1). This allowed a dynamic fluid that favored the prebiotic synthesis in reducing and reactive habitats; this mix might be less available in a purely volcanic and tectonic venue.
2. Sequestered high crater rims, which physically compartmentalized biomolecules, were ideal for concentration and complex reactions; contradistinct, in the global ocean, most of the organic compounds from cosmic and volcanic sources would have been diluted and dispersed, inhibiting prebiotic synthesis.

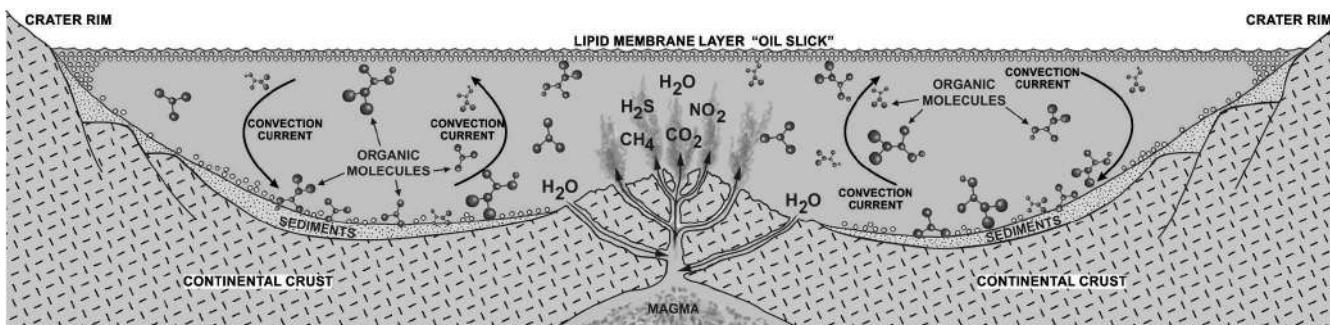

FIGURE 5.3.1 The crucible of life. During the early Archean period (~4 Ga), freshwater crater basins with hydrothermal vent system at their central peak would have offered a protective sanctuary for the origin of life. The boiling water was rich in organic molecules brought by meteorites. On the water's surface, primitive lipid membranes and hydrocarbons float like an oil slick. The minerals along the floor of the basin acted as a catalytic surface for the concentration and polymerization of monomers. The bubbling, biotic soup was thoroughly mixed by convection currents. These same currents also circulated some of the lipid membranes down to the basin floor, where they attached to the porous mineral layers, encapsulating biopolymers such as RNA and amino acids. Heat, gases, and chemical energy such as ATP released from the hydrothermal vent brewed and condensed the prebiotic soup, which began to collect at the mineral substrate, at the bottom of the basin. (After Chatterjee, S., *Phys. Chem. Chem. Phys.*, 18, 20033–20046, 2016.)

3. The chemical content of vent water, which originates in a complex set of reactions between lake water and hot, newly minted impact melt rock, nourishes a chain of living microbial communities, and very likely, it did so during biogenesis. Impact-induced fracturing at the floor of the crater basin increased the surface area available for the concentration of polynucleotides and polypeptides (Cockell 2006).
4. Terrestrial crater basins with low ionic composition are compatible with those of modern cells, thus favoring the likely site for life origin (Mulkidjanian et al. 2012).
5. The hydrothermal reactions were the main source of the metal-rich sediments and nodules that carpet the crater floor. The diverse metal sulfides, clays, and zeolites that were available in crater basins functioned as catalysts for complex sequences of reactions and polymerization of amino acids and nucleotides (Chatterjee 2016; Cockell 2006; Hazen 2005). The ‘Iron-Sulfur World’ inside the hydrothermal vents acted as an early form of metabolism before nucleic acids appeared and promoted a variety of chemical reactions (Wachterhäuser 1993). Mineral surface bonding and pore spaces are seen as functional precursors of cellular enclosure and of bonding enzyme surfaces.
6. Wet and dry cycles of tidal pools, near the surface of the crater, favored condensation reactions of polymers (Damer and Deamer 2015; Deamer 2011).
7. High temperate ranges (~60°C–90°C) and pH values near neutrality (pH 5–8) are ideal for stabilizing the membrane vesicles of emerging hyperthermophilic microbes (Damer and Deamer 2015; Deamer 2011).
8. Additionally, solar and tidal sources of energy were available for the evaporation and concentration of polymers (Mulkidjanian et al. 2012).
9. Shocked rocks from impacts would offer shelter against harmful UV radiation when Earth still lacked a protective ozone layer (Osiniski et al. 2013).
10. Because of the huge amount of energy from impacts, impact melt rocks could keep the vent environments hot and reactive for a long time during biosynthesis (Osiniski et al. 2013).
11. Hydrothermally altered and precipitated rocks would have provided life-long sources of nutrients and habitats, even when hydrothermal activity ceased (Osiniski et al. 2013). All hydrothermal crater lakes are rich in H₂S, a source of nourishment for the emerging thermophiles.
12. Impact craters could provide protected sedimentary basins and hospitable environments for sustaining communities of primitive organisms (Osiniski et al. 2013).

These 12 geochemical and environmental characteristics favor hydrothermal crater lakes as the likely site for life’s origin rather than the submarine hydrothermal vents model.

Hydrothermal crater lakes encompass a multiplicity of physical, chemical, and mineralogical gradients that may shape the structure of the microbial communities inhabiting these systems. The environmental complexity of the crater basin was a necessary requirement for the origin of biologic complexity, because a wide range of environmental conditions was required to produce a living cell from organic precursors. The anoxic crater lakes in a pre-plate tectonic Earth are unique in geologic history and are very different from the submarine black smokers or the Lost City. The cold freshwater of the crater lake is heated by hot magma from the central peak and reemerges from the vents, reaching a relatively moderate temperature (40°C–90°C). The fluctuating temperature gradient created a convection current within the lake water, mixing the assorted chemicals, both cosmic and vent-spewing reduced gases (such as H₂S, H₂, CH₄, CO₂, and NH₃). These mixed hydrothermal fluids formed a complex solution of thick, prebiotic soup. The alternate wet/dry cycles of the lake surface facilitated condensation reactions for the polymerization of monomers such as nucleic acids and nucleotides.

The ecosystem of a hydrothermal crater vent includes a gradient of temperature, nutrient abundance, a chemical environment, and pH, even within a single thermal regime.

5.3.6.3.1 Morphology and Distribution of the Impact Crater Lakes

Impact craters are formed when meteorites smash into a planet or a moon with a hard-crustal surface. All the bodies in our solar system have been heavily bombarded by meteorites throughout their early history. The landscapes of the Moon, Mars, and Mercury have beautifully preserved the LHB record because the surfaces of these relatively small planetary bodies have remained unchanged for millions of years, without any plate tectonic activity. Crater formation is mediated by an energy-transfer mechanism, where the kinetic energy of the impactor is transferred into heat, fracturing, displacing, and excavating the target rocks. Impactor velocity ranges from 10 to 70 km/s, with an average of 20 km/s on Earth. Over 150 impact craters have been identified on our planet, in a wide diversity of biomes and target rocks (Grieve 1990).

Hydrothermal impact crater lakes are good indicators for the presence of subsurface water and appear to be the most plausible location for the beginning of life (Chatterjee 2016; Cockell 2006; Osiniski et al. 2013). Like hot springs and geyser on land, hydrothermal vents formed in impact induced crater lakes. Large impacts that excavated huge craters also shattered the central peak across the diameter, creating volcanically driven geothermal vents in concert with ground water. As rains filled up the crater basins, underwater hydrothermal vents developed and crater lakes formed. The reduced gases from hydrothermal vents mixed with the cosmic biomolecules created ideal prebiotic soup for biogenesis.

Impact craters are divided into two groups based on their morphology: simple and complex craters (Grieve 1990). Simple craters are relatively small, up to 3 km in diameter, with uplifted and overturned rim rocks, surrounding a bowl-shaped depression, partially filled by breccia, with a maximum depth at the center. Complex craters and basins are large, generally 4 km or more in diameter, with a distinct central uplift in the form of a peak and/or ring, an annular trough, and a slumped outer rim, with relatively low depth/diameter ratio. Any hypervelocity impact capable of forming a complex crater lake can potentially generate a hydrothermal system (Figure 5.3.2). Small and complex crater lakes, sequestered by crater rims, are ideal sites for the concentration of reactants during prebiotic synthesis.

Terrestrial hydrothermal impact crater lakes have been proposed as the most likely environments for biogenesis (Chatterjee 2015, 2016; Cockell 2006; Osiniski et al. 2013), and, by analogy, on Mars (Farmer 2000). These crater lakes could have also provided a refuge for the earliest thermophilic life during late, giant-impact events. Craters were presumably plentiful on the Eoarchean crust; this period also overlaps with the evidence of the earliest life on Earth. Moreover, modern subaerial hydrothermal lakes are widely colonized by hyperthermophilic, thermophilic, and mesophilic bacteria and archaea.

Every impact onto water-bearing crustal surfaces generates a long-term hydrothermal activity in the resulting craters; this is due to the transfer of kinetic energy from the impactor to the target. Impact events trigger shock pressures and temperatures that can melt substantial volumes of target material. There are three main potential sources of heat for creating impact-generated hydrothermal systems (Osiniski et al. 2013): (1) impact melt rocks and impact melt-bearing breccias; (2) elevated geothermal gradients in central uplifts; and (3) energy deposited in central uplifts due to the passage of the shock wave. Any

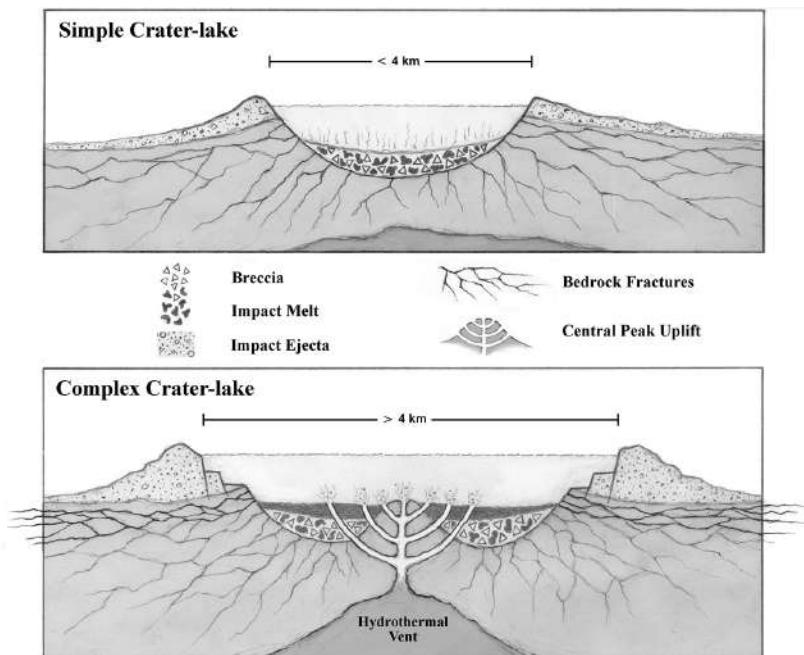

FIGURE 5.3.2 Impact craters are divided into two groups based on morphology: simple and complex. Complex craters (>2–4-km diameter) with central peaks generated a dynamic hydrothermal system, creating the ideal environment for these first crucibles of life.

hypervelocity impact capable of forming a complex crater (>4-km diameter) can potentially generate a hydrothermal system. It appears that small complex hydrothermal crater lake would enhance the concentration of biomolecules than the larger ones and would be an ideal site for life synthesis.

Impact craters are of high interest in planetary exploration because they are considered as possible sites for the evidence of life. Evidence for impact-generated hydrothermal activity is recognized at over 70 of the ~180 craters on Earth, from the ~1.8-km-diameter Lonar Crater structure in India to the ~250 km diameter Sudbury impact structure in Canada. Complex impact craters with central peaks sustain a hydrothermal system for a longer period than the simple, bowl-shaped crater (Figure 5.3.2). In large craters, thermal activity causes convection of ground and meteoric water. There is an extensive zone of fractured rocks at the floor, favorable to the circulation of the prebiotic soup. Moreover, the shock deformation of mineral surfaces stimulates reactions between minerals and active fluids (Cockell 2006; Osiniski et al. 2013). Impact-generated silicate debris in the crater basins would produce clay minerals, and hydrothermal fluid would precipitate pyrites; both minerals played a critical catalytic role in the organic synthesis of prebiotic biopolymers such as nucleic acids and proteins (Chatterjee 2016; Hazen 2005).

In terrestrial setting, the interaction of melt rock with the ground water generates a hydrothermal system (Figure 5.3.2). Eventually, the groundwater and rainwater would fill up the crater to form a lake, but the floor of the crater sustained the hydrothermal system for a long period. The crater rim rises considerably above the lake level and forms an ideal sequestered basin for the concentration of biomolecules. Impacts on a water-rich planet like Earth or even Mars can generate hydrothermal activity, that is, underwater areas boiling with heat (Farmer 2000). The central peak of a complex crater might be fractured due to impact with elevated geothermal gradient, spewing chemicals similar to the axis of the submarine hydrothermal vent, and might be an important source of heat for creating a hydrothermal system. The small complex crater (~5-km diameter) like the Gardnos crater of Norway and Gow crater of Canada would be ideal for prolonged biosynthesis. Near the surface of the crater, evaporative heating and drying organic compounds are proposed as the concentrating mechanism (Cockell 2006; Deamer 2011).

There is no constraint on the length of time required for the origin of life. The duration of impact-generated hydrothermal systems is poorly known. In general, the larger the crater, the longer the duration of hydrothermal activity. For example, in the 4-km-diameter Kärdla crater in Estonia, a hydrothermal system lasted for several thousand years, whereas in the 24-km-diameter Haughton crater in Canada, a hydrothermal system was maintained for more than 10,000 years. Sudbury crater (~250 km) probably retained hydrothermal activity at least for ~2 myr (Abramov and Kring 2004; Osiniski et al. 2013). However, during the Eoarchean time, the crust was relatively thin and the heat flow was higher through the crust than that at present, so these crater lakes possibly retained hydrothermal activity for a longer period. Moreover, the

continental crust had greater heat production than it does today, given the greater abundance of heat-producing isotopes in the early part of Earth's history. The gradual cooling of the crater basin was advantageous for biogenesis, creating simple to complex organic compounds at different thermal gradients.

5.3.6.3.2 Microbial Colonization in Hydrothermal Impact Crater Lakes

The inhabitants of current hydrothermal crater lakes represent relict microbial communities that have remained distinct from other surrounding terrestrial organisms for millions of years, retaining their stamp of extreme antiquity. Hydrothermal crater lakes today harbor rich ecosystems and variable energy sources, which stem mainly from vents and impact melt rocks, and are favorable habitats for microbial colonization (Parnell et al. 2004; Reysenbach and Cady 2001). Many of these microbes are holdovers from the Archean ecosystems and have retained their ancestral characteristics. Thus, the hydrothermal crater lakes we have today are a refuge for novel derivatives of ancient forms of young Earth. The high-temperature vents of modern crater basins are perhaps the oldest ecosystem reminiscent of early Earth. Inside the crater basins are reactive gases, dissolved elements, and chemical and thermal gradients that range bottom to top from hyperthermophilic, to thermophilic, to mesophilic on the water surface (Figures 5.3.3 and 5.3.4).

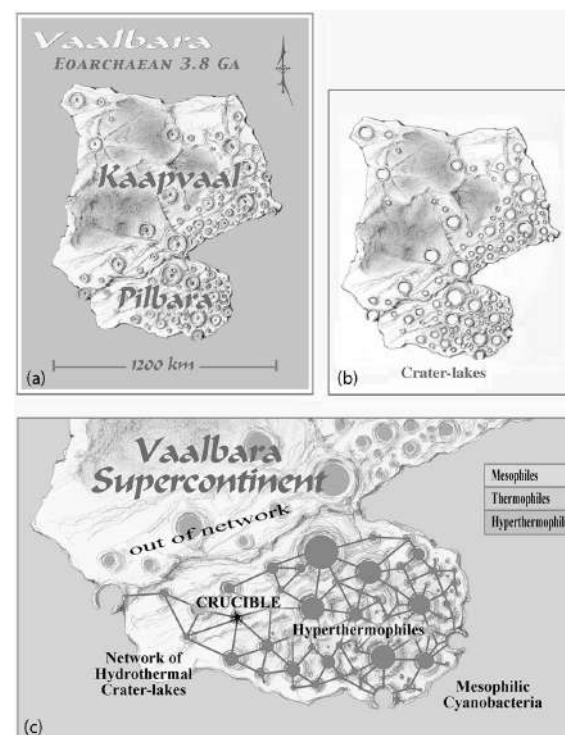

FIGURE 5.3.3 Hydrothermal crater lakes become the first sites for the origin of life: (a) the highly cratered surface of Earth's first supercontinent Vaalbara is pockmarked like the Moon; (b) from rain and aquifer, crater lakes with hydrothermal systems, rich in cosmic ingredients, are formed; (c) An underground network forms within the bedrock fractures, interconnecting the various closely linked crater lakes, exchanging heat and life-building chemical ingredients.

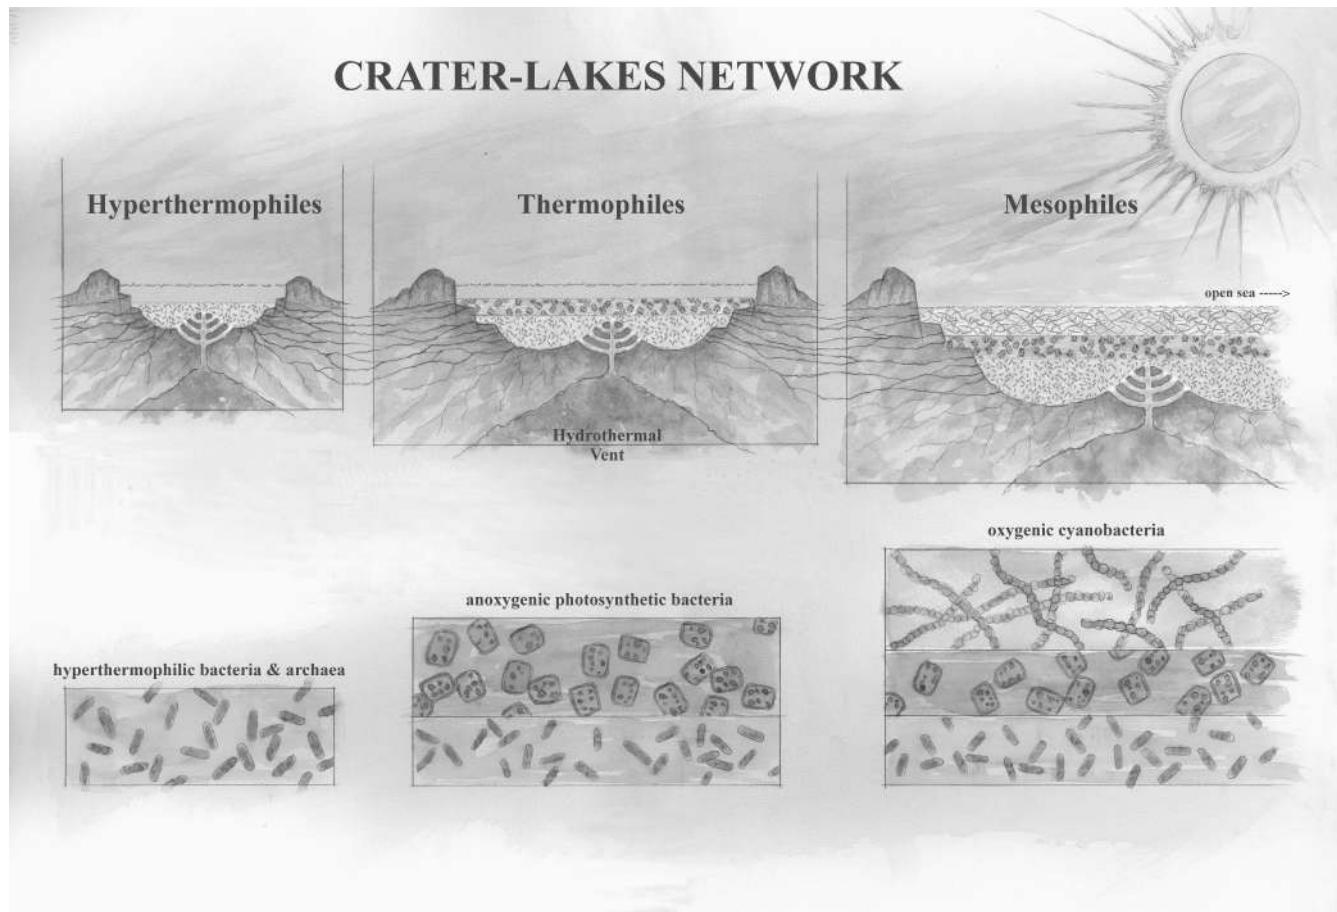

FIGURE 5.3.4 Along the top of the illustration, three cross-sections of crater lakes of different sizes show (1) the underground fissure networks that connect the closely spaced crater basins, and (2) the vertical gradients of microbial communities. Within these percolating crater lakes, three microbial zones form. The first hyperthermophilic zone, along the bottom of the crater lake, is where bacteria and archaea first emerge. Above that, the thermophilic zone forms, and in that layer, anoxygenic photosynthetic bacteria evolve. Within the top mesophilic zone, as the crater lake merges with the ocean, oxygenic cyanobacteria evolve and begin to photosynthetically harness the Sun's energy—Earth's first oxygen is the by-product of photosynthesis. Along the bottom of the illustration, those three microbial zones are enlarged.

The vent microorganisms are self-sufficient. Vent chemicals sustain hyperthermophiles, while photoautotrophs require solar power that comes easily in a planktonic lifestyle near the surface.

There are several examples of impact crater lakes that harbored microbial communities. The Siljan impact crater in Sweden, which formed during the Late Devonian (~378 Ma), is the largest known impact structure in western Europe, with a diameter of 52 km. The structure has preserved remnants of biofilm-forming fossilized microbial communities (Cockell 2006).

The impact that created the Ries crater (~24-km diameter) in Germany formed about 14 Ma; microbial trace fossils occur there as tubular features in impact glasses. The tubules have complex forms—consistent with tunneling behavior of microbes—and contain organic molecules associated with biologic activity. The Ries crater may have generated hydrothermal activity as long as 10,000 years, giving microbes enough time to colonize (Sapers et al. 2015).

The Miocene Haughton impact structure of Devon Island in the Canadian high Arctic (~20-km diameter), with its

hydrothermal vent systems, contains the fossil of microbial communities (Parnell et al. 2004). The target rocks excavated at the site included massive gypsum-bearing carbonate rocks of the Ordovician age. Microbial communities such as cyanobacteria were found in the highly porous and shocked gypsum crystals. The community shows two species of cyanobacteria: *Gloeocapsa alpine* and *Nostoc commune*. With more empty spaces, microorganisms can better colonize porous minerals and extract nutrients from them more easily. Several features of the Haughton crater, specifically its freezing environment, serve as a potential Martian analog in the ongoing search for life, thus initiating the NASA's Haughton-Mars Project.

The Lonar crater of India is one of the youngest and best-preserved impact structures on Earth. The 1.8-km-diameter simple crater formed entirely within the Deccan Traps around 50,000 years ago, making it an important analog for small craters on the basaltic surfaces of the Moon and Mars. The impact event that generated the Lonar crater probably tapped groundwater supplies in the underlying basaltic aquifer, producing the fluidized ejecta blanket. As water from this lake began to interact with the hot, porous impact melt deposits, a hydrothermal

system developed. Samples from the cores drilled into the Lonar crater flow show that some clay mineral formed at temperatures between 130°C and 200°C in extremely hot, hyperthermophilic environments (Hagerty and Newsom 2003). The Lonar crater is a hypersaline and hyperalkaline soda lake with a diverse microbial community. Environmental constraints have favored a distinctive mesophilic microbial community: methylotrophs, anoxygenic purple sulfur and non-sulfur photosynthetic bacteria, and oxygenic cyanobacteria. The microbial assemblage includes largely *Proteobacteria* (30%), *Actinobacteria* (24%), *Firmicutes* (11%), and *Cyanobacteria* (5%), but other microbes such as *Bacteroidetes* (1.12%), *BDI-5* (0.5%), *Nitrospirae* (0.41%), and *Verrucomicrobia* (0.28%) were detected in minor abundances in the ecosystem (Paul et al. 2016).

5.3.6.3.3 Reconstruction of the Archean Impact Crater Lakes

Although hydrothermal crater lakes seem to be the likely incubators for the origin of life, and the Eoarchean environments during the LHB support this view, no pristine craters from this age have been preserved. However, the greenstone belts containing the oldest fossil record may shed new light on the ecology and environment of these basins. The origins of Eoarchean greenstone belts in Canada, Greenland, Australia, and South Africa (>3.5 Ga) are controversial, often cited as the result of plate tectonics (Condé 1981). However, a recent study suggests that plate tectonics did not start before ~3 Ga, about 500 million years later than the origin of the greenstone basins (Tang et al. 2016). It appears that some megatectonic process other than plate tectonics contributed to the origin of greenstone belts.

Bickel et al. (1994) argued that greenstone belts are not oceanic crust, but continental. In cross-section, the central part of greenstone belts shows an anticlinal structure representing the central peak of an ancient crater, which is flanked on either side by synclinoriums, dominated by ultramafic, basic, and andesitic rocks. The volcano-sedimentary sequences in two synclinoriums containing basalt, chert, and the Algoma-type banded iron formation, all suggest a hydrothermal crater environment (Furnes et al. 2004). Bilateral symmetry of the greenstone belts resembles the geometry of a complex crater. Similarly, the environment of Eoarchean greenstone belts suggests that these basins may be the relics of ancient hydrothermal crater lakes (Chatterjee 2016; Green 1972). Studies of ancient hydrothermal impact crater lakes can provide important constraints for reconstructing the history of hyperthermophilic ecosystems on early Earth.

A felsic hydrothermal crater setting for Earth's oldest fossils, found in the Dresser Formation (~3.5 Ga) of the Pilbara craton, has been proposed (Van Kranendonk 2006). The habitat combines a high-energy input for chemosynthesis. Recently Djokic and co-workers concluded that the fossil-bearing horizons of the Dresser Formation were formed in terrestrial hot springs or crater lakes, not in the ocean (Djokic et al. 2017).

There is a growing body of evidence that the Archean Vaalbara supercontinent, including the Pilbara craton of Australia and the Kaapvaal craton of South Africa, yield the

oldest microfossils that preserve multiple impact-cratering events during 3.5–2.5 Ga, in the form of glass spherules (Byerly et al. 2002; Glikson 2010). This crucial geologic record from the ancient Vaalbara continent offers the possibility for extrapolating earlier impact-cratering events during the LHB, which must have created innumerable crater basins with hydrothermal systems hosting the ideal niches for early life.

Presumably, the Eoarchean crusts of the Nuvvuagittuq craton, the Isua craton, the Pilbara craton, and the Kaapvaal craton, the nuclei of ancient continents, were heavily pock-marked during LHB by post-impact craters of varying sizes, as those on the Moon and Mercury. Unlike the Moon and Mercury, those primordial craters were filled up with water, forming innumerable lakes with hydrothermal systems. These Eoarchean craters—the crucibles of life—were deformed, modified, and even erased by later erosion and plate tectonic activity.

Environmental conditions and habitats at the Eoarchean surface of the Nuvvuagittuq craton, the Isua craton, the Pilbara craton, and the Kaapvaal craton were conducive for the emergence and early evolution of life. These greenstone belts with hydrothermal crater lakes were the ideal location for biosynthesis (Figure 5.3.3). Interstellar particles, micrometeorites, small comets, and chondrites were suitable carriers for the safe delivery of the cosmic biomolecules to these crater lakes. Earth's young atmosphere slowed down these carriers of life's first building blocks such as fine dust, as they lightly settled upon the crater surface. These crater lakes became enriched with cosmic ingredients and were mixed by the convection current of the hydrothermal systems to form a concentrated, prebiotic soup.

Instead of a single crucible, the closely spaced crater basins on the Vaalbara supercontinent were interconnected through an extensive underground network of tunnels and cracks that interlinked closely spaced craters. Cosmic ingredients and temperature gradients could move from one crater to another through these elaborate underground networks, thus increasing the chances for the right crucibles to form life (Figure 5.3.4). These crater lakes were separated and isolated by raised rims on the surface but were interlinked through underground cracks and crevices. These networks connected craters, ranging in size from 5- to 500-km diameter, had a higher probability of forming the ideal crucible systems for the origin of life than a single crater. The bootstrapping network of crater lakes becomes increasingly suited to facilitate the prebiotic synthesis, enhancing the condition for biosynthesis. This network of impact crater lakes invokes a system something like the Mono Lake in California, where a series of lakes from higher to lower elevation have a linked flow of groundwater.

A smaller complex crater, such as the Gow crater of Canada (~5-km diameter), has the advantage of a rapid concentration of building block molecules. Chemical reactions work best in small crucibles when the biomolecules involved are closely crowded together, constantly bumping into one another, and eventually linking to form complex molecules. On the other

hand, larger craters (~500-km diameter), with their larger vents, have a higher energy input for chemosynthesis and can retain hydrothermal activity for more than millions of years. Thus, a network of craters, both small and large, has the optimal possibility for processing the life synthesis. Among these hydrothermal crater networks, a single, small crater with a dynamic central peak would be the ideal site for the concentration and synthesis of biomolecules, assisted by the other craters in maintaining heat and a supply of ingredients. This small crater was interconnected with adjacent larger craters by an extensive underground network, exchanging heat and the chemicals necessary for life processing. The reduced gases from the hydrothermal vents mixed with the cosmic biomolecules, creating the thick ideal prebiotic soup for biogenesis. Once life emerged in a small hydrothermal crater, it migrated from crater to crater through the underground system or by overflowing, ultimately spilling into the ocean where mesophilic photosynthesis first developed. These oldest crater-basin ecosystems on Earth are preserved as relicts and remnants in the Eoarchean greenstone belts in Canada, Greenland, Australia, and South Africa.

Differentiating Archean lacustrine deposits from their marine equivalents is challenging. The depositional environment of the widespread occurrence of stromatolites in the Dresser Formation (~3.49 Ga) of the Pilbara craton has been interpreted to be a terrestrial, hydrothermal crater lake environment, perhaps a felsic volcanic caldera, but not a shallow marine basin (Van Kranendonk 2006). The volcanic caldera may actually represent the central peak of a hydrothermal impact crater in the Vaalbara supercontinent that contains a 20-km-thick succession of dominantly volcanic rocks of the Pilbara Group associated with hydrothermal chert layers and sedimentary rocks. Similarly, Westall and co-workers claimed that thermophilic, anoxygenic, and photosynthetic bacteria likely built the desiccation-cracked mats of the Paleoarchean (~3.33 Ga) Josefsdal Chert of the Barberton Greenstone Belt, South Africa, located in a nearshore hydrothermal setting that was periodically subaerial (Westall et al. 2015). Perhaps, the Josefsdal Chert was deposited in a hydrothermal crater lake near a coastal region that was periodically flooded. If so, then life should have been able to withstand the transition from periodically exposed settings of lakes to a coastal environment (Figure 5.3.4).

A similar transition from lacustrine to a coastal environment is documented in the Frotescue Group of Australia. During the Late Archean, the Pilbara craton of western Australia was an emergent landmass upon which the Frotescue Group was deposited. The group consists of 6.5 km-thick flood basalts, volcanioclastic and siliciclastic sediments, and carbonates that presumably accumulated in a continental setting like the Warrawoona Group. Awramik and co-workers suggested that the ~2.72 Ga old Meentheena Member of the Tumbiana Formation, Frotescue Group, was formed in a giant lake (~680-km diameter) in the Pilbara craton. Both the volcanioclastic and carbonate sediments and stromatolites from the Tumbiana Formation have been interpreted as a hydrothermal lacustrine environment (Awramik and Buchheim

2009; Buick 1992). Thus, the Josefsdal Chert of the Kaapvaal craton of South Africa and the Tumbiana Formation of the Pilbara craton are direct evidences that giant hydrothermal lake systems existed during the Archean time. Carbon isotope data suggest that both bacteria and archaea inhabited the Tumbiana lakes. The abundance and diversity of complex microbial communities with oxygenic cyanobacteria and stromatolites indicate that, by Archean time, cyanobacteria had adapted to the shallow-water lacustrine environment, indicating the antiquity of oxygenic photosynthesis. These environments were dynamic and underwent repeated transgression and regression.

Impact-induced hydrothermal systems are very diverse, with the widest range of pH and temperature gradients possible (Cockell 2006; Kring 2000; Nisbet and Sleep 2001; Osinski et al. 2013). The dominant mineral assemblages include zeolites, calcite, clays, and pyrite: zeolites and calcite play crucial roles as catalysts in chiral selection of amino acids and sugars, whereas clays and pyrite are important for polymerization of monomers such as nucleotides and amino acids (Hazen 2005). Hydrothermal crater lakes hosted many microenvironments, offering a number of possible niches for prebiotic chemistry. The convection current inside the crater basin mixed hot, concentrated prebiotic soup thoroughly and caused simple chemicals to grow into larger, more complex ones by combinatorial chemistry, with a chaotic mix of energy sources and organic compounds released from vents (Deamer 2011; Martin et al. 2014). Reactive vent molecules such as H_2S , CH_4 , NH_3 , and H_2S , as well as metabolic energy such as ATP mediate energy flow in the chemical evolution. Infinite combinations must have taken place in the vent environments, and an infinite number must have dissolved, rejected, and vanished. If life assembled from combinations of these already-stable and selected biomolecules, rather than a random combination of raw molecules from scratch, the process would have been much more efficient. Natural monomers such as nucleotides and amino acids were selected from a large pool of cosmic ingredients from the biotic soup for their cooperation and molecular recognition and were polymerized at pores and pockets of mineral substrates to create RNAs and protein enzymes respectively. These biopolymers were encapsulated by lipid membranes to initiate endosymbiosis. The final assembly of the first cell was produced through combinatorial chemistry and natural selection (Chatterjee 2016, in press; Damer and Deamer 2015; Deamer 2011).

5.3.6.3.4 Post-Impact Crater Lakes on Mars

Building on the recent NASA exploration of Martian life, the hydrothermal crater lake of early Earth is the terrestrial equivalent of the habitable environment of the Gale Crater of Mars, which is characterized by neutral pH, low salinity, and variable redox states of both iron and sulfur compounds (Grotzinger et al. 2014). The long-term habitat stability and the wide distribution of the hydrothermal crater basin have major implications for understanding the evolution of microbial life on other planets.

Impact craters on Mars larger than 1 km exist by the hundreds of thousands, and many of them were hydrothermal crater lakes in its early history. Because subsurface fluids and crustal heat sources could have coexisted on Mars, hydrothermal deposits are important targets in NASA's planetary exploration and their ongoing search for extraterrestrial life. Mars has always been situated at the outer edge of our solar system's habitable zone, and the probability of finding life is high. Hydrothermal environments appear to have been widespread on Mars early in the planet's history and are considered high targets in the exploration for a Martian fossil record (Farmer 2000). Martian surface features have been divided into three age groups, the Noachian, Hesperian, and Amazonian on the basis of intersection relations and the numbers of superimposed impact craters (Carr and Head 2010). Four billion years ago during the Noachian Period, when life was arising on Earth, Mars enjoyed a warmer climate, with abundant liquid water on its surface; river valley networks, large crater lakes, and oceans may have been present. Noachian-aged surfaces on Mars are scarred by many large impact craters. Dried-up river beds, impact crater lake deposits, polar ice caps, and minerals that form in the presence of water suggest that Mars had habitable environments for microorganisms. The habitats for microorganisms in many impact craters on Earth could be useful in the search for life on Mars, given the extraordinary number of craters there. Low temperatures and extremely low water availability govern the surface of the planet, but impact craters could provide a sheltered habitat. The ability of impacts to create hydrothermal systems is a major reason why NASA scientists are looking for ancient craters (such as the Gale crater) to search for early Martian life. Although Mars looks desolate today, it may have harbored life in the past. The long-term habitat stability and the wide distribution of hydrothermal crater basins throughout the solar system have major implications for evolution of microbial life on other planets.

5.3.7 ARCHEAN BIOSIGNATURES AND MICROFOSSILS: THE DAWN OF LIFE

Impact-generated hydrothermal systems have prevailed throughout the geological history of Earth, and their ancient deposits provide clues to understanding Earth's earliest biosphere (Parnell et al. 2004; Reysenbach and Cady 2001). The hydrothermal systems of the Eoarchean greenstone belts are promising sites for preserving the earliest evidence of life.

We live on a planet that records its own history, encrypted in the physical and chemical features of sedimentary rocks. Part of this history is paleontological (Knoll 2003). Paleontology is the most important tool for studying the emergence of life in the oldest volcano-sedimentary rocks. Biosignatures of earliest life fall into three categories: (1) carbonaceous remains of microbial cells or chemofossils; (2) bona fide cellular fossils; and (3) microbially influenced sedimentary structures such as stromatolites. Burial is an integral part of fossilization, in

part, because walls and envelopes are more likely to survive microbial decay. Moreover, thin layers of sediment would have sealed microorganisms from the overlying water levels, whereas mineral precipitation can fossilize microorganisms in three-dimensional detail.

The search for the earliest life on Earth relies on finding ancient volcano-sedimentary rocks where biosignatures are still preserved. Biosignatures such as chemofossil, microfossil, and stromatolite records in the Archean are very patchy and fragmentary and often controversial. The oldest fossils discovered have been found in the sedimentary deposits of shallow-water hydrothermal habitats in four Archean greenstone belts: the Nuvvuagittuq craton of Canada, the Isua craton of Greenland, the Pilbara craton of Australia, and the Kaapvaal craton of South Africa. The biosignatures from these cratons are described in the subsequent sections. These earliest Archean fossil records are both difficult to find and difficult to decipher because of their microscopic size. However, Early-Mid Archean biosignatures demonstrate that microbial life was abundant and possibly even more diverse than currently believed.

5.3.7.1 CHEMOFOSSILS: INDIRECT EVIDENCE FOR LIFE

Microbes may be recorded by distinctive chemical signatures. The first traces of life on Earth date back to early Archean, around 4 Ga in the form of chemofossils, but the microfossil record only extends to ~3.8 Ga. The best record of early life in sedimentary rocks from the Archean greenstone belts comes from carbon and sulfur isotopes in the form of chemical fingerprints, called chemofossils (Grassineau et al. 2006). Metabolic processes produce distinctive isotopic fractionations of carbon and sulfur isotopes. The residual $\delta^{13}\text{C}$ and $\delta^{34}\text{S}$ signatures in the sediments, found both in organic matter and in associated minerals, are particularly useful tools to understand the nature and extent of microbial activity. In living organisms, the light isotope of carbon (^{12}C) dominates the heavier isotope of carbon (^{13}C), whereas in inorganic limestones, carbon (^{13}C) is dominant. Another biosignature of early life is the sulfur isotope ratio. Intense biological sulfur cycling characterizes modern microbial mats as well as their ancient counterparts—stromatolites. A growing body of evidence suggests that life existed on Earth around 4 billion years ago in the form of chemofossils. The earliest indications of life on Earth come from isotopic measurements of biogenic carbon (^{12}C), preserved in a 4.1-billion-year-old zircon from Jack Hills, western Australia (Bell et al. 2015).

The next record of biogenic carbon (^{12}C) comes from the early Archean Akilia and Isua supracrustal rocks of Greenland, about 300 million years later than the carbon inclusions in Jack Hills (Fedo and Whitehouse 2002; Mojzsis et al. 1996; Rosing 1999). Unfortunately, these greenstone rocks of Greenland have been subjected to intense metamorphism, to the degree that any microfossils that may have existed have long since been destroyed by heat and pressure. The Greenland graphitic residues are enriched in ^{12}C to an extent that indicates

chemical traces of early microbial life (Mojzsis et al. 1996; Rosing 1999). Carbon isotopes of this type, however, cannot tell us which organisms were present in Greenland.

5.3.7.2 MICROFOSSILS AND STROMATOLITES: DIRECT EVIDENCE FOR LIFE

Microfossils are the preserved remains of microbial organisms. In the young Earth, the earliest life found are single-celled prokaryotes, such as bacteria and archaea. They are microscopic, only a few tens of microns in size, and need electron microscope to study. Early microbes are preserved as microfossils, in the forms of spheroids, ellipsoids, or filaments, given the presence of highly durable envelopes or extracellular membranes that resist postmortem decay. Similarly, stromatolites provide important proxy information on the distribution of microbial mat communities; they are laminated sedimentary structures accreted as a result of microbial growth, movement, or metabolism. As such, they are trace fossils of microbial activity and thus give less evidence for life than microfossils.

The record of Archean microfossils is sparse. Of the few authentic fossil assemblages, most are from shallow-water hydrothermal settings, and they are typically associated with laminated, stromatolitic sedimentary rocks. Some of the earliest habitable environments may have been hydrothermal crater lakes. Microfossils from deep-sea hydrothermal systems have not been reported in Precambrian rocks, although hyperthermophilic microbes are ubiquitous in modern seafloor hydrothermal settings (Rasmussen 2000). The microfossils from the Archean volcano-sedimentary rocks of the greenstone belts are discussed in the next section.

5.3.7.3 MICROFOSSILS FROM THE NUVVUAGITTUQ CRATON OF CANADA

The putative earliest microfossils (~3.7-Ga-old) from the Nuvvuagittuq craton on the eastern shore of Hudson Bay of Canada have been discovered in the form of tiny filaments and tubes in hydrothermal setting; they provided a habitat for Earth's first life-forms reminiscent of hyperthermophilic bacteria (Cates and Mojzsis 2007; Dodd et al. 2017). Today, they live around hydrothermal vents and grow as filaments, feeding on iron compounds and creating tube-shaped cavities in the sediment. Similar filaments contain iron compounds in the Nuvvuagittuq rocks and are attached to round clumps that resemble the tiny anchors that bacteria use to hold on to rock surfaces. The fossils were also surrounded by minerals containing phosphorous, an element incorporated into the building blocks of life and released by decaying organisms. The rocks also contain organic carbon (carbon-12) that has been created by bacteria. Although the recognition of ancient microfossils through morphology turns out to be difficult, there are chemical traces of life within Precambrian rocks that very often provide positive identification (Brasier et al. 2002; Schopf et al. 2007; van Zullen et al. 2002).

5.3.7.4 STROMATOLITES FROM THE ISUA CRATON OF GREENLAND

The Isua rocks are known to contain a unique biogenic carbon signature (Mojzsis et al. 1996; Rosing 1999), but it was unclear whether the signature had been created by ancient life-forms or changes caused by heat and pressure. Recently, Nutman and co-workers reported stromatolites of possible bacterial origin from 3.7-billion-year-old Isua Greenstone Belt in Greenland in a shallow marine carbonate setting (Nutman et al. 2016). They were identified by rare earth and yttrium trace elements, rather than a hydrothermal, lacustrine, or estuarine environments. These sedimentary rocks, created by ancient storms, contain evidence of ripple marks. Sequestered in the middle of the sedimentary layers are structures resembling stromatolites—microbially mediated macroscopic structures. The biogenic stromatolitic structures are about 1–4 cm high and have an overall conical shape with low amplitude and internally a finely layered texture. Stromatolitic structures are compositionally distinct from interlayered bedded sedimentary structures, but there are no organic or cellular remains. As the product of cyanobacterial communities, Greenland stromatolites suggest that life had attained a certain degree of sophistication and complexity around 3.7 billion years ago. The chemistry of life favors a terrestrial origin, rather than oceanic. By that time, cyanobacterial life may have invaded shallow seas from the hydrothermal crater basins and used solar energy for photosynthesis. It follows from this find that some considerable amount of time had probably passed with the emergence of cyanobacteria since the origin of life itself. The fossil evidence of cyanobacterial stromatolites from the Isua Greenstone Belt however push the origin of hyperthermophilic life back further, near the start of the Earth's sedimentary record; this corroborates with the genetic molecular clock that placed life's origin in the Hadean Eon (>4 Ga) (Hedges 2002). This find, if confirmed, would make these stromatolitic fossils the oldest direct evidence of microbial life on Earth.

5.3.7.5 THE VAALBARA SUPERCONTINENT OF AUSTRALIA AND SOUTH AFRICA

The Warrawoona Group of the Pilbara craton in western Australia and the Onverwacht Group of the Kaapvaal craton in South Africa host some of the oldest and best-preserved early Archean microfossils in the world from the hydrothermal volcano-sedimentary rocks. These microfossils provide crucial evidence for the habitat and nature of early life on Earth in the ancient Vaalbara continent. The stunning correlation of the Onverwacht Group with the Warrawoona Group suggests that South Africa and western Australia were spatially contiguous in the Earth's oldest supercontinent Vaalbara that formed beginning 3.6 Ga and was broken apart by ~2.8 Ga (De Koch et al. 2009; Zegers et al. 1998). The rock types of Onverwacht and Warrawoona groups consist of several kilometer-thick piles of impact-generated basaltic to

komatiitic lava flows interbedded with sediments that were completely silicified to chert by hydrothermal activity. Fossil microorganisms from these chert horizons suggest that single-celled bacterial and archaeal lives in the form of microscopic filaments and spheres were already thriving ~3.5 Ga, leaving a much narrower window than previously thought for life to develop in the Archean world. Those early cells were complex enough to imply that long chains of evolutionary steps preceded the fossil record. The finding of microfossils from the greenstone belts of western Australia and South Africa shrink that window to a mere 400-million-year time span. In the Vaalbara supercontinent, there is evidence for four large bolide impacts that created large craters, deformed the target rocks, and altered the environment. These impacts left their imprint for the next 300 million years between 3.5 Ga and 3.2 Ga in both the Pilbara and Kaapvaal cratons, as documented by four horizons of spherule/ejecta layers when life had diversified (Byerly et al. 2002).

It appears that early life was tougher and more resilient than is usually believed and survived catastrophic bombardments in benthic vent environments. Given the variety of fossil biosignatures likely to survive in hydrothermal deposits, the possibility that ancient microbial life survived in hydrothermal niches has important implications for tracing the earliest forms of life (Furnes et al. 2004; Räyssenbach and Cady 2001; Westall et al. 2001). Hydrothermal cherts associated with well-preserved pillow lavas (~3.5 Ga) are a major component of Archean greenstone belts that show promising sites for tracing ancient microbial activity. The presence of microbial remains in hydrothermally silicified crater floor sedimentary rocks would not be surprising, as hydrothermal crater systems in the early Archean have been suggested as favorable habitats for early life (Chatterjee 2015, 2016, in press; Cockell 2006; Osiniski et al. 2013). In Vaalbara supercontinent, both the Pilbara and the Kaapvaal cratons are two pristine Archean greenstone belts (~3.6–2.7 Ga) of continental lithosphere that have yielded the earliest known life on Earth.

5.3.7.6 MICROFOSSILS AND STROMATOLITES FROM THE PILBARA CRATON OF AUSTRALIA

The Pilbara craton of western Australia is one of the rare geological regions that provide insight into the early evolution of life on Earth (Wacey 2012). The 30-km-thick Pilbara Supergroup contains one of the best and most prolific sections of Archean volcano-sedimentary rocks and is a valuable site for searching early cellular life. The oldest sequence is the Warrawoona Group (~3.5–3.4 Ga), which is interspersed with thin chert horizons and felsic volcanic rocks and is overlain by the Kelly Group. There are three potential horizons within the Warrawoona volcanoclastic rocks that may contain evidence for Earth's earliest life. These formations, from the oldest to the youngest, are the Dresser Formation (~3.49 Ga), the Apex Chert (~3.46 Ga), and the Strelley Pool Formation (~3.43 Ga). Carbonaceous remains and possible remnants of cell walls from the hydrothermal black cherts of the Warrawoona Group suggest that hyperthermophilic bacteria and archaea

were the major contributors to the ancient microbial activity. Moreover, the diverse Warrawoona fossils indicate that the two domains of life, bacteria and archaea, were already split from the LUCA during this time, supporting the view that life originated on Earth at least 600 million years earlier, as indicated by the chemofossils from Jack Hills of western Australia (Bell et al. 2015).

The Dresser Formation (~3.49 Ga) at the North Pole area of the Pilbara craton is a complex volcano-sedimentary unit, long known for the earliest record of stromatolites, but their biogenicity has been debated over three decades. Chert-barite beds of the Dresser Formation are a very promising source of microbial remains due to the occurrence of biogenic carbons within low-stress thermal stress environments. Hyperthermophilic microfossils that lived in methanogenic vent environments have been found in bedded chert and hydrothermal black silica veins in the Dresser Formation (Ueno et al. 2006). Two types of filaments are found in the bedded chert, unbranched and tubular, perhaps representing methanogens or methane-producing hyperthermophilic archaea. Recently, Djokic and co-workers discovered a diverse variety of microbial activity and stromatolites from the Dresser Formation in terrestrial hot spring deposits (Djokic et al. 2017). They posited that the deposits were formed on land, not in the ocean, by identifying the presence of geyserite—a mineral deposit formed from near-boiling-temperature, silica-rich fluids that is only found in terrestrial hot springs and hydrothermal craters. This shows that a diverse variety of life existed in freshwater, as well as on land, very early in Earth's history. While stromatolites are commonly found in warm, shallow marine environments, such as Shark Bay in western Australia, they are also found in many freshwater hot springs around the world.

Noffke and co-workers (2013) reinterpreted the stromatolites from the Dresser Formation. They identified various morphotypes of stromatolites, including domal, nodular, wavy-laminated, conical, and stratiform, that thrived in coastal flat environments. They suggested that the microbial mats that produced these stromatolites could be anoxygenic photosynthetic bacteria. If this interpretation is correct, complex photosynthetic communities appeared fairly quickly through mutation, evolving from hyperthermophiles during the origin and early evolution of life. This discovery suggests that microbial life invented photosynthetic machinery from H₂S earlier than previously thought and changed its habitat from benthic to planktonic.

Perhaps the most famous and controversial evidence for Archean life comes from a chert unit within the Apex Basalt Formation (~3.46 Ga) of the Pilbara craton. The microbial assemblage of the Apex chert includes 11 taxa of filamentous microorganisms, which are allied to cyanobacteria (Schopf 1993, 1999). However, doubts about the biogenicity of the Apex microfossils have been raised (Brasier et al. 2002) and rebutted (Schopf et al. 2007). In my estimation, the Apex microbial fossils are among the oldest evidence of bacterial remains, but a cyanobacterial affinity cannot be decided by the filamentous morphology alone. Given that the filamentous microfossils are encased in hydrothermal silica, barite,

and native metals, it seems likely that the Apex microbiota were ancient hyperthermophilic bacteria and archaea, not cyanobacteria (Pinti et al. 2009; Raysenbach and Cady 2001; Schopf et al. 2007).

The Strelley Pool Formation (~3.43) has emerged as one of the best sequences for the study of early life on Earth, where both stromatolites and microfossils have been discovered. The formation is sandwiched between the Warrawoona and the Kelly Groups in a shallow water environment. The stromatolites complex morphology occurred in a silicified carbonate unit which was most likely biologically mediated (Wacey 2012).

Discovery of filamentous microfossils of sulfur-based bacteria from the Sulfur Springs Group (~3.2 Ga) indicates the proliferation of thermophilic bacterial life in hydrothermal vent environments (Rasmussen 2000; Wacey et al. 2011). The fossils are very clearly preserved, showing cell-like structures all of a similar size. The cells are clustered in groups, and associated with pyrite grains. These microfossils possibly represent anoxygenic photosynthetic bacteria like our modern sulfur bacteria. Apparently, these primitive anoxygenic bacteria used bacteriochlorophyll pigment to tap sunlight and produced glucose and sulfur as by-products. Pyrite crystals associated with the microfossils are very likely the by-products. The sulfur bacterium has been thought to be an important transition during the evolution of cyanobacteria.

5.3.7.7 MICROFOSSILS AND STROMATOLITES FROM THE KAAPVAAL CRATON OF SOUTH AFRICA

Like the Pilbara craton of Australia, the Kaapvaal craton of South Africa is another rare archive for the earliest remains of life, especially the emergence of primitive hyperthermophilic bacteria and archaea from the hydrothermal cherts associated with pillow lavas (Furnes et al. 2004). The Barberton Greenstone Belt of the Kaapvaal craton contains the oldest known volcano-sedimentary sequences that have yielded evidence for Archean life. The 23-km-thick Swaziland Supergroup of the eastern Transvaal is one of the oldest, relatively unmetamorphosed volcanic and sedimentary sequences on Earth. The Swaziland Supergroup is divided into the basal volcanic-sedimentary Onverwacht Group, followed in the middle by the succeeding sedimentary Fig Tree Group, with the Moodie Group at the highest level, all containing tantalizing evidence of early life. Strata of the Onverwacht Group (~3.5 Ga) are composed mainly of volcanoclastic chert alternating with basalt layers, mimicking the sequences of the Warrawoona Group of the Pilbara craton, Australia. Both groups contain four distinct layers of impact spherules and are regarded as promising niches for the Earth's oldest fossils (Byerly et al. 2002).

Paleontological and geochemical studies have provided evidence for the existence, as early as 3.8 Ga, of a rich microbial ecosystem, possibly hyperthermophilic methanogenic archaea and bacteria (Cockell 2006; Dodd et al. 2017; Farmer 2000; Kring 2000; Osinski et al. 2011; Parnell et al. 2004; Sapers et al. 2015; Ueno et al. 2006). In this environment,

microbes colonized in the impact glasses of melt rocks, extracting energy and nutrients from the glass by dissolving it and leaving indirect biomarkers that reveal their former presence. The microbial community is directly preserved as filamentous and spherical structures of carbonaceous matter and microbial mats in cherts (Banerjee et al. 2006; Glikson et al. 2008; Walsh 1992; Westall et al. 2001). Westall and co-workers reviewed the bacterial fossils from the finely laminated Onverwacht cherts (~3.3–3.5 Ga) and recognized small spherical and rod-shaped structures of biogenic origin (Westall et al. 2001). Walsh and co-workers reported long, filamentous microfossils from the Onverwacht Group (Walsh and Lowe 1985). In the 3.5-billion-year-old lavas from the Barberton Greenstone Belt in South Africa, Banerjee and co-workers have discovered mictrotubules apparently bored by hyperthermophiles that resemble modern microbe borings (Banerjee et al. 2006). The microbes etched their way into the lava flows of the seafloor in the Archean Eon. The margins of the tube contain organic light carbon, suggesting that microbial life colonized these underwater volcanic rocks around hydrothermal vents. This biologically mediated corrosion of synthetic glass is a well-known phenomenon in the microbial world (Furnes et al. 2004). The geologic setting of the Onverwacht Group suggests that underwater volcanic rocks were the likely habitats of early hyperthermophilic microbial life in much the same way as modern black smokers or hydrothermal crater lakes.

Tice and Lowe (2004) found anoxygenic photosynthetic microbial mats, from the Buck Reef Chert (~3.4 Ga) of the upper Onverwacht Group, preserved in shallow marine environments, supersaturated with silica. Although these microfossils have been altered by metamorphism, they show filamentous structures, and the organic matter preserved in these rocks appears to be of biological, not hydrothermal, origin. The bacteria that inhabited the Earth at that time were anaerobic photosynthetic bacteria (such as purple and green bacteria) existing in a primitive ecosystem devoid of molecular oxygen.

The overlying Fig Tree Group consists of terrigenous clastic sedimentary units interstratified with volcanoclastic and volcanic rocks. It has yielded stromatolites, kerogens, and spheroidal microfossils from the chert bed (Byerly et al. 1986). Knoll and his mentor documented a well-preserved population of spheroidal carbonaceous microfossils that contains not only isolated individuals and common paired cells but also the intermediate stages of binary fission (Knoll and Barghoorn 1977). Another tantalizing discovery of early Archean life comes from the 3.2-billion-year-old Moodies Group in the form of bacterial cells associated with stromatolites in tidal-flat settings.

Noffke and co-worker described the microbial mats of anoxygenic bacteria from the siliciclastic tidal deposits of the Moodies Group (~3.2 Ga) of the of Kaapvaal craton associated with stromatolites (Noffke et al. 2006). These stromatolites reveal carpet-like, laminated fabric characteristics of microbial mats. This discovery suggests that siliciclastic tidal-flat settings became the habitat of thriving ecosystems

of anoxygenic photosynthetic bacteria. The microbial mats of anoxygenic bacteria (such as green and purple bacteria) created the sedimentary structures in the tidal flats of the Moodie Group. Similarly, Javaux and co-worker reported the oldest and largest Archean, organic-walled spheroidal microfossils from the siliciclastic deposits of the Moodies Group (Javaux et al. 2010). These large organic-walled microfossils suggest a cyanobacterial affinity.

In summary, life's first dawn on the young Earth began with hyperthermophilic bacteria and archaea and evolved to anoxygenic photosynthesizers and finally to oxygenic cyanobacteria; this phenomenon is fully documented in the fossil record of the Pilbara craton and the Kaapvaal craton of ancient Vaalbara supercontinent. Recreating that Vaalbara ecology, the evolution of microbial life is illustrated in the cross-section of three crater basins that flow from terrestrial to shallow marine setting and are dynamically interconnected by underground networks; this illustrates the emergence of Earth's first microbial life during the Archean Eon (Figure 5.3.4).

5.3.8 EVOLUTION OF THE ARCHEAN BIOSPHERE

A growing body of geochemical, stromatolitic, and morphological evidence suggests that the Archean microbial diversity arose around 3.2 Ga. Contemporary microbial mats provide insight into ancient microbial life and the processes of mineralization that led to the formation of certain sedimentary rocks. During the early Archean time, the land would be barren for visible life. Only in shallow freshwater crater lakes and intertidal marine basins, the accumulation of biofilms and microbial mats thrived, which were highly structured communities of prokaryotes. They were layered communities that continue to develop today as carpets, often many centimeters thick (Figure 5.3.4). The top surface layer, the canopy, primarily consists of oxygen-producing bacteria, the cyanobacteria. The cyanobacteria, together with anoxygenic phototrophs that carry out photosynthesis, sustain a remarkable diverse “understory” of other microorganisms. At the bottom of the crater lakes or deep oceans, at the hydrothermal vents, hyperthermophilic microbes proliferate in hot, deep, dark, and anaerobic environments, where sunlight is not available. The layered microbial habitats usually exhibit pH values close to neutrality (pH 6–8).

5.3.8.1 THE EARLIEST MICROBIAL MATS

Three distinct microbial regimes can be reconstructed from the Archean fossil records in stratified sequences from the bottom to the top: In the earliest stage, microbial mats of coexisting hyperthermophilic bacteria (such as Thermotogales) and archaea (such as Methanococcales) emerged concurrently in the early Archean and independently adapted a benthic, hyperthermophilic lifestyle around the vent of the hydrothermal crater basin (Figure 5.3.5). These hyperthermophiles were chemosynthetic and anaerobic, harnessing energy that was

stored in chemicals such as iron and hydrogen sulfide from the vent. An experimental study suggests evidence for the hyperthermophilicity of ancestral life (Akanuma et al. 2013). Recent phylogenetic analysis suggests that the first enzymes were fully adapted in those hot environment (Nguyen et al. 2017).

In the second stage of microbial evolution, anoxygenic photosynthetic bacteria evolved first in a thermophilic and then in a mesophilic environment. Nisbet and Fowler (1999) suggested that photosynthesis began as an adaptation of thermotaxis, a behavior in which an organism directs its locomotion up or down a gradient of temperature. There was a gradual change of temperature gradient and niche from extremely hot vent sites (hyperthermophilic) to the moderate temperature (thermophilic) near the surface of the crater basin, where the primitive, anoxygenic, photosynthetic bacteria (such as green sulfur bacteria and purple bacteria) began to appear in a hydrogen-sulfur world. These anoxygenic microbes initially tapped infrared thermal radiation from the hydrothermal vents below the photic zone. Geothermal light at otherwise dark and deep environments may have provided a selective advantage for the evolution of photosynthesis from a chemosynthetic microbial ancestor that used light-sensing molecules. Soon, the motile forms spread to the shallow water of the hydrothermal systems, where they shifted from a vent source of infrared radiation to direct solar radiation, using bacteriophyll pigment during photosynthesis. Green sulfur bacteria have a very high tolerance of sulfur; they are exclusively anaerobic and very oxygen-sensitive. In contrast, purple bacteria can tolerate oxygen and occur at a higher level, just below the cyanobacterial mat.

In the third stage of microbial evolution, advanced, oxygenic, photosynthetic bacteria (such as cyanobacteria) emerged at the water surface of the crater lake, adapting to a normal-water-temperature niche (mesophilic). As they began to harness the visible solar energy by using chlorophyll, cyanobacteria began to invade the global oceans and produced oxygen. The evolution of oxygenic photosynthesis in cyanobacteria, using chlorophyll rather than bacteriophyll, was crucial in creating the modern biosphere (Nisbet and Fowler 1999).

These vertically stratified temperature regimes and niche partitions in crater basins encouraged different kinds of microbes to adapt thermotolerance and diversify (Figure 5.3.5). As cyanobacterial life invaded the ocean surfaces from the hot- to the normal-temperature regime, the associated enzymes coevolved to keep life's chemical reactions going and shifted their optimal temperature range gradually to cooler environment (Nguyen et al. 2017). These researchers used a technique called ancestral sequence reconstruction to figure out what the enzyme's genes might have looked like at different points in the last 3 billion years. They edited *Escherichia coli*'s genes to make the bacteria produce those probable ancient enzymes and then looked at how the reincarnated molecules held up under different temperatures.

Both kinds of photosynthetic bacteria, anoxygenic and oxygenic, created distinctive stromatolite horizons in the Pilbara and Kaapvaal sequences that indicate their microbial activity

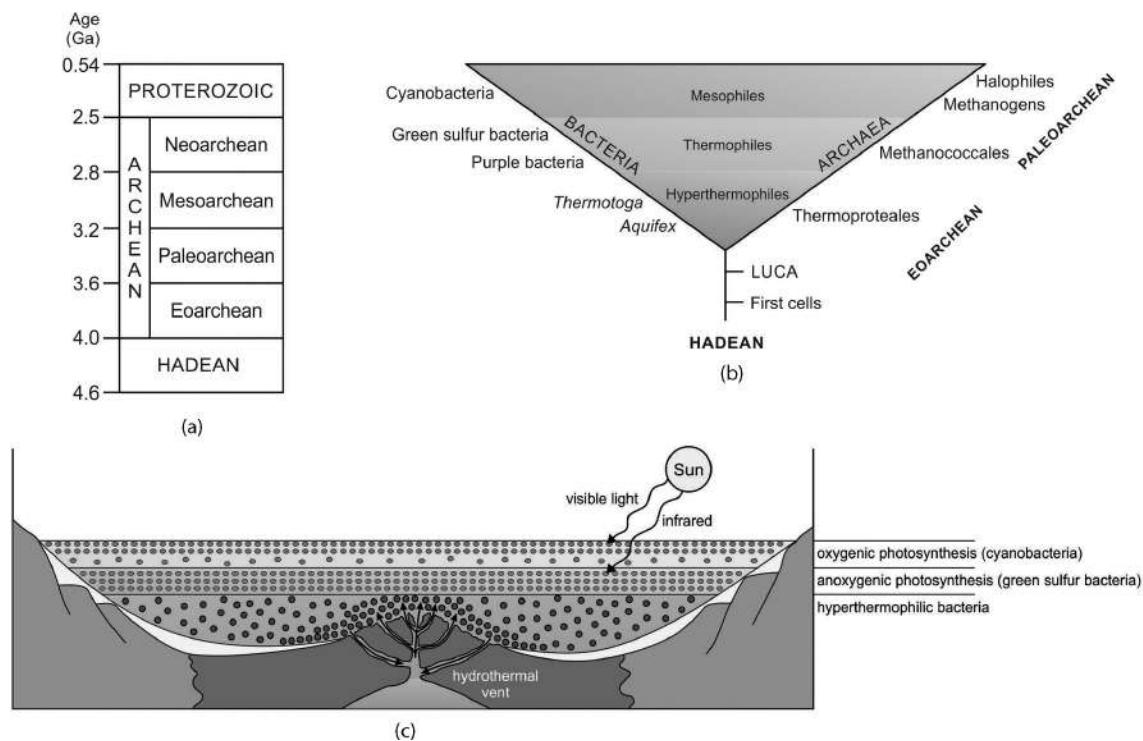

FIGURE 5.3.5 The evolution of the Archean biosphere (a) delineates the geological timescale of the Archean Eon, and (b) illustrates the origin and early evolution of life in an Archean hyperthermophilic, benthic crater lake. Two distinct domains of life, bacteria and archaea, are preserved in the fossil record (~3.5 Ga) of the ancient Vaalbara continent. Both domains show the gradual reduction of thermotolerance over time: from hyperthermophilic to thermophilic to mesophilic. In the first hyperthermophilic habitat, both bacteria and archaea appear. In the second, thermophilic habitat bacteria evolve as anoxygenic photosynthesizers. In the final mesophilic habitat, bacteria congregate at the upper surface of the crater lake; they begin to tap solar energy and evolve into oxygenic cyanobacteria. Over time, these cyanobacteria spread globally through the ocean and begin to produce oxygen. Hyperthermophilic archaea, on the other hand, evolve through two stages: as thermophilic Methanococcales and then as mesophilic Methanogens and Halophiles, the latter thriving in the hypersaline environment of ponds and lakes. (c) A cross-section of a hydrothermal crater lake showing the evolution of photosynthesis. This occurs through three stages of an evolving microbial community: first, on the bottom, hyperthermophilic bacteria emerge; next, in the thermophilic middle stage, the anoxygenic photosynthetic green sulfur bacteria appear; and in the final stage, at the upper mesophilic level, oxygenic photosynthesizing cyanobacteria form and begin the production of oxygen.

and distinctive habitats. Anoxygenic photosynthesis predates the oxygenic photosynthesis in standard phylogenetic models (Nisbet and Sleep 2001). Microbial mats are a unique ecological niche representative of early life on Earth. This is due, in part, to the persistence of fossilized mat counterparts, stromatolites. Rapid nutrient cycling across microgradients, coupled with putative niche differentiation within mat layers, enables diverse metabolic processes to occur in spatial proximity. On a broad scale, these early ecosystems of cyanobacteria on the top layer of the water surface played a major role in the oxygenation of the ocean and atmosphere, paving the way for oxygen-dependent life such as respiratory bacteria.

The hallmark of early bacterial and archaeal adaptation to novel environments, from benthic to planktonic, with decreased thermotolerance, might be linked to physiological differentiation and ecological opportunity, whereby evolved organisms interact with their environments differently than their ancestors. In bacteria, physiological change may be effected by a single-gene acquisition, perhaps mediated by horizontal gene transfer, as well as mutation (Doolittle 2000). Genes acquired by lateral transfer play a major role

in the evolution of microbial organisms that adapted to different habitats. Acquired genes can confer novel functions, allowing effective competition in new environments by virtue of the novel biochemical processes they encode. The early hyperthermophilic bacteria and archaea were entirely benthic and chemosynthetic and depended upon the chemical nutrients and energy from the vent environments. As these bacteria invaded the planktonic lifestyle near the water surface to become photosynthetic, they tapped new source of abundant energy from the Sun and became more mobile and widespread. Ecological differences in the hydrothermal crater lakes in stratified sequences allow for genetic isolation and rapid speciation of the microbial community in the Archean world (Figure 5.3.4).

5.3.8.2 METABOLIC EVOLUTION OF ARCHEAN MICROBIAL COMMUNITIES

Metabolism mediates the flow of matter and energy through the biosphere. Carbon is so important to living things that organisms are sometimes referred to as “carbon-based life.”

The acquisition of cellular carbon from CO₂ is a prerequisite for life, and it marked the transition from the prebiotic to the organic world. Early microbes that synthesized carbons contributed substantially to the evolution of planetary environments through numerous important geochemical processes. Early Archean microbes were essentially autotrophs. Autotrophs are the organisms that can derive some or all of their organic carbon and nutrients from inorganic sources. Autotrophs are capable of manufacturing their own food (such as sugars and carbohydrates). They take energy from the environment in the form of inorganic chemicals or sunlight. In the archaean, we see two major kinds of autotrophs: Chemoautotrophs, such as thermophiles, obtain chemical energy through oxidation in vent environments, and photoautotrophs, such as sulfur bacteria and cyanobacteria, obtain energy from sunlight. The chlorophylls of photoautotrophs capture solar energy and convert it to chemical energy stored in sugars and other organic molecules. The process is called photosynthesis. Autotrophs were the dominant microbes in the early Archean ecosystems and may shed light on the evolution of photosynthesis. Autotrophs are the producers of the food chain; they synthesize their own energy, creating organic compounds, which are consumed by heterotrophs. The Eoarchean ecology was dominated by autotrophs.

Autotrophs govern the isotopic composition of the living world. The isotopic makeup of autotrophs is largely controlled by the mix of isotopes in the gases and simple nutrients they take in from environment. For example, compared with atmospheric CO₂, autotrophs are enriched with organic carbon ¹²C. As discussed earlier, isotopic composition of chemofossils from the Eoarchean deposits provides reliable clues to the presence of autotrophs in the young Earth. Here, we discuss three kinds of autotrophs that prevailed during the early Archean biosphere: hyperthermophilic microbes, anoxygenic photosynthetic bacteria, and oxygenic photosynthetic bacteria. Much of our understanding of metabolic evolution of Archean microbes is based on our observations of extant life, yet we have no idea either of the degree to which extant life reflects early life or of how similar both might be.

5.3.8.2.1 Chemoautotrophs: Hyperthermophiles

The volcanic and associated sedimentary rocks containing the earliest record of life document an anaerobic Earth (Westall et al. 2015). Anaerobic conditions are mandatory for the emergence of hyperthermophiles. No prebiotic reactions can take place in the presence of oxygen because of the immediate oxidation of the reduced carbon compounds. This means that first cellular life was anaerobic and chemosynthetic; indeed, life continued to be anaerobic and hyperthermophilic until the advent of mutations that led to the innovation of photosynthetic metabolism. The first traces of life on Earth date back to early Archean, between 4.1 Ga and 3.8 Ga, in the form of chemofossils, microfossils, and stromatolites, which provide little clue to the habitat and nature of early life during the LHB. This is the time interval when the first cellular life and the LUCA originated in harsh environments (Woese 1994). Because the photic zone was vulnerable for large asteroid

impacts, life must have originated in sheltered benthic environment of hydrothermal crater lakes. The LUCA was hyperthermophilic, as molecular phylogeny suggests (Gaucher et al. 2003, 2008; Pace 1997). Small hydrothermal crater lakes may have hosted the first living systems on Earth; this is consistent with the hyperthermophilic origin of life (Chatterjee 2015, 2016, *in press*; Cockell 2006; Osiniski et al. 2013).

The oldest fossil evidence suggests that hyperthermophilic organisms were already present on Earth at least 3.8 billion years ago or even earlier (Dodd et al. 2017). Around 3.5 Ga, life was diversified into two distinct domains, bacteria and archaea, as revealed from the fossil record. The universal tree of life shows that both kinds of hyperthermophilic microbes evolved early, but archaea were more derived than bacteria (Woese 1987). Soon, there was a drastic change in the metabolism of microbes. Instead of thermal energy from the vent, they began to harness new source of energy from the Sun, when anoxygenic photosynthetic bacteria and oxygenic photosynthetic bacteria appeared in quick succession (Figure 5.3.5). These asexual microbes remained the only forms of life for more than 1 billion years, until the appearance of the first eukaryotes. It may have taken nearly half a billion years to evolve from the LUCA, with over 500 genes, to full-blown microbes such as Cyanobacteria, which contain more than 3000 genes (Koonin 2003). Bacteria and archaea shared genetic information by horizontal gene transfer that led to the rapid evolution of these two domains (Doolittle 2000). As the LUCA survived and evolved in the harsh environment of early Archean crater basins, it gave rise to two distinct domains, bacteria and archaea, as revealed from the microfossil record from the Pilbara and Kaapvaal cratons (~3.5 Ga), very early in the history of life.

Cumulative fossil evidences from the Nuvvuagittuq craton, the Isua craton, the Pilbara craton, and the Kaapvaal craton provide an unusual window into the origin and ecology of the Archean life. Surprisingly, three broad groups of fossil microbes, which are known from the Archean fossil record, include hyperthermophilic bacteria and archaea, thermophilic anoxygenic phototrophs, and mesophilic oxygenic phototrophs; they all survive today in hydrothermal settings, which provide critical information about the habitats of early microbial organisms (Figure 5.3.4). For examples, some hyperthermophilic communities in the Yellowstone National Park can grow into thick mats. Within those mats, hyperthermophile species may migrate up or down, depending on the water and air temperatures and other conditions, demonstrating that these communities are dynamic and ever-changing. This migratory behavior of early hyperthermophiles in hydrothermal crater vent environment may give rise to photosynthetic bacteria, as they migrate up to the water surface. Similarly, a diverse group of anoxygenic photosynthetic bacteria thrives in habitats characterized by extreme temperature, pH, or salinity. These anoxygenic phototrophs are optimally adapted to the conditions of their habitats and are ideal models for defining the physiochemical limits of photosynthesis. For example, the carbonate- and sulfide-rich Mammoth Hot Springs of the Yellowstone National Park contain rare

examples of laminated microbial mats formed by purple sulfur bacteria, which are precursors to cyanobacteria. They are anoxygenic photosynthesizers, which means that they harness energy for metabolism from light. These bacteria use hydrogen sulfide in chemosynthetic reactions, producing sulfur instead of oxygen as a by-product. Finally, there are many examples today of living cyanobacteria inhabiting geothermal habitats, as in the Archean world. For example, the hydrothermal Lonar Crater Lake in India and Haughton crater lake in Canada show cyanobacterial diversity in pelagic and benthic habitats (Hagerty and Newsom 2003; Parnell et al. 2004; Paul et al. 2016). All these modern examples of living bacteria in geothermal setting could be used to reconstruct the habitats of three distinct communities of early microbes in Archean time (Figure 5.3.5).

The hyperthermophilic microbes are of the size of a typical prokaryotic cell ($\theta \sim 0.5\text{--}2 \mu\text{m}$) and employ a variety of different morphotypes, including rods, thin filaments, disc, and cocci. Once life evolved, groundwater networks dispersed these early microbes, some going to larger hydrothermal crater lakes (Figure 5.3.4). There is evidence that hyperthermophily arose independently in the archaea and bacteria during the Archean Eon because of their similar adaptation at the high-temperature regime (Figure 5.3.5b) (Boussau et al. 2008; Nisbet and Sleep 2001). Hyperthermophilic bacteria (such as Thermotogales) and archaea (such as Methanococcales) appeared concurrently around the vent of the hydrothermal crater basin. The hydrogen-based ecosystem was the early driving energy. Hyperthermophilic bacteria and archaea probably used hydrogen and carbon dioxide, coupled with sulfur, for metabolism, whereas methanogenic archaea produced methane as hydrogen reduced carbon dioxide. Although the recognition of ancient microfossils just by morphology turned out to be very difficult, molecular phylogeny of microbes and their habitats for early life may provide important clue about their affinity. Microbial fossils from the Archean are consistent with hyperthermophily, based on morphological similarities with living prokaryotes. Carbonaceous matter from the hydrothermal black cherts (~3.5 Ga) of the Pilbara and Kaapvaal cratons has yielded transmission electron microscopy images that are suggestive of hyperthermophilic microbial life (Glikson et al. 2008). In these hot, Archean pillow lavas, only hyperthermophilic bacteria and archaea could survive (Furnes et al. 2004). An early evolution of archaea is supported by the discovery of ^{13}C -depleted methane in hydrothermal fluid inclusions in cherts from the Pilbara craton. Ueno et al. (2006) reported evidence for the existence of an ancient population of methane-producing archaea (Methanococcales) from the Dresser Formation (~3.5 Ga) of the Pilbara craton. Archaea produces only methane, suggesting that the split between the two domains of life, bacteria and archaea, must have occurred at least 3.5 Ga.

Life began very early in Earth's history, about 4 billion years ago, and achieved remarkable level of metabolic sophistication before the end of the Archean (~2.5 Ga). It thus appears that the Archean fossils from the Nuvvuagittuq, Isua, Pilbara, and Kaapvaal cratons provide crucial evidence for

three phases of environmental temperatures and niche adaptation over 300 million years: in the first period, hyperthermophilic bacteria and archaea adopted high thermotolerance around the vent of the crater basin, nourished by chemicals from spewing vents (Arndt and Nisbet 2012). In the second period, the thermotolerance decreased with the emergence thermophilic anoxygenic photosynthetic bacteria near the water surface; they used hydrogen sulfide to produce glucose and sulfur as by-products, powered by infrared. In the third phase, cyanobacteria adapted to the normal temperature regime at the water surface to become mesophilic; they used water to build glucose and oxygen as by-products, powered by visible sunlight. It thus appears that chemosynthesis preceded phototrophy (Figure 5.3.5).

5.3.8.2.2 Photoautotrophs: Anoxygenic Photosynthetic Bacteria

The advent of photosynthesis is one of the central events in the development of Archean microbial communities. Nisbet and co-worker suggested that photosynthesis began as an adaptation of thermotaxis (Nisbet and Fowler 1999). We know very little about the origin of photosynthesis, but Archean fossils give some clue. Early hyperthermophiles were entirely chemosynthetic and benthic and lived in proximity to the vents for energy and nutrition. Phototrophy is a process by which organisms trap light energy (photons) and store it as chemical energy in the form of ATP. There is suggestive evidence that photosynthetic organisms were present in the younger sequences of the Kaapvaal and Pilbara cratons (~3.4–3.2 Ga) in the form of stromatolites and microfossils, which are inferred from morphology or geological context (Javaux et al. 2010; Noffke et al. 2006; Westall 2004).

Photoautotrophic bacteria exhibit great diversity with regard to the biochemistry of photosynthesis. There are two kinds of photosynthetic bacteria: primitive (anoxygenic) photosynthetic bacteria (such as sulfur bacteria) and advanced (oxygenic) photosynthetic bacteria (such as cyanobacteria). Phylogenetic analysis supports that anoxygenic photosynthesis developed first. Though closely related, the two forms of photosynthetic bacteria, primitive anoxygenic and advanced oxygenic organisms, differ in their metabolism (Blankenship 2010; Schopf 1999). The primitive photosynthetic bacteria (such as green sulfur bacteria and purple bacteria) absorbed near-infrared rather than visible sunlight and produced sulfur or sulfate compounds rather than oxygen. They differ from oxygenic photosynthesis in the nature of the terminal reactants (e.g., hydrogen sulfide rather than water) and in the by-product generated (e.g., elemental sulfur instead of molecular oxygen). Therefore, water is not used as an electron donor. Anoxygenic phototrophs use molecules such as H_2S , as opposed to H_2O . Their pigments (possibly bacteriochlorophylls) were predecessors to chlorophyll. H_2S is supplied in the vent environment by geothermal activity, and the metabolism of anoxygenic phototrophs produces sulfur as a by-product and builds glucose, the universal cellular fuel. They use infrared instead of visible light for metabolism. The origin and evolution of photosynthesis have long remained enigmatic, owing to a lack

of sequence information of photosynthesis genes across the entire photosynthetic domain. Xiong and co-worker obtained new sequence information from the green sulfur bacterium *Chlorobium* and the green nonsulfur bacterium *Chloroflexus* and demonstrated conclusively for the first time that the major lineages of pigment (bacteriophyll) involved in anoxygenic photosynthesis arose before the development of oxygenic photosynthesis (chlorophyll) (Xiong et al. 2000).

The appearance of anoxygenic photosynthesis would have made shallow-level and subaerial hydrothermal systems much more productive. Anoxygenic photosynthetic bacteria in the Archean were still thermophilic enough to drive a primordial sulfur cycle. As hyperthermophiles originated in superheat vent environments, the association of anoxygenic bacteria with hyperthermophiles suggests that anoxygenic bacteria appeared in the surface environment of the crater lakes to trap solar energy while still adapting to the thermophilic lifestyle. They acquired global significance only after sulfate concentrations had considerably increased in the Proterozoic oceans. There are many examples of living anoxygenic phototrophs such as *Chloroflexus*, *Rosieflexus*, *Thermochromatium*, and *Chlorodium*, which are adapted to thermophilic habitat. Hydrothermal vents have the potential for hosting anoxygenic photosynthetic life (such as green sulfur bacteria), using infrared radiation emitted by hot water. Eventually, these anoxygenic photosynthetic bacterial would tap infrared radiation directly from the Sun as they became planktonic. There is little doubt that anoxygenic photosynthesis preceded the oxygenic photosynthesis, as suggested by the Archean fossil record from the Pilbara and the Kaapvaal cratons. The development of anoxygenic and then oxygenic photosynthesis allowed life to escape the hydrothermal setting. By about ~3.2 Ga, most of the principal biochemical pathways that sustain the modern biosphere had evolved.

5.3.8.2.3 Photoautotrophs: Oxygenic Photosynthetic Bacteria

By the late Archean, a more complicated form of photoautotrophy, the oxygenic photosynthesis, evolved, as manifested by cyanobacteria associated with their stromatolites. In cyanobacterial synthesis, the pigment is chlorophyll, hydrogen is always provided by water, and glucose and oxygen are given off as by-product. Solar radiation was overwhelmingly the new source of energy for cyanobacteria to access different chemistries rather than the energy provided by other sources, such as hydrothermal vents, because of the unique characteristics of photochemistry that differentiate it from conventional hyperthermal chemistry. The ecological transition of the Archean life from the benthic thermophilic life to the anoxygenic photosynthetic bacteria in the crater vent environment and finally to planktonic mesophilic cyanobacteria in the shallow marine environment was rather rapid, as documented in the Pilbara and Kaapvaal cratons (Figures 5.3.4 and 5.3.5b, c). However, we are left with the possibility that the photic (sunlit) zone could have been destroyed intermittently throughout the Archean Eon, as revealed by the spherule ejecta layers

between 3.5 and 3.2 Ga (Byerly et al. 2002). Perhaps, after the cessation of large bolide impacts after 3.2 Ga, obligate photosynthetic cyanobacteria could continuously evolve. This is the time when the paleontological record indicates highly evolved photosynthetic systems, transforming the atmosphere, and permitting the evolution of eukaryotes. The Archean fossils from South Africa and western Australia shed new light on the origin and early evolution of photosynthesis from their hyperthermophilic bacterial ancestors.

One of the most important developments in Earth's history is the change from the anaerobic environment of the early Earth to the aerobic and highly oxidizing environment that we have today, with 21% atmospheric oxygen. Although the "great oxidation event" that led to the oxygen bloom occurred on our planet in the early Proterozoic (~2.3 Ga) with the proliferation of cyanobacteria, the chlorophyll-based photosynthesis originated fairly early in the bacterial domain in the Archean (~3.2 Ga). This led to the onset of global oxygenation in the atmosphere-biosphere system in the early history of the Earth. The accumulation of oxygen in our atmosphere was an exceedingly protracted process. It is still enigmatic how the early cyanobacteria developed the ability to oxidize water and produce oxygen as a by-product (Figure 5.3.5). Photosynthesis generates a distinctive chemical signature in the form of a carbon isotopic, composed of the organic material produced. During photosynthesis, ¹²C (carbon-12 in CO₂) is selectively absorbed by the photosynthetic machinery, compared with ¹³C (carbon-13); that is, it reacts faster with the enzymatic system and is therefore selectively incorporated into the organic compounds produced. The carbon-12 isotope ratio has been used to trace the early evidence of life in Greenland ~3.8 Ga (Mojzsis et al. 1996).

Phylogenetic studies of 3,983 gene families across the three domains of life onto a geological timeline suggest the rapid evolutionary innovation of microbial life during a brief period in the Archean Eon around 3 Ga, which coincides with a rapid diversification of bacterial lineages and genetic expansion; the microbial gene expansion was mediated by gene duplication and horizontal gene transfer. Genes arising after this expansion show the increasing use of molecular oxygen and redox-sensitive transition metals such as iron and nickel (David and Alm 2011; Doolittle 2000).

5.3.8.3 RADIATION OF ARCHEAN MICROBIAL COMMUNITIES

Life has been built on the evolution and innovation of microbial metabolisms. Microbes have become integral components of the biogeochemical cycles that drive our planet. Life may have originally started on the crater floor of deep and dark hydrothermal vent environments, when oxygen was not yet present in the water or atmosphere, but life would ultimately spread into vast sunlight-exposed ocean surfaces. Early microbial evolution refers to that phase of biological history that began with the emergence of life-forms such as hyperthermophiles, followed by purple and green sulfur

bacteria in the anaerobic environment and the explosive diversification of aerobic photosynthesizers such as cyanobacteria. Initially, hyperthermophiles and anoxygenic photosynthesizers clustering around hydrothermal vents may have been great contributors to microbial metabolisms in early Archean. Eventually, oxygenic photosynthesis would evolve and eclipse its anoxygenic cousins, becoming the driver of the global carbon cycle.

The development of oxygenic photosynthesis by cyanobacteria around 3.2 billion years ago, or even earlier, transformed Earth forever. This grand biogeochemical shift set into motion the evolution of subsequent microbial metabolisms and lifestyles. The abundance of life on Earth is almost entirely due to oxygenic photosynthesis. Once life emerged on Earth, it proliferated across the global ocean by mutation through Darwinian evolution. The ability of oxygenic photosynthetic bacteria to capture hydrogen by splitting water was an extraordinary innovation in the microbial community. The virtually unlimited supply of hydrogen in water freed life from its sole dependence on the abiotic chemical sources found in hydrothermal vents. Communities sustained by oxygenic photosynthesis could thrive wherever supplies of sunlight, water, and nutrients were sufficient. Three billion years later, photosynthesis continues to play a vital role in regulating atmospheric levels of oxygen and carbon dioxide. Photosynthetic microbial communities have left a relatively robust fossil record because of their extremely high productivity on stable continental shelves; this contributed to sediments with excellent potential for long-term preservation. Although cyanobacteria emerged during the mid-Archean or even earlier, their microfossil record is robust throughout the Proterozoic.

The oxygen, as the result of photosynthetic activity by cyanobacteria, was so pervasive and so productive that it eventually reached levels sufficient to drive the emergence of respiratory bacteria, eukaryotes, and complex multicellular life in the Proterozoic. The endosymbiotic merging of cyanobacteria with respiratory bacteria drove a complex eukaryote biosphere (Margulis 1981). The origin of eukaryote cells is considered a milestone in the evolution of life, because they comprise all multicellular organisms—plants, fungi, animals, and us. Without eukaryotes, we wouldn't be here to discuss the question of the origin of life. The fossil record doesn't tell much about the time of their origin. The oldest fossil record of eukaryotes goes back 2.7 billion ago, with the discovery of eukaryotic biomarkers in ancient oil. The oldest eukaryotic body fossil is *Grypania spiralis* from the 2.1-billion-year-old Negaunee Iron Formation of Michigan. Molecular evidence suggests that three domains of life—bacteria, archaea, and eukaryotes—appeared in the Archean Eon (Arndt and Nisbet 2012). For eukaryotes to thrive, oxygen had to be present in the atmosphere in higher amounts than what existed on early Earth. A great diversity of microbial and aerobic habitats must have existed in the late Archean time. Eukaryotes are more closely related to archaea than to bacteria, at least in terms of nuclear DNA and genetic machinery (Woese 1987; Woese et al. 1990).

5.3.9 SUMMARY

Earth is approximately 4.6 billion years old. Massive bolide bombardments of the planet took place during the first 500 million years, followed by the LHB (~4.1–3.8 Ga). The young Earth, upon which first life was eventually to appear, was very different than today. It was dominated by violent meteoritic impacts associated with strong volcanic and hydrothermal activities. Comets and carbonaceous asteroids delivered large amount of building blocks of life to the primitive Earth, thus playing a vital role in the origin of life. Extraterrestrial bolide impacts were more numerous and larger during the LHB, which created thousands of impact crater lakes with hydrothermal systems across the proto-continents. But instead of sterilizing the planet, the impacts encouraged microbial life to emerge. In these sequestered crater lakes, the cosmic building blocks of life concentrated and were churned by convective currents, producing more complex organic compounds. The chemicals and energy found in these hydrothermal crater lakes fueled many of the chemical reactions necessary for prebiotic synthesis and the resulting emergence of life. The chemical nature of the hydrothermal crater lakes, with their neutral pH and high K^+/Na^+ ratio, resembles the living cell's cytoplasm more closely than that of the submarine hydrothermal vents. There are striking parallels between the chemistry of the living cell's cytoplasm, present in terrestrial hydrothermal systems, and the core energy metabolic reactions of some modern microbial communities. The hypotheses that life originated in a very hot environment is supported by present-day hyperthermophiles, which are the direct descendants of the LUCA. Here, I argue that Eoarchean hydrothermal crater lakes provided the stable, anaerobic, and hot environments in which hyperthermophilic life could have emerged and become established. These terrestrial hydrothermal crater lakes were geochemically reactive in the far-from-equilibrium setting and contained an assortment of cosmic and terrestrial organic compounds. The hydrothermal vent was powered by volcanic, chemical, and solar energies and created convection cells that drove the prebiotic synthesis into more complex organic molecules, initiating molecular symbiosis and providing physically and chemically diverse and secured habitats for microbial life. The widespread occurrence of hydrothermal crater lakes on the Eoarchean crust has led to the suggestion that such environments may have constituted the crucible of life on Earth. It was on this chaotic and violent Earth, before the onset of plate tectonics, around 4 billion years ago, that first life probably emerged in hydrothermal crater lakes. The atmosphere was anoxic, consisting mostly of CO_2 .

Other settings have been proposed for the prebiotic synthesis for life, most notably the submarine hydrothermal vents, but this popular theory has several drawbacks: (1) large global oceans extended from pole to pole during the Eoarchean; in this vast ocean, cosmic and terrestrial biomolecules could not be concentrated into a compact environment because of the vastness of the oceans; organic compounds would be diluted and

dissipated, prohibiting the assembly of the complex molecules of life; (2) submarine hydrothermal vents could not be formed at the spreading ridge axis, because plate tectonics did not start at that time, and there was no spreading ridge; (3) the chemistry of modern cellular fluid is drastically different from that of ocean water, thus affirming that life could not have started in the ocean.

The paleoecology Earth's earliest fossil records favor impact-generated hydrothermal systems as the most likely incubators for biosynthesis. Impacts during the LHB played a seminal role in shaping the Eoarchean and Paleoarchean volcano-sedimentary sequences (evident in the greenstone belts in Canada, Greenland, South Africa, and western Australia) and in the emergence of early microbial life. Fossil records suggest that both hyperthermophilic bacteria and archaea appeared simultaneously, followed by the evolution of anoxygenic photosynthetic bacteria and then oxygenic photosynthetic bacteria. The arrival of oxygenic photosynthesis allowed life to escape the hydrothermal setting and invade an utterly new frontier—broad continental shelves. Cyanobacteria contributed to the geological processes by producing vast amounts of carbonate sediments and stromatolitic structures in the shallow seas; they formed oxygen as the by-product, transforming the ocean and the atmosphere around 3.2 billion years ago and triggering an explosive evolution. This development led to the origin of eukaryotes.

ACKNOWLEDGMENTS

I thank Vera M. Kolb for inviting me to contribute this article in *Handbook of Astrobiology* volume and for critically editing the manuscript. I owe an immense debt of gratitude to the many authors, who have helped me with their thoughtful, well-documented, and enlightening expositions in the origin of life research. I thank David Deamer for his insights and Oliver McRae for reading the manuscript and helpful suggestions. I thank Oliver McRae, Volkan Sarigul, and Jeff Martz for illustrations. This work was supported by P. W. Horn Professor grant from Texas Tech University.

5.4.1 INTRODUCTION

In this chapter, the role of hydrothermal systems in prebiotic evolution is exposed. When Oparin and Haldane presented the first scientific explanation about the origin of life in the late 1920 decade, neither the Earth's structure nor its dynamics were understood. Oparin started exposing his ideas about the origin of life at a time when plate tectonics was not an existing theory, and yet, he considered a possible relationship between igneous processes and chemical evolution (Oparin 1936 in Holm 1992). Later, the first experiments performed by Miller and Urey in 1953 highlighted the role of the atmosphere and ultraviolet (UV) radiation in chemical evolution (Miller 1953). Such experiments considered some of the geological variables known at the time, which were only a promising start in comparison with the present wealth of knowledge about the Earth's dynamics and history. However, the arrival of new knowledge led to new paradigms.

Little is known about the first stages of the Earth, since geological evidence has been wiped out by erosion, modified by metamorphism, or concealed by later rocks. The oldest the geological records the poorest its preservation Step by step, geologists have contributed to solve the puzzle and new evidence is still comes to come to better understand those epochs. Even so, the study of the origin of life has matured based in part on the growing geological evidence. One amazing breakthrough that brought with it a completely new wealth of knowledge was the discovery of submarine hydrothermal vents in the 1980 decade. Among other side effects, such discovery promoted many attempts in order to connect these systems with the origin of life on Earth.

Hydrothermal vents are environments that could have been important for chemical evolution since they harbor a great combination of physical, chemical and geological conditions that probably conditioned prebiotic synthesis. In this chapter, the role of such systems in prebiotic chemistry will be

discussed. With this aim, we focus on (1) characterizing the link between the origin of life and hydrothermal systems, (2) the variety of geological settings that could have accounted for chemical evolution, by describing the main geological variables that could have contributed to chemical evolution, and (3) presenting a review of the types of experiments that have been performed in order to model prebiotic reactions in hydrothermal systems.

5.4.2 THE LINK BETWEEN THE ORIGIN OF LIFE AND HYDROTHERMAL SYSTEMS

The study of the origin of life is a very complex matter, provided that the emergence of life depended largely on variables and events that cannot be observed in the meantime. In fact, many of them have left little or absolutely no trace in the geological record (Cleaves 2013). Some facts await more evidence for their fully understanding; among them are (1) the nature of the atmosphere, (2) the amount and action of different types of energy, and, most importantly, the available amount of them for organic synthesis, (3) the temperature at the planet's surface, and (4) the pH of the oceans and their salinity, to name some of the most relevant unknowns (Delaye and Lazcano 2005). All these variables certainly conditioned the reaction of molecules on Earth and other bodies in the solar system; of course, they determined the emergence of life and its evolution in our planet. In fact, even if the time, place and mode in the origin of life are not fully understood (Walker 2017), life in this planet came out from the fortunate convergence of physical, chemical and geological processes.

As emphasized by Walker (2017), the research on origin of life started historically as a chemical problem. This was a natural consequence of the development of organic chemistry and biochemistry on the twentieth century that made possible the understanding of the metabolic pathways and the genetic coding of living beings (Schwille 2017). The main attributes of life are known, although life itself is not fully understood. The incomplete knowledge of the rules that underlie the biological processes has not thwarted the research nonetheless. The first experiments were thus designed to synthesize organic molecules known to be relevant for living beings: amino acids, nucleic bases, sugars, and carboxylic acids, among the most important ones.

The geologic time scale on Earth defined the Hadean Eon, as the time running from the origin of the Earth as a planet ~4.65 to 4.0 Ga (International Commission on Stratigraphy 2017), when the oldest vestiges of continental crust had been found. If the planet is as old as 4.6 Ga (Jacobsen 2003) and the oldest true fossils were dated at 3.4 Ga (Wacey et al. 2011a, 2011b), life must have appeared and evolved much earlier than the latter. The inclusion trails in sandstones of the Strelley Pool in Australia (dated at 3.4 Ga) when analyzed by nanoscale secondary ion mass spectrometry (NanoSIMS) indicate that their formation is the result of biological activity (Wacey et al. 2008). Evidence suggests that life emerged in a relatively short geological time in our planet (Bada and

Lazcano 2009). If the available geochemical evidence is analyzed, there is a gap of 1 Ga during which the chemical reactions that preceded the life must have occurred. However, there is not much information about the rhythm or rate of chemical evolution (Cleaves 2013).

Lazcano and Miller (1994) suggested that it took a few million years for life to originate from a completely inert world. The precedent hypothetical period before the origin of life has been called "*chemical evolution*." This term includes all the chemical processes that led to the formation of relevant organic compounds, those that structurally, genetically, or metabolically constitute present living beings. This is a fundamental point, provided that life is crucially organized along these three axes: structure, metabolism, and genetics (Ruiz-Mirazo et al. 2014).

5.4.2.1 PREBIOTIC CHEMISTRY

The synthesis of complex molecules must have required simpler molecules as raw material and the action of one or more energy sources to induce reactions. If those conditions were fulfilled then the synthesis of more complex organics would have been possible. An energy source could be considered as any physical or chemical process that triggered chemical prebiotic reactions (Stüeken et al. 2013). The relevance of a source was directly related to its availability, abundance, and its ability to promote reactions in specific environments on prebiotic Earth. In chemical evolution studies, to determine the best suitable location for chemical reactions to occur constitutes a major question. Different environments were subjected to diverse energy sources.

Undoubtedly, the most abundant energy source on primitive Earth by far was cosmic rays; these are charged particles (electrons, neutrons, and atomic nuclei) accelerated by astrophysical sources and that originate beyond the Earth's atmosphere, and they constituted the main source of ionizing radiation (Ferrari and Szuszkeiwicz 2009). The advantage of ionizing radiation is their ability to form free radicals that quickly react to form more stable species. This energy source was effective for promoting reactions in almost every environment due to its penetrating power.

For a long time, UV radiation, emitted by the Sun, was considered the most important energy source for the early Earth. It was capable to generate photolytic reactions in the atmosphere; this kind of reactions is still important on the planet and determines the atmospheric chemistry. Another energy source is shock energy originated by the impacts of different objects, such as meteorites and comets, and it was very important during the early stages of the planet, when the planetesimals that did not accrete impacted the inner planets, including Earth (Chyba and Sagan 1992).

Radioactivity due to the decay of radionuclides was also relevant, even if it was undervalued for many years, since it was thought that its main effects were confined to the lithosphere (Miller 1993). However, it is now known that radiogenic atoms were also abundantly produced in the atmosphere, and some of them (*i.e.*, ^{40}K) might have also been present in water

bodies in which they could have promoted many chemical reactions (Draganić et al. 1991). Geothermal energy, responsible for processes such as mantle convection, plate tectonics, and hydrothermal circulation (Stüeken et al. 2013), has been traditionally underestimated as well. Geothermal energy generated by volcanoes and hydrothermal springs was capable of promoting the synthesis by pyrolysis of organic compounds; even so, besides its direct contribution as heat, this energy also can result in electrochemical energy (Stüeken et al. 2013).

Nature itself is a continuum and environments are not isolated but connected, which must also have been the case in primitive environments. Accordingly, energy sources must have acted simultaneously to promote chemical reactions. This means that some specific environment must have been under the influence of different energy sources, and that the products that were synthesized by a sole energy source could be modified later by another one.

Some environments have been considered as the most plausible for chemical synthesis on prebiotic Earth. The supply of organics and the presence of energy must be a requisite in them. The atmosphere, the water bodies, the interfaces, and the hydrothermal environments (Cleaves 2013) all meet the requisites of holding organics and energy. They also represent the main plausible scenarios in which chemical reactions could have occurred on early Earth. For instance, the composition of the atmosphere determined the nature of the chemical reactions that could have taken place in it. The atmospheric composition was very important not only for the synthesis, but it also affected the amount of radiation that reached the surface (Cnossen et al. 2007) and determined its density. Consequently, it also determined the erosion that experienced bodies (such as comets, asteroids, and dust) when entering the atmosphere (Chyba and Sagan 1992). As a result, the atmosphere composition also affected the type and flow of organic compounds that reached the surface of early Earth (Cleaves 2013). Another relevant factor was the availability of continental areas, which allowed the concentration of some organics by evaporation. In those environments, the action of solar radiation was also combined with the presence of minerals that could have acted as surface concentrators or catalyst of reactions.

However, depending on the aggregation state, the type and abundance of molecules, and the availability of energy, some places surely were more efficient in promoting synthesis than others. In chemical evolution, to determine the best suitable location for chemical reactions to occur constitutes a major question, and here relies the importance of analyzing contemporary natural environments. Just by understanding the variables present in such places, more realistic experiments can be designed in prebiotic chemistry studies. Hydrothermal vents constitute natural complex environments in which many variables interact and can be characterized in active systems. Some environmental variables in such systems would have contributed to the increase in complexity of molecules on primitive Earth, whereas others would have inhibited it (Cleaves 2013), even in association within a single hydrothermal manifestation. As explained in the next section, several

types of hydrothermal systems may meet the physicochemical requirements for hosting and promoting prebiotic reactions.

5.4.2.2 THE RELEVANCE OF OCEANS AND HYDROTHERMAL VENTS FOR PREBIOTIC CHEMISTRY

The primitive hydrosphere must have played a fundamental role in chemical evolution. In fact, the presence of liquid water on the surface for long periods of time is a necessary condition for life to emerge and evolve (Komiya et al. 2008). Some hydrothermal processes would have occurred on primitive oceans, and many organic compounds could have formed, diffused, and eventually reacted to form more complex molecules in oceans. The composition and physicochemical properties of oceans (including, but not restricted to, pH, salinity, temperature, etc.) surely inhibited some reactions and favored others.

Oceans were formed very soon (Kasting 1993a). Direct evidence, such as turbiditic sandstone beds, shales, conglomerates, silica sediments, and banded iron formations (BIFs), indicates the unequivocal presence of water at about 3.8 Ga (Nutman et al. 1984). However, there is evidence for the presence of liquid water during the Hadean time at 4.4 Ga: $\delta^{18}\text{O}$ positive anomalies in zircons can be explained by the presence of liquid water (Wilde et al. 2001; Valley et al. 2002; Cavosie et al. 2005). The formation of the oceans began shortly after the planetary accretion period ended. As stated above, isotopic evidence of liquid water and oceans on the surface of the Earth goes back to a little more than 4.4 Ga (Wilde et al. 2001), but what happened between this time and the first geologic (not isotopic) record of sediments deposited in the ~3.8 Ga ancient seas of the Isua Greenstone Belt in southwest Greenland (Mojzsis et al. 1996) is not known and probably will never be known; the oldest continental crust and hence the first possible evidence of plate tectonics processes and deep recycling of materials, which constitute the life engine of the modern Earth, goes back only to the 4.03 Ga metamorphic rocks that constitute the Acasta Gneiss of northern Canada (Bowring and Williams 1999).

Probably, one of the latest catastrophic events that contributed most to the destruction of the oldest continents was the so-called Late Heavy Bombardment (LHB), variously estimated to have occurred between 4.1 billion and 3.9 billion years based on a time scale calibrated for the Moon, where the record was not erased by subsequent geological evolution as happened on the Earth. Models associated to the effects of LHB on the environmental conditions of the epoch are divided between those that (a) consider a fortunate cosmic event that may have triggered the first emergence of life because of some massive contribution of biogenic compounds, such as methane and water, to the outer layers of the primitive Earth, as well as by the building of ideal environmental niches where chemical evolution eventually originated life (*e.g.*, Gladman et al. 2005; Cockell 2006), or (b) those that blame such event for having caused the total extinction of former living matter that possibly evolved in the preceding 500 million years elapsed between the emplacement of the

earliest oceans (4.4 Ga) and the peak of the LHB (~3.9 Ga) (Ryder 2003). Continuous bombardments must have generated a highly dense vapor atmosphere; when the temperature changed, the dispersed water (in the form of vapor) condensed to form the oceans (Kasting 1993b).

Geological evidence indicates that both plate tectonics and liquid water on the surface would have been present at 4.0 Ga (Bowring et al. 1990; Bowring and Williams 1999; Iizuka et al. 2006, 2007). There is sound evidence for plate tectonics and the presence of an open sea at 3.8 Ga (Komiya et al. 1999). One direct consequence of plate tectonics was the formation of hydrothermal systems.

Due to the lack of geological evidence, the physicochemical conditions of the primitive oceans (pH, temperature, ionic strength, etc.) are ill defined. However, some inferences can be made from the available wealth of data. The oceanic pH depended strongly, as ever, on the chemical composition of the atmosphere and the lithosphere. When examining sedimentary deposits, Holland (2003) found that the most abundant minerals in Archean oceans were calcite [CaCO_3], aragonite [CaCO_3], and dolomite [$\text{CaMg}(\text{CO}_3)_2$], which means that the ocean must have been saturated with salts containing high amounts of calcium and magnesium. If the atmospheric values of $p\text{CO}_2$ are considered, the pH of the Archean oceans must have been close to ≥ 6.5 (Holland 2003). The initial salinity of the oceans probably ranged between 1.5 and 2 times the present values, and it must have remained high during the Archean, due to the absence of continental cratons, which are deemed necessary to sequester large quantities of halite [NaCl] and/or brines (Knauth 2005).

The oceanic temperature was estimated to have ranged between 0°C and 100°C during the Archean, as evidenced by the occurrence of pillow lavas, and cross-bedding or other sedimentary structures (Knauth 2005). It is assumed that the first ocean must have been completely anoxic (just like the atmosphere) and that the oxygen content increased little by little, although in a variable way. The solubility of oxygen in water is governed by temperature and salinity, and these variables have changed drastically through time on Earth (Knauth 2005). Estimates based on the content of cerium and carbonate mineral anomalies indicate that the concentration of oxygen in seawater was very low until at least 1.9 Ga (Komiya et al. 2008). This, with low or null oxygen concentration, allowed easily oxydizable organic molecules to remain in the environment (Parker et al. 2011). In this context, in primitive Earth, it has been estimated that the concentration of many organic compounds dissolved in the ocean would have ranged between 0.003 M and 0.03 M (Miller and Orgel 1974). Despite such low concentrations, some key organic reactions might have formed nonetheless.

5.4.3 GEOLOGICAL SETTINGS FOR HYDROTHERMAL SYSTEMS

After the discovery of the first marine hydrothermal springs (Ballard and Van Andel 1977; Corliss et al. 1979) some researchers proposed those environments as possible niches

for the origin of life (Corliss et al. 1980; Corliss et al. 1981; Baross and Hoffman 1985). Corliss et al. (1981) suggested that hydrothermal systems could be “ideal sites for abiotic synthesis” [sic] due to the high availability of geochemical variables (*i.e.*, water, rocks, gases, thermal energy, gradients in chemical concentration, temperature, and pH). The combination of these variables would eventually lead to the formation of “protocells” and the proliferation of the “*first organism in the vicinity of hydrothermal vents*” [sic]. As soon as these ideas were published, several experiments questioned the viability of these environments as plausible niches for the origin of life, due to the high instability of organic molecules at the conditions present in hydrothermal springs, namely, high pressures and temperatures (Bernhardt et al. 1984; White 1984; Miller and Bada 1988). Subsequently, it was proposed that hydrothermal systems could have been involved in the process of chemical evolution, but they were hardly propitious places for the origin of life (Miller and Bada 1988; Bada and Lazcano 2002; Becerra et al. 2007).

Later, the discovery of a different type of hydrothermal system, the “Lost City Hydrothermal Field” (LCHF) (Kelley et al. 2001, 2002; Proskurowski et al. 2008), rekindled such discussion. The LCHF is located on an ultramafic basement with smoother physicochemical conditions than black smokers, in association with lower temperature and alkaline fluids. This discovery reinforced the idea that important geochemical processes would have been likely in ancient settings and that they probably contributed to the synthesis of organics on primitive oceans (Kelley et al. 2001, 2002; Martin et al. 2008; Proskurowski et al. 2008; Konn et al. 2015; McDermott et al. 2015).

To support the idea of hydrothermal systems as “niches for chemical evolution,” it is fundamental at first to identify the natural settings where hydrothermal systems may occur. Then, to understand the physicochemical processes that occur, it is necessary to identify the geochemical variables involved on them (Table 5.4.1) and to evaluate those that could be involved in prebiotic chemical reactions. Such steps are necessary to guide systematic experimental studies that, in turn, will determine if such environments served as places for synthesis and complication or, instead, these were the environments in which decomposition predominated. It is necessary to take into account the geochemical variables in laboratory experiments, even if that means to increase the complexity of experiments (Holm and Andersson 2005; Kawamura 2011). It is also relevant to consider that some variables must have contributed to the increase in complexity of molecules on primitive Earth whereas other variables would have limited it (Cleaves 2013). For instance, during the LHB, Earth was exposed to a constant impact of bodies that might have terminated organics. However, already synthesized organics might have lingered on for subsequent reactions “protected” by hydrothermal vents and deep sediments (Holm 1992).

Many geological settings may harbor hydrothermal activity whose likeliness to be associated with chemical evolution needs to be tested. For that matter, in this section the geological, chemical and physical characteristics of selected settings

TABLE 5.4.1
Some Geochemical Variables at Hydrothermal Springs; All Are Relevant for Studies of Chemical Evolution and Origin of Life

Energy Sources	Dissolved Elements	Gradients	Minerals
Geothermal energy	Cl	Temperature	Sulfides

	Ni		
	Mg		
	Ag		
	Hg		
	As		
	Sb		

that are widely distributed in time and space are described and evaluated. First of all, though, it is necessary to comprehensively describe some key geological notions.

A hydrothermal system is an environment where hot fluids circulate below the Earth's surface and may (or not) reach the surface, as hot springs or vents. There are two main components of a hydrothermal system: a heat source and a fluid phase. In addition, fluid circulation requires faults, fractures, and permeable lithologies (*e.g.*, Pirajno 2009). The most common heat sources comprise anomalously high geothermal gradients due to a broad panoply of magmatic foci or tectonic setting that implies crustal thinning. Fluid phases in such systems are typically aqueous (hence the hydro- prefix) that comprise vapor, supercritical fluids or water with very variable salinity (brines) or volatile contents, but these can also be CO₂, H₂S, hydrocarbons, and several other species (Roedder 1990), and even molten sulfur. The sources for such fluids are very variable as well: magmatic, sedimentary-diagenetic, meteoric, oceanic, metamorphic, etc. Such sources determine the physical and chemical characteristics of such fluids, which, in turn, determine the ability of fluids to mobilize and carry ions in solution and, therefore, the mineralogy of precipitates that were formed from them in key geological environments.

Therefore, hydrothermal systems can be classified according to their tectonic setting, the characteristics of their emplacement, including rock permeability, the sources for fluids and their physical and chemical major variables (*i.e.*, anions and cations in solution, pH, Eh, temperature, pressure, density, oxygen and sulfur fugacity, etc.), and the resulting mineral associations, among other geological variables. Upon such characteristics and their natural variations,

geological environments are typified, classified, and categorized for the sake of reasonably guiding further research or exploration endeavors. Such is the essential usefulness of the emphasis in branding types of mineral deposits (for fossil instances) and their active manifestations. Our understanding of the processes that govern the formation of (fossil) mineral deposits is boosted by the understanding of their presently active analogues, and *vice versa*. It is not always possible to resort to uniformitarianism to explain any geological process, but when conceptual models are wisely used, they can provide clues to the past or the present, which would not be obtained otherwise. Such is the reason for grouping fossil and present examples of key hydrothermal environments in this chapter (see Table 5.4.2). As for the matter of prebiotic synthesis, a variety of such environments have been invoked as likely sites to harbor the plausible chemical reactions thus involved. These can be classified between submarine and sub-aerial hydrothermal systems, and similar systems associated with impact cratering. The latter will not be discussed here; see Chapter 5.3 in this book (Chatterjee 2018) and references therein.

Mineral parageneses are a key for the definition of physicochemical parameters that characterize the conditions for mineral precipitation, including timing. Mineralization in submarine magmatic-hydrothermal systems (volcanogenic massive sulfide [VMS]-type systems) is a product of the chemical and thermal exchange among the ocean, the lithosphere, and the magmas emplaced within it and the fluids exsolved from them. Mineralization in submarine sedimentary-exhalative (SEDEX)-type systems is a product of the chemical and thermal exchange among the ocean, the lithosphere, and sedimentary brines. Mineralization in epithermal systems is a product of the chemical and thermal exchange among magmas and magmatic fluids, the lithosphere, and meteoric water, besides other plausible minor contributors. Mineralization in submarine seafloor serpentinitization systems is a product of the chemical and thermal exchange among the ocean, the lithosphere, the mantle, and the fluids derived from them all. Mineralization in shallow submarine to subaerial hydrothermal systems may be the result of chemical and thermal exchange among the ocean, the lithosphere, magmas, magmatic fluids, sedimentary brines, and meteoric water. In all these cases, hydrothermal minerals can be found in many different ways, with regard to (1) type of mineralized structure (vein, veinlet, stockwork, lens, stratum, layer, etc.), (2) geometric relationship between mineralized structures and host rocks (stratiform, stratabound, and cross-cutting), (3) time relationship between mineralized structures and host rocks (syngenetic and epigenetic), (4) types of crystal aggregates (massive, disseminated, laminated, banded, etc.), and (5) grain size (fine to coarse). Several aspects in each category may coexist in each model for mineral deposition, and most of them may be exposed on the surface during the lifetime of hydrothermal systems due to syndepositional faulting, diapirism, or slope sliding. The latter, no matter how obvious it may be, means that some mineral association on the surface does not necessarily have been deposited there. This broadens the spectrum of mineral species that could have had a role in

TABLE 5.4.2
Comparison between Shallow Hydrothermal Environments (Both Fossil Ore Deposits and Present Examples)

Type of Deposit and Metallic Associations	Main Types of Mineralizing Fluids and Mechanisms	Association with Volcanism	Other key characteristics of Fluids and Geological Processes	Range of Temperatures	Sources for Sulfur	Mineral Variability in Surface Exposures during Hydrothermal Activity*	Age Distribution	Fossil Examples	Presently Active Examples	Further Readings
Volcanogenic massive sulfide deposits (VMS); Cu-Ph-Zn-Ag-Au	Arc to back-arc settings (Kuroko and Besshi types), and mid-ocean ridges (Cyprus type).	Close time, space, and genetic association between volcanism and hydrothermal activity.	Euxinic environment; pH very acidic to alkaline; reduced to oxidized fluids; broad variations in salinity (lower than seawater up to >50 wt % NaCl equiv.); no bubbling unless in atypical shallow locations; sources for fluids are magmatic, fresh, and deeply evolved seawater. Possible associated submarine brine and molten sulfur pools.	<100°C to >500°C. Important marine water gradients (evolved within the crust). Seafloor venting.	Magmatic, also from seawater sulfate.	Sphalerite, galena, pyrite, chalcopyrite, pyrrhotite, wurtzite, bornite, covellite, arsenopyrite, marcasite, tetrahedrite-tennantite, tólkingite, acanthite, cubanite, boulangerite, pyrosite-pyrrhotite, stannite, cassiterite, realgar, orpiment, cinnabar, microcrystalline varieties of silica, hematite, barite, anhydrite, gypsum, Mn and Fe oxides, and hydroxides, native sulfur, talc, chrysotile, chlorite, illite, smectite, montmorillonite, kaolinite, nontronite, jarosite, calcite, dolomite, siderite, ankerite, kumohorite, native sulfur, cerussite. Possible precipitation of silica gels.	Since the Archean (ca. 3.5 Ga); numerous Paleozoic examples.	Pilbara craton (Australia), Noranda, Abitibi, Windy Craggy (Canada), Troodos ophiolite (Cyprus), Hokuroku and the Green Tuff region (Japan), Semai ophiolite (Oman), Iberian Pyrite Belt (Spain, Portugal), Almadén (Spain).	Mid-ocean ridges; Lucky Strike, Lost City, East Pacific Rise at 21°N, Sonne Field.	Franklin (1996), Barrie and Hammington (1999), Allen et al. (2002), Franklin et al. (2005), Hammington et al. (2005), Piercy (2011)
Sedimentary-exhalative deposits (SEDEX) and subaqueous brine pools; Zn-Pb-Ba-(Cu)-Fe-Mn	Advanced stages of continental rifting, failed rifts, and passive continental margins.	None, but volcanic rocks can be present in the hosting sedimentary series.	Euxinic environment; pH very acidic to alkaline; reduced to oxidized fluids; broad variations in salinity (lower than seawater up to <50 wt % NaCl equiv. in brine pools); no bubbling unless in atypical shallow locations; sources for fluids are sedimentary brines, fresh and deeply evolved seawater. Possible associated submarine brine pools.	<50°C to >300°C. Important temperature gradients possibly occurred. Seafloor venting and precipitation from seawater combined.	Seawater sulfate.	Pyrite, galena, sphalerite, microcrystalline varieties of silica, barite, anhydrite, gypsum, pyrrhotite, marcasite, chalcopyrite, arsenopyrite, tólkingite, siderite, ankerite, kumohorite, dolomite, magnesite, calcite, aragonite, hematite, Mn and Fe oxides and hydroxides, Cu-Fe-Ag-Pb sulfosalts, nontronite, talc, jarosite, stevensite, attacanite, caminitite, anglesite, montmorillonite, chlorite, apatite, cassiterite, scheelite, celian, native sulfur, native silver.	Since the late Paleoproterozoic (ca. 1.8 Ga); peaking during the Matheranbhire System (?).	Broken Hill, Mount Isa, McArthur River (Australia), Sullivan (Canada), Mathanbhire (Cuba), Rammelsberg, Meggen (Germany), Rajputra-Dariba (India), Molango (Mexico), Gansberg-Aggeney's (South Africa), Red Dog, Anarraaq (USA).	Atlantis II Deep (Red Sea), Salton Sea, lakes in the East Africa Rift System.	Russell et al. (1981), Goodfellow et al. (1993), Lydon (1996), Jorge et al. (1997), Hammington et al. (2005), Leach et al. (2005), Lyons et al. (2006), van der Zwan et al. (2015), Schardt (2016), Sangster (2018)
Shallow submarine or subaerial to subaerial exhalative deposits; Mn-Fe-Cu-Zn-Co-Ba-Hg-As-Sb-Ag-Pb	Incipient to advanced stages of continental rifting, failed rifts, and passive continental margins; also shallow manifestations in volcanic arcs (similar to VMS deposits except for their depth).	Close time, space and genetic association between volcanism and hydrothermal activity, or none at all due to high heat flux related to crustal thinning.	Fresh marine and modified marine water to magmatic. Seafloor venting to subaerial precipitation.	≤100°C, eventually higher in magmatic-derived systems.	Seawater sulfate or magmatic.	Oxidized to euxinic environments; pH very acidic to very alkaline (normally moderately acidic to alkaline); reduced to oxidized fluids; in general, salinities lower than seawater; bubbling very common; sources for fluids highly variable upon their geological location.	Seawater sulfate or magmatic.	Opal, calcite, aragonite, barite, celestite, Mn and Fe oxides and hydroxides, microcrystalline varieties of silica, braunite, rhodochrosite, pyrite, marcasite, cinnabar, caninitie, orpiment, realgar, zeolites, illite, smectite, montmorillonite, chlorite, talc, kaolinite, zeolites, cladonite, apatite, native sulfur, native mercury Pb-Cu-Ag oxychlorides. Precipitation of silica gels.	El Bofo-Lucifer and Concepción peninsula (Mexico), Watangzi (China), Tara Mts. (Poland), Valle del Azogue (Spain), sedimentary phosphorites (?), Bay of Plenty (New Zealand), Lihir island (Papua-New Guinea).	Tercelin et al. (1993), Fan et al. (1999), Tarasov et al. (2005), Canet and Pro-Ledesma (2006), Conly et al. (2011), Papavassiliou et al. (2017)

Metaliferous black shales (and closely associated phosphorites); Zn-Cu-Pb-(Mo-Au-Ni)-PGE-U-V-P-Se, Cu-Co-Zn, Sb-W-Hg, etc.	Intracontinental rift-related sedimentary basins.	Unclear, may be correlated with mantle plumes; may occur without associated magmatism or associated with mafic volcanism.	Sedimentary brines, fresh marine, and modified marine water. Seafloor venting? Precipitation from seawater? (Impact-related?).	<100°C to >300°C.	Seawater sulfate.	Pyrite, vesicle, gendofrite, jordsite, millerite, polydymite, sphalerite, chalcopyrite, galena, clausenthalite, illite, smectite, montmorillonite, kaolinite, apatite and other phosphates (particularly in sedimentary phosphorites), collohosphate, Mn and Fe oxides and hydroxides, dolomite, calcite, fluorite, barite, anhydrite, gypsum. Precipitation of colloidal phases (e.g., Ni-Mo sulfides and carbides).	Black Sea, Caspian Sea, Ontong Java Plateau.	Pášava (1993), Coffin and Eldholm (1994), Mossman et al. (2005), Laznicka (2006), Johnson et al. (2017)
Seafloor serpentization; Ni-Co-Cu-Fe, PGE-Au-Ag, Cr-Ti-V	Mid-ocean ridges; close time-space and genetic association between volcanic settings, and incipient stages of continental rifting.	Marine, fresh marine, and modified marine water (evolved within crust and/or slab-derived fluids). Hydrothermal activity.	<450°C to 500°C. Important temperature gradients occur from the seafloor to the oceanic crust inward.	Euxinic environment; pH acidic to alkaline; reduced to oxidized fluids; board variations in salinity (lower than seawater up to <40 wt % NaCl equiv.); no bubbling; sources for fluids are magmatic (related to the dehydration of subduction slab in forearc settings), fresh and deeply evolved seawater.	Seawater sulfate, also magmatic.	Olivine, pyroxene, amphibole, plagioclase, serpentinite group minerals (anorthite, enstatite, lizardite), (Fe)-brucite, talc, chlorite, fuchsite, Mg-rich clays (smectite, sepiolite, palygorskite/zeolite), amphibole, aragonite, calcite, dolomite, magnesite, garnet, clinzoisite, prehnite, pumpellyite, lawsonite, barite, spinel, magnetite, hematite, pyrite, calcopyrite, pentadite, Co-pentadite, hazedowodile, millerite, marcasite, vallevite, violarite, Fe-Ni-(Co)-alloys s.s. bornite, covellite, Platinum Group Minerals (PGM), native gold and minor Mg-Fe-hydroxychlorides (fwaitite, pyravite-sigemite group).	Greenstone belts: Ista (Greenland), Barberon (South Africa), Journa Complex (Finland), Ophiolites: Semados (Oman), Troodos (Cyprus), Zambales (Philippines), Minecka (Japan), Leka (Norway).	Frost (1985), Bach et al. (2004, 2006), Früh-Green et al. (2004), Deschamps et al. (2013), Frost et al. (2013)
Epithermal deposit; Au-Ag, Ag-Pb-Zn-Au	Continental and island arcs; transform boundaries (minor setting).	Closed time-space and genetic association between volcanism and hydrothermal activity.	Magnetic, fresh meteoric, and modified meteoric water. Epiphreatic structures and subaerial activity.	-50°C to ~400°C. Important temperature gradients occur from central to peripheral springs.	Between >1500 m and subaerial paleosurfaces.	Oxidized environment; pH very acidic to mildly alkaline; reduced to oxidized fluids; generally low salinities; bubbling and formation of aerosols common in geothermal fields; sources for fluids are magmatic, fresh to deeply evolved meteoric water.	Vastly Cenozoic; silicate and carbonate minerals in siners (mostly opal and calcite), kaolinite, alunite, native sulfur, barite, anhydrite, gypsum, celestine, Mn and Fe oxides and hydroxides, montmorillonite, illite, smectite, chlorite, epidote, calcite, dolomite, zeolites, adularia, quartz, chaledony, cristobalite, tridymite, pyrite, cinabar, realgar, orpiment, stibnite, and other minor sulfides and halides. Precipitation of silica gels.	Campi Flegrei (Italy), Los Azules, Cerro Prieto (México), Taupo Volcanic Zone, White Island (New Zealand), Yellowstone, Steamboat Springs, The Geysers (USA).

C., *Understanding Mineral Deposits*, Kluwer Academic Publishers, Dordrecht, the Netherlands, 845 p., 1999; Jébrak, M., and Marcoux, E., *Géologie des ressources minérales*, Ministère des ressources naturelles et de la faune du Québec, Québec, Canada, 667 p., 2008; Pirajno, F., *Hydrothermal Processes and Mineral Systems*, Springer, East Perth, Australia, 1250 p., 2009.

^a Besides those in host rocks. The listed minerals would belong to precipitates or alteration assemblages on the surface or near it, but also to deeper areas that could be exposed by faulting or syndepositional slope sliding.
(?) Indicates debatable locations.

chemical evolution, as one must account equally for minerals that were deposited on the surface and those that were formed somewhere else and eventually made available on the surface while hydrothermal activity still is on. The last (but not least) relevant characteristics for the matter would be the mineral species itself and its particular variation in chemical composition. However, in spite of the geological complexity of each family of depositional environments, many mineral families, groups and classes are shared by most of them (Table 5.4.2), namely silica-group minerals (or silica gels), clay minerals, serpentine minerals and other phyllosilicates, sulfides (especially base-metal sulfides, including arsenides, antimonides, etc.), sulfates, oxides (especially Fe and Mn oxides and hydroxides), phosphates, halides, native elements (including alloys), and many miscellaneous silicates (zeolites, feldspars, amphiboles, scapolites, epidote-group minerals, etc.). It is important to note that these are minerals that form as hydrothermal precipitates or replacements (passive and reactive associations, respectively), but also rock-forming minerals in host rocks should be added to the list above. Among the latter, zircon can be considered as a “cosmopolitan” mineral due to its resilience.

5.4.3.1 SUBAQUEOUS HYDROTHERMAL SYSTEMS

Submarine vents in association with magmas at or near mid-ocean ridges are usually described as the likeliest hydrothermal systems to be associated with the emergence of life on Earth (*i.e.*, Corliss et al. 1981; Nisbet and Sleep 2001). A common case for the formation of submarine hydrothermal vents occurs when seawater migrates through fractures into the crust and reaches the vicinity of a magmatic intrusion. While approaching the magmas, water is heated up by the anomalously high thermal gradient induced by their emplacement. Additionally, magmas release aqueous fluids upon their cooling down. Therefore, hydrothermal fluids in magma-related systems may come from magmatic, marine or meteoric sources. Similarly, sulfur, iron, copper, zinc, and other metals may come from magmas, ocean water or host rock leachates. The dissolved minerals nourish chemosynthetic bacteria that constitute the base of the food chain for a variety of invertebrates, including large tubeworms (*e.g.*, Levin 2009).

The importance of submarine hydrothermal vents for studies related to the origin of life lies in: (1) providing hot water to surficial environments, (2) upwelling fluids interact with seawater, provide agents for chemical imbalance, thus potentially allowing the synthesis of organic compounds, (3) they produce a rapid crystallization of carbonates and silicates at low temperatures; this increases the local potential to preserve microbial organisms as fossils and their chemical signatures, despite later diagenetic or low-grade metamorphic processes (Pope et al. 2006), and (4) even debatable, some authors suggest that the oldest forms of terrestrial life might have been autotrophic-thermophiles (Pope et al. 2006).

Submarine or sublacustrine hydrothermal systems can be divided into those linked to magmatism as both source for heat, water, and other chemical components, and those associated

with venting of basinal brines or other fluids. Such environments correspond, respectively, to volcanogenic massive sulfide (or VMS; Figure 5.4.1) and sedimentary-exhalative (or SEDEX; Figure 5.4.2) deposits and their present-day analogues, which are well-established types of ore deposits and depositional environments, both submarine. Another case, similar to the latter, is constituted by hydrothermal systems that are associated with early stages of continental rifting or lingering activity in more tectonically evolved environments (*e.g.*, along the eastern side of the Baja California peninsula; Canet and Prol-Ledesma 2006; Camprubí et al. 2008). Such systems may occur between shallow submarine and subaerial manifestations, including intertidal venting (Figure 5.4.3). Seafloor serpentization and paleo-hydrothermal submarine systems associated with metalliferous deposits in black shales are also likely to be accounted among keen environments for prebiotic synthesis. Most theoretical and experimental approaches to prebiotic reactions have been carried out considering VMS-like hydrothermal systems, while neglecting the others. The following account does not intend to be exhaustive, but demonstrative of the variability of hydrothermal scenarios that might have had a role in chemical evolution. Some authors even proposed that BIFs could be related to hydrothermal activity (*e.g.*, Ohmoto et al. 2006), which could be at least the case of Algoma-type deposits (Jébrak and Marcoux 2008).

5.4.3.1.1 Volcanogenic Massive Sulfide-Type Systems

The so-called “black smokers” are the most conspicuous submarine hydrothermal manifestations in VMS-type systems (Figure 5.4.1) and are also interpreted to occur in SEDEX-type systems (Figure 5.4.2; see Larter et al. 1981; Boyce et al. 1983; Russell et al. 1989). These are hydrothermal fumaroles with abundant sulfides and sulfates in suspension that upon precipitation form mounds along favorable faults or within submarine calderas. In VMS systems associated with divergent margins, these are usually located close to mid-ocean ridges. In these fumaroles, due to their proximity to magmas, water may attain temperatures above 400°C and low pH (see Table 5.4.2; also, Von Damm et al. 1985; Camprubí et al. 2017). The latter facilitates the leaching of iron and other metals as the water seeps through the country rocks, which is a feature shared with the other systems hereby described. Such fluids come in contact with cold seawater, thus generating a rapid nucleation of sulfides and other minerals and resulting in a turbid suspension resembling a cloud of black smoke. Salinities of sulfide-rich ore-forming fluids are generally up to 20 wt.% NaCl equiv. although extremely high-salinity polysaline brines may eventually reach the sea bottom as well (up to 65 wt.% NaCl and ~44 wt.% KCl, at >500°C; Camprubí et al. 2017). That being the case, it is likely that brine pools can be associated with VMS-type systems. Another type of hydrothermal vents is dubbed “white smokers,” which are generally more distant from their heat source than the black ones (Figure 5.4.1). Black and white smokers may coexist in the same submarine hydrothermal field, but they generally represent proximal and distal vents, respectively, to the main

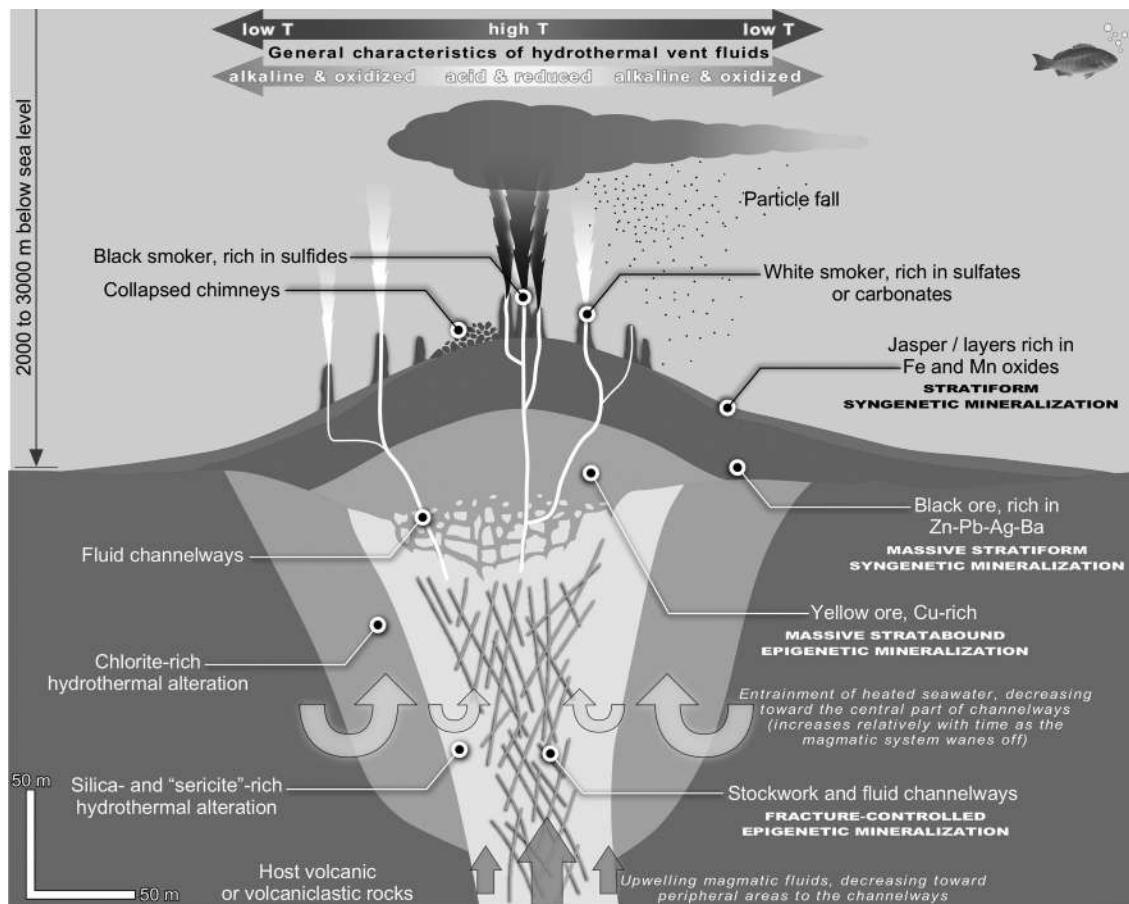

FIGURE 5.4.1 Structural section that combines evidence from active submarine magmatic-hydrothermal vents and from fossil volcano-genic massive sulfide (VMS) deposits, especially in Kuroko-type settings, including all typical styles of mineralization and hydrothermal assemblages. “Sericite,” not a valid mineral species name, stands for filosilicates that range between illite and fine-grained muscovite. Key: T = temperature. (Adapted from Colín-García, M. et al., *Bol. Soc. Geol. Mex.*, 68, 599–620, 2016, and based on Lydon, J. W., Volcanogenic massive sulphide deposits, Part 2: Genetic models, in *Ore Deposit Models*, R. G. Roberts and P. A. Sheahan (Eds.), pp. 155–181, Geological Association of Canada, Geoscience Canada, Reprint Series, 3, St. John’s, Canada, 1988, and Hannington, M. D. et al., Sea-floor tectonics and submarine hydrothermal systems, in *Economic Geology One Hundredth Anniversary*, Vol. 1905–2005, J. W. Hedenquist, J. F. H. Thompson, and R. J. Goldfarb (Eds.), pp. 111–142, Society of Economic Geologist, 2005.)

upflow zone (Figure 5.4.1). However, white smokers correspond mostly to waning stages of such hydrothermal fields, as magmatic heat sources become progressively more distant from the source (due to magma crystallization) and hydrothermal fluids become dominated by seawater instead of magmatic water (see references in Table 5.4.2 for VMS systems). The temperature in white smokers can be as low as 40°C to 75°C and are alkaline (pH ranges between 9 and 9.8; Kelley et al. 2001). Mineralizing fluids from this type of vents are rich in calcium, and they form dominantly sulfate-rich (*i.e.*, barite and anhydrite) and carbonate deposits. These may form giant chimneys, the largest of which stand almost 60 m above the bottom of the ocean at the LCHF (Kelley et al. 2001). Hydrothermal fluids in this location contain methane, ethane, and propane and organic acids in the form of formate and acetate; these are produced in association with this hydrothermal system (Proskurowski et al. 2008). The global frequency distribution of depths for the occurrence of actualistic examples of VMS deposits (magmatic-hydrothermal seafloor

vents, either black or white smokers) shows a dominant range between 2000 and 3000 m (Figure 3 in Colín-García et al. 2016; Figures 2 and 3 in Hannington et al. 2005), which is consistent with calculated depths of fossil examples (see Table 5.4.2 and references therein). In spite of this, much shallower examples are known both in present-day manifestations as well as in fossil VMS deposits (*e.g.*, Camprubí et al. 2017).

Different mineral associations precipitate during the typical stages of mineralization that characterize the life span of VMS-type systems (Figure 5.4.1). Comprehensive reviews of this subject have been published (*e.g.*, Franklin et al. 1981, 2005; Lydon 1988; Ohmoto 1996; Barrie and Hannington 1999; Hannington et al. 2005). Minerals present in a hydrothermal system or a fossil VMS deposit are deposited passively or reactively. Mineral associations may vary (1) in different mineralized structures, either syngenetic (namely, passive precipitation in chimneys, mounds, and stratiform deposits) or epigenetic (structures that correspond to feeder channels, and replacements of host rocks or pre-existing

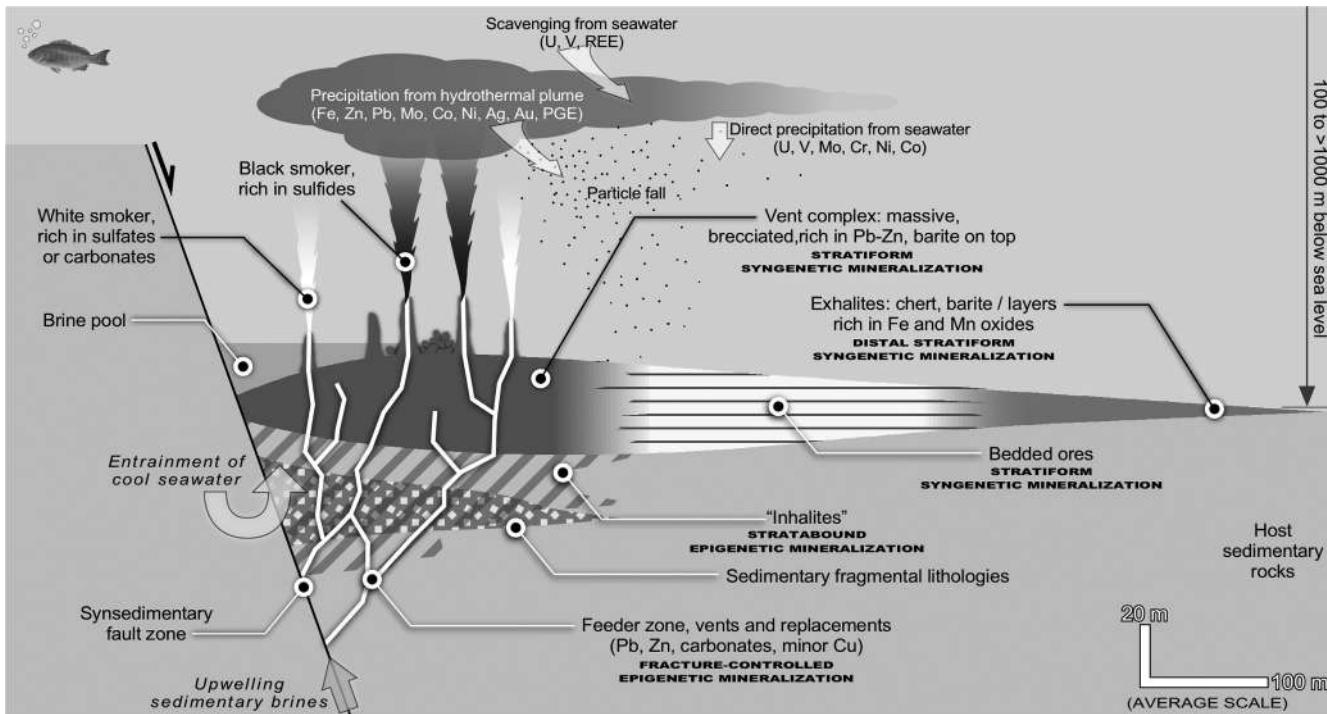

FIGURE 5.4.2 Structural section that combines evidence from active submarine non-magmatic hydrothermal vents, from fossil sedimentary exhalative (SEDEX) deposits and from an analogy with VMS deposits (see Figure 5.4.1), including all typical styles of mineralization and hydrothermal assemblages. It is important to note that this model corresponds to proximal-to-vent deposits in the model of (Lydon 1996), because feeder zones in most SEDEX deposits, which are commonly more distal to vents than this model exemplifies, have not been found.

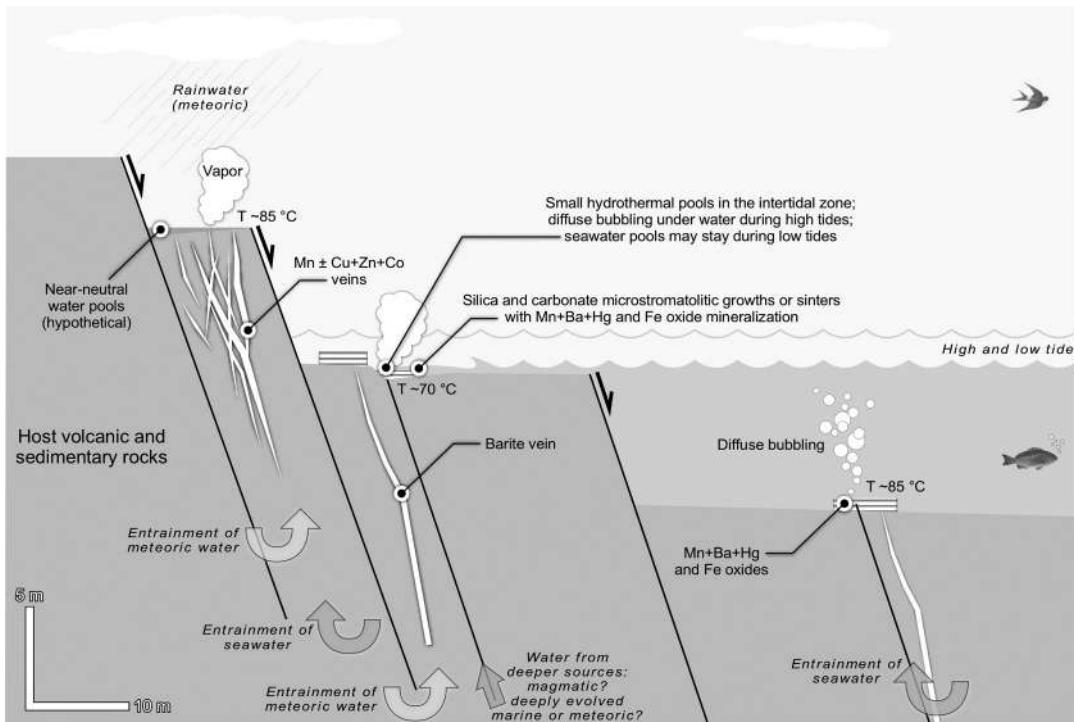

FIGURE 5.4.3 Structural section that combines evidence from active submarine non-magmatic (?) hydrothermal vents and from fossil Mn \pm Cu + Zn + Co deposits that formed during early stages of continental rifting, as based in the models for evidence in the eastern Baja California Peninsula in Mexico. The intertidal and submarine hydrothermal manifestations illustrated here would be those around the Concepción Bay area and the ore deposits would be El Boleo, Lucifer, and those in the Concepción peninsula. (Model adapted from Canet, C., and Prol-Ledesma, R. M., *Bol. Soc. Geol. Mex.*, 58, 83–102, 2006; Camprubí, A. et al., *Island Arc*, 17, 6–25, 2008; and references therein.) The (?) here indicates a dubious origin or debatable origin for these vents.

massive sulfide bodies), or *structural zonation*, (2) from proximal to distal associations with respect to venting areas within the same stratigraphic horizon, or *horizontal zonation*, (3) from deep to shallow associations (*i.e.*, stockworks to mounds), or *vertical zonation*, (4) from early and climactic to late stages of mineralization (dominated by sulfides, and sulfates or oxides, respectively), or *temporal zonation*, and (5) in various volcano sedimentary contexts, depending essentially on the composition of volcanic rocks and, ultimately, on the tectonomagmatic context. The most common minerals in ore-bearing associations of VMS deposits (non-metamorphosed or oxidized) and their modern analogues are summarized in [Table 5.4.2](#). The most common hydrothermal alteration assemblages are chloritic (including Mg-rich ones) and phyllitic (dominated by “sericite,” mostly illite), and also silification, deep and shallow talcose alteration, and ferruginous (including Fe oxides, carbonates, and sulfides) alteration. Although not necessarily associated with these systems, molten sulfur lakes may occur in association with submarine volcanism (de Ronde et al. 2015). The precipitation of silica and iron oxide gels in VMS-type systems is also possible (Grenne and Slack 2003).

5.4.3.1.2 Sedimentary-Exhalative-Type Systems

Sedimentary-exhalative systems and those associated with metalliferous black shales provide all geological and physicochemical characteristics that would have favored prebiotic reactions as effectively as VMS systems, such as temperature gradients, euxinic environments, and a wide range of depths of formation (see [Table 5.4.2](#)). Sedimentary-exhalative-type systems also provide strong mineralogical and geochemical gradients, and similar pH and Eh gradients to those in VMS-type systems. In addition, the occurrence of submarine brine pools in association with these environments ([Figure 5.4.2](#)), such as those interpreted for ore deposits (Boyce et al. 1983) and present-day examples found in the Red Sea (*e.g.*, Schardt 2016), provides strong salinity (and geochemical) contrasts among them, seawater, and more dilute vent fluids.

The problem in the involvement of SEDEX systems with prebiotic reactions resides in the age of the oldest examples of such systems, as no known deposits are older than late Paleoproterozoic (*ca.* 1.8 Ga; Lydon 1996). Metalliferous black shales can be significantly older (middle Paleoproterozoic, *ca.* 2.1 Ga or older; Mossman et al. 2005) than SEDEX or shallow submarine/sublacustrine deposits (see [Section 5.4.3.1.3](#)). However, neither type has yet been found to be old enough as to be coeval with prebiotic processes or, least of all, be involved with them. In contrast, Archean VMS deposits are numerous (*ca.* 3.5 Ga; Barrie and Hannington 1999). The striking lack of Archean SEDEX deposits can be associated with the *limiting effect of high reduced iron contents on the activity of reduced sulfur in anoxic oceans* (*sic*, Goodfellow 1992) in which *metals in hydrothermal fluids [...] were dispersed because a lack of reduced sulfur to precipitate them* (*sic*, Misra 1999). Therefore, it is likely that SEDEX-type hydrothermal systems did effectively exist during the Archean, despite being unable to generate

sulfide deposits because reduced sulfur in the oceans would have been previously “sequestered” by iron to precipitate iron sulfides directly from seawater. After the oxygenation of Earth’s oceans SEDEX deposits formed, during worldwide anoxic events of the Paleozoic, as might also be the case for Proterozoic deposits (Misra 1999).

Sedimentary-exhalative-type systems ([Figure 5.4.2](#)) span different mineralogical styles that are similar to those in VMS-type systems, although their mineral associations are typically more diverse than in the latter. Comprehensive reviews of this subject are published (*e.g.*, Russell et al. 1981; Goodfellow et al. 1993; Hannington et al. 2005; Leach et al. 2005; Lyons et al. 2006; Sangster 2018). Massive and layered sulfide deposits, and exhalites are similar to syngenetic stratiform associations in VMS deposits, whereas “inhalates” are similar to epigenetic stratabound associations in VMS deposits. Exhalites can be constituted by silica-rich, nontronite, montmorillonite, chlorite, carbonate, phosphate, and Fe-Mn oxide-hydroxide layers, and all deposits normally show strong mineralogical banding. Although the SEDEX term is usually reserved to Pb-Zn deposits, their mineralogical diversity allows to classify them into barite, Sb-W-Hg in black shales, Fe-Mn, Sn, and base-metal deposits (Jorge et al. 1997). The latter are subdivided into (type I) deposits with metallic sulfides alone, (type II) deposits with metallic sulfides and exhalites (chert + barite), and (type III) deposits with metallic sulfides, Fe-Mn oxide-hydroxide layers, and exhalites (Sangster and Hillary 1998). Unlike VMS-type systems, feeder zones are rarely found (supra-vent systems; [Figure 5.4.2](#)). The most common minerals in ore-bearing associations of SEDEX deposits (non-metamorphosed or oxidized) and their modern analogues are summarized in [Table 5.4.2](#). A particular feature found in association with active SEDEX-type systems is the occurrence of submarine brine pools (*e.g.*, Schardt 2016). Owing to the relatively shallow character that these systems may have, gasohydrothermal activity (bubbling) can be common.

5.4.3.1.3 Shallow Subaqueous Hydrothermal Systems

Hydrothermal systems that are associated with early stages of continental rifting (and later stages as well) share some similarities with SEDEX systems, starting with their specific tectonic setting (early to late stages of continental rifting, respectively). The former, however, stretches between shallow submarine (up to ~200 m deep; neritic zone) or sublacustrine to subaerial hydrothermal to gasohydrothermal systems, including intertidal environments, at temperatures <100°C. The associated aqueous fluids have generally weaker gradients in pH and Eh than in VMS- and SEDEX-type environments, although the genetic variability of these systems, between magmatic-derived and sedimentary-marine-meteoric, implies a large chemical variation within this group of environments. Also, intertidal environments provide an interesting gradient, which is implied by low- and high-tide cycles, with thermochemical gradients between upwelling fluids and seawater that can be pooled during low tides ([Figure 5.4.3](#)). In addition, the occurrence of gasohydrothermal fluids in this environment

induces generalized diffuse bubbling (*e.g.*, Tarasov et al. 1990; Vázquez-Figueroa et al. 2009; Canet et al. 2010). Diffuse bubbling is normally absent in VMS- and SEDEX-type environments due to high pressures from the water column above them, unless these are atypically shallow. Such gases are rich in CO₂ in most cases, in N₂ and CH₄ in systems that interacted with sedimentary rocks, and in H₂S in association with fumarolic activity (Canet and Prol-Ledesma 2006, and references therein). Little is known about the oldest possible ages of the fossil deposits generated in this environment because of their scarcity in the geological record, but the oldest known example is the Mesoproterozoic Wafangzi Deposit in China (Fan et al. 1999). However, with regard to the most likely geodynamic setting for these systems, which encompasses incipient to advanced stages of continental rifting, the crustal dynamics in the Archean could have furnished plenty of such systems.

Shallow submarine/sublacustrine to subaerial hydrothermal systems are as mineralogically diverse as their possible geological settings. Some of them could be ascribed to VMS- or SEDEX-type environments and their characteristic tectonic settings (see Table 5.4.2 and Canet and Prol-Ledesma 2006). However, a tectonic setting that is seemingly the most characteristic for these systems, which is represented by incipient stages of continental rifting and into advanced stages but confined to the resulting passive margins (Figure 5.4.3). Sedimentary phosphorites may perhaps be the largest deposits in association with such environments (*e.g.*, those formed during the breakup of Pangea in NE Mexico and during the Miocene rifting-off of the Baja California peninsula; see Camprubí [2013]), and a possible hydrothermal origin has been postulated for them (*e.g.*, Slack et al. 2015; Caird et al. 2017), although it is not a necessary condition (Jébrak and Marcoux 2008). Such phosphorites are constituted by amorphous to cryptocrystalline apatite-group phases, generally carbonate-fluorapatite or francolite and rarely hydroxilapatite (Jébrak and Marcoux 2008). Note that phosphorites can be associated with SEDEX deposits and metalliferous black shales as well. However, the most common minerals in shallow settings are silica-group minerals and microcrystalline varieties, carbonates, barite, Fe-Mn oxides and hydroxides and pyrite. Silica minerals and carbonates are most characteristic forming sinters, microstromatolitic growths and veins. Intertidal environments are characteristic to this group of environments (Figure 5.4.3), which means high and low tides twice a day, but also fully subaerial pools are possible in association with Mn ± Cu+Zn+Co deposits. Both tide variations onto hydrothermal venting and permanent subaerial ponds imply the plausibility of concentration mechanisms. The latter is also valid for epithermal systems (see Section 5.4.3.2). Besides all the possible minerals in the various settings in which such hydrothermal systems occur, the precipitation of silica gels is also possible (Tiercelin et al. 1993). Owing to the shallow character of these systems, gasohydrothermal activity (diffuse bubbling; Figure 5.4.3) is very common.

5.4.3.1.4 Seafloor Serpentization Systems

The seafloor serpentization processes consist in the hydration of the oceanic lithosphere, which is mainly formed by mantle peridotites (*i.e.*, dunites, harzburgites, lherzolites, and piroxenites) and lower crustal plutonic rocks. These rocks comprise ~20% or more of the ocean crust and are usually located in the vicinity of spreading ridges, passive margins, arc-subduction environments and could constitute the host rocks for VMS-type systems. The serpentization process constitute a sequence of exothermic reactions at variable temperatures (below 450°C–500°C), which provide strong mineralogical and geochemical gradients controlled by pH and Eh changes in hydrothermal fluids that were derived from seawater and/or the mantle (*e.g.*, Früh-Green et al. 2004; Alt and Shanks 2006; Klein et al. 2009; Deschamps et al. 2013; Frost et al. 2013; see Table 5.4.2). The process starts with the hydration of olivine to form serpentinite and ferroan brucite, in presence of high pH and reducing fluids, thus promoting the dissolution of sulfides from the peridotitic host rock. The evolution of the system results in the formation of magnetite, from the breakdown of ferroan brucite in presence of SiO₂-rich, acidic, and oxidizing fluids, subsequently releasing significant amounts of H₂ and forming sulfides, oxides, and metal alloys (*e.g.*, Alt and Shanks 1998, 2003; Bach et al. 2004, 2006). A byproduct of serpentization under highly reducing conditions is the venting of methane- and hydrogen-rich fluids, which can lead to the formation of carbonate mounds and chimneys similar as those described in the LCHF (Kelley et al. 2001). Mixing zones of these reduced hydrothermal fluids with seawater above peridotite outcrops (subseafloor mixing zones, according to Klein et al. 2015) represent niches for chemolithoautotrophic microbial communities associated with the serpentization of the oceanic mantle (*e.g.*, Alt and Shanks 1998; Kelley et al. 2001; Früh-Green et al. 2004). Fossil examples of seafloor serpentization systems are found as ancient sections of the Earth's oceanic crust (*i.e.*, ophiolitic sequence defined at the Penrose Conference, 1972) (Juteau and Maury 1997). The temporal frequency of ophiolites ranges between the Archean (*i.e.*, greenstone belts; de Wit 2004) and the Phanerozoic (Table 5.4.2; Misra 1999), thus suggesting that the modern plate tectonics, the formation of oceanic crust, and the seafloor serpentization systems operated since the early Archean (Furnes et al. 2014).

The mineralogical styles shown in seafloor serpentization systems are similar to those described in VMS- and SEDEX-type systems, while their mineral assemblages depend largely on the primary mineral association of the altered peridotitic rocks. For comprehensive reviews on this subject see (Sakai et al. 1990; Alt and Shanks 1998, 2003; Kelley et al. 2001; Klein and Bach 2009; Frost et al. 2013; Schwarzenbach et al. 2014, 2016; Klein et al. 2015). Sulfide-rich serpentinites, talc-rich serpentinites, carbonate-rich serpentinites (associated with magnesite deposits), listvenites (*i.e.*, CO₂- and SiO₂-rich serpentinites), and rodingites (hydrated gabbros with calcium silicates) are products of the hydrothermal alteration (*i.e.*, carbonation and/or silicification) of serpentinites. These

serpentinites are enriched in sulfides, oxides, alloys, and metallic and non-metallic elements (Co, Ni, Fe, Cu, Zn, Mn, Na, Ca, K, and S) relative to peridotitic protoliths (Uçurum 1998, 2000; Hansen et al. 2005; Tsikouras et al. 2006; Nasir et al. 2007; Falk and Kelemen 2015; Hinsken et al. 2017), which are key minerals/elements to promote prebiotic reactions. The types of serpentines listed previously, especially fossil examples associated with magnesite deposits, are currently the subject of numerous studies due to their usefulness as a “natural laboratory” for CO₂ sequestration and storage (Hansen et al. 2005; Kelemen et al. 2011; Beinlich et al. 2012; Power et al. 2013; Falk and Kelemen 2015). The most common minerals in ore-bearing associations of seafloor serpentization deposits (non-metamorphosed or oxidized) and their modern analogues are summarized in [Table 5.4.2](#).

5.4.3.2 SUBAERIAL HYDROTHERMAL SYSTEMS

Aside from those mentioned above for shallow submarine/sublacustrine to subaerial exhalative deposits in continental rifts, hydrothermal manifestations are abundant in subaerial settings, particularly in association with convergent plate boundaries (continental and island volcanic arcs), but also occur in transform boundaries. For instance, hydrothermal activity is known to occur in the Salton Sea, in association with the San Andreas Fault System but, unlike volcanic arcs, this case is normally placed among modern equivalents to SEDEX deposits and their associated subaqueous brine pools (see [Table 5.4.2](#) and [Figure 5.4.2](#)). The most relevant and numerous recent/active hydrothermal fields are found in geothermal and magmatic-hydrothermal contexts, which are normally considered as the modern analogues of low-sulfidation and high-sulfidation epithermal deposits, respectively (which, in both cases, may include intermediate-sulfidation deposits); (Simmons et al. 2005; Camprubí and Albinson 2006, 2007; Sillitoe 2015). The uppermost part of such systems has a tendency to display wide variations in temperature, salinity, volatile content, pH, and redox potential ([Figure 5.4.4](#)) and hence the broad range in reactivity between the associated hydrothermal fluids and host rocks. Additionally, such differences in physicochemical variables and reactivity determine broad mineralogical variations on the surface or near it. The above variables are largely controlled by the vertical or lateral nearness of hydrothermal discharge zones to their parental intrusions (see Figure 1 in Sillitoe 2015) and the geological and hydrological characteristics in each area (White and Hedenquist 1990). Besides the broad temperature and salinity gradients that may occur in the actual variety of such environments, the occurrence of deep hypogene low- to intermediate-sulfidation fluids (generally near-neutral and reduced; geothermal context) or high- to intermediate-sulfidation fluids (acidic and oxidized; magmatic-hydrothermal context) determines (1) the possible zonation of alteration assemblages around the fluid conduits, and (2) the mineralogy of the mineral precipitates (if any) that may occur on the surface. In addition to the

“original” physicochemical characteristics of hydrothermal fluids, their chemical characteristics may vary depending on the occurrence of (relatively) near-surface boiling, which may generate H₂SO₄-rich fluids locally in steam-heated grounds (shallow hypogene acidic fluids), independently from the composition of pre-boiling fluids (e.g., Sillitoe 2015). This means that hydrothermal fluids of any kind that undergo boiling may generate acidic fluids upon condensation of boiled-off steam, and the associated alteration assemblages and surficial hydrothermal features.

Acidic fluids from either deep or shallow hypogene sources generate alteration assemblages that result from extremely reactive to relatively mild reactions between fluids and host rocks, from proximal to distal areas to hydrothermal upflow. No surface sinter deposits, either carbonate- or silica-rich, can be expected from highly reactive high-sulfidation type fluids. In this environment, silica is the only residue after extreme acid leaching of every other mineral, or as a late overprint. Common hydrothermal manifestations of the high-sulfidation type are high-temperature solfataras and fumaroles centered on recent volcanic edifices, and hyper-acidic crater lakes. Near-neutral low-sulfidation type fluids, on the contrary, may develop sinter deposits in hot spring environments unless the hydrothermal discharge occurs in high-relief terrains. Common hydrothermal manifestations of the low-sulfidation type are hot springs and geysers. Common manifestations associated with steam-heated grounds are fumaroles, steaming grounds, and mud pots (or mud “volcanoes”). The position of the groundwater table is sensitive to seasonal variations in rainwater availability, climatic and tectonic changes, or several other phenomena (e.g., Sillitoe 2015).

Paleosurface features for the various types of subaerial/sublacustrine magmatic-hydrothermal systems (*i.e.*, epithermal-like systems; [Figure 5.4.4](#)) and their mineralogy were summarized in detail by Sillitoe (2015) as (1) steam-heated grounds, with opal/chalcedony, alunite, kaolinite and smectite, (2) groundwater table silicification, with opal/chalcedony, (3) lacustrine amorphous silica sediments, with opal and cristobalite, (4) hydrothermal eruption craters and breccias, with illite and smectite, (5) hot spring sinter, with opal/chalcedony, (6) hot spring travertine, with calcite and aragonite, (7) hydrothermal chert, with opal/chalcedony, and (8) silicified lacustrine sediments, with opal/chalcedony. See their occurrence and nature schematized in Figure 11 by Sillitoe (2015), as replacements, open-space, or on-surface (subaerial or subaqueous) precipitation. Cases 6 to 8 (particularly case 6) occur distally to their hydrothermal upflow zone, which implies that their temperatures are lower than in proximal features and their chemical characteristics are attenuated by interaction with meteoric water. Such features and their particular mineral assemblages may be found topping various hydrothermal alteration assemblages in association with either acidic or near-neutral to alkaline fluids (high-sulfidation and intermediate- to low-sulfidation fluids, respectively), but not necessarily. Alteration assemblages in the uppermost part of these systems are characteristically zoned as follows, from the central portion of hydrothermal upflow outwards into

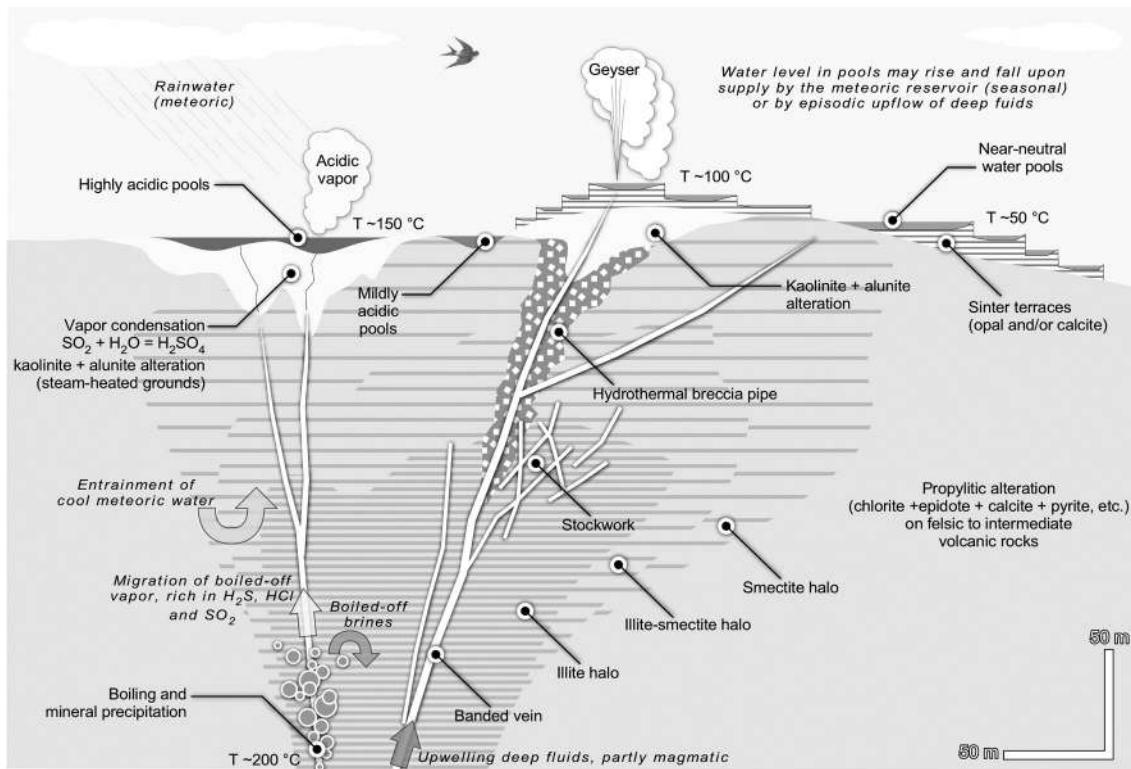

FIGURE 5.4.4 Structural section that combines evidence from active geothermal fields with neutral to alkaline fluids and from the uppermost portion of fossil low-sulfidation epithermal deposits, including all typical styles of mineralization and hydrothermal assemblages. (Loosely based on Buchanan, L. J., Precious metal deposits associated with volcanic environments in the Southwest, in: *Relations of Tectonics to Ore Deposits in the Southern Cordillera*, Vol. 14, W. R. Dickinson and W. D. Payne (Eds.), pp. 237–262, Arizona Geological Society Digests, 1981; Corbett, G. J., and Leach, T. M., *Southwest Pacific Rim Gold-Copper Systems: Structure, Alteration and Mineralisation*, Society of Economic Geologists, Boulder, CO, Special Publications No. 6, 238 p, 1998; Albinson, T. et al., Controls on formation of low-sulfidation epithermal deposits in Mexico: Constraints from fluid inclusion and stable isotope data, in: *New Mines and Discoveries in Mexico and Central America*, T. Albinson and C. E. Nelson (Eds.), pp. 1–32, Society of Economic Geologist Special Publications No. 8, 2001.)

non-altered host rocks (see Stoffregen 1987; Corbett and Leach 1998; Camprubí and Albinson 2006, 2007):

1. High-sulfidation systems: residual quartz (with opal, cristobalite and tridymite), advanced argillic (from silica + alunite to alunite + kaolinite outwards), argillic (from kaolinite + silica to kaolinite + silica + smectite outwards), and illite- or smectite-rich phyllitic, from montmorillonite to chlorite-rich propylitic alteration, including zeolites and carbonates (calcite and dolomite), in association with the most alkaline fluids;
2. Intermediate- to low-sulfidation systems: phyllitic to propylitic alteration, with the same mineral assemblages as those described for high-sulfidation systems.

Additionally, all the features in the uppermost portions of epithermal deposits and their modern analogues may have anomalously high concentrations of Mn, As, Sb, Hg, Tl, Se, Au, Ag, Ga, and W (Hedenquist et al. 2000; Sillitoe 2015). These anomalies occur in association with minerals such as pyrite, cinnabar, stibnite, orpiment, realgar, native sulfur, livingstonite, corderoite, several amorphous phases, and, exceptionally,

borates (Sillitoe 2015, and references therein). The precipitation of silica gels in epithermal systems is very common. The occurrence in present-day geothermal fields (broadly regarded as the active examples of epithermal deposits) of phenomena such as geysers and phreatomagmatic eruptions add another interesting feature for prebiotic reactions: the formation of aerosols and the occurrence of minute mineral particles alongside them (see subsequent sections).

Other possible hydrothermal environments associated with volcanism that might have harbored similar conditions as epithermal-type systems are Algoma-type BIFs, which were formed during the Archean. Such deposits are rich in magnetite, hematite, siderite, pyrite, pyrrhotite, quartz (as cherts), chlorites, amphiboles, feldspars, biotite, chalcopyrite, and apatite, and the precipitation of colloidal silica would have also occurred (Jébrak and Marcoux 2008).

5.4.4 PREBIOTIC EXPERIMENTS RELATED TO HYDROTHERMAL VENTS

Even if hydrothermal vent systems effectively harbored chemical synthesis, it is necessary to remind that the formation of relevant molecules is only the first step toward the origin of

life. The permanence of molecules in these environments is a crucial factor to guarantee the formation of more complex molecules (even polymers) that are necessary for the emergence of living beings. In the forthcoming sections some experiments that aimed to reproduce the environmental conditions in some hydrothermal systems are discussed.

Although hydrothermal systems are the combination of a broad number of geochemical variables, the vast majority of experiments that consider the “conditions of hydrothermal springs” have been initially oriented to test the effect of high temperatures on prebiotic reactions. Thermal energy has been considered as a synonym of energy in hydrothermal systems and other energy sources have been neglected. Therefore, the research in the matter started by testing the stability of organic molecules at high temperatures, which is one of the most straightforward possibilities. Lately, pressure has also been incorporated in simulations as many of the experiments deal with the simulation of deep submarine environments where the pressure is a critical variable. In submarine environments pressure affects the physical state of fluids: water and other molecules (CO_2 and CH_4) behave as supercritical fluids, hence their high efficiency as solvents for organics (Holm 1992).

5.4.4.1 STABILITY OF ORGANICS AT HIGH TEMPERATURES AND PRESSURES

The stability of organic molecules exposed to high temperatures is a fundamental issue. The endurance of molecules allows to increase their concentration and the chance for further chemical reactions. The formation of polymers, such as nucleic acids, proteins, and polysaccharides, requires a low decomposition rate of the monomers that constitute them. Some groups of molecules are seemingly good candidates to be the objects in these experiments; the tested molecules include amino acids, sugars, nitrogenous bases, and organic acids, among others (Table 5.4.3). Half-life values ($t_{1/2}$) provide an estimate of the time span molecules may last in the environments under the tested environmental conditions, for an excellent review of half-lives values see Weber (2004) and references therein.

Amino acids are essential molecules for life and their behavior has been largely studied. Amino acids at high temperatures (*i.e.*, 250°C) and pressures (*i.e.*, 250 atm) are very short-lived, as they are stable for only a few hours (Abelson 1954; Bernhardt et al. 1984; White 1984; Miller and Bada 1988; Bada et al. 1995). These results would suggest that hydrothermal springs in such conditions would not fit the requirements for being considered “niches for chemical evolution.” However, it is essential to emphasize that most of these experiments do not incorporate many of the physicochemical parameters (*e.g.*, oxidation state, pH, dissolved gas species, presence of inorganic surfaces, etc.). Also, such studies did not recreate the entire natural variability in temperature and pressure and their existing gradients even at the scale of a single vent. Consequently, the stability of the organic molecules could have been largely underestimated (Holm and Andersson 2005).

Other relevant molecules are sugars, which are essential constituents of nucleic acids and the basis for structural polymers in cells. The studies regarding the thermolysis of sugars (Larralde et al. 1995) showed that these compounds are very unstable ($t_{1/2}$ ribose ≈ 77 min) at temperatures as low as 100°C. The same behavior is observed for nitrogenous bases. The half-life of adenine is $t_{1/2} \approx 1$ year at 100°C (Levy and Miller 1998), which is a very short availability for further reactions. Similarly, considering the effect of pH and high pressures (*e.g.*, 7.2 MPa), uracil and adenine are even more labile ($t_{1/2} < 1$ h) than in the previous case (White 1984; Balodis et al. 2012). All in all, this only emphasizes the high lability of organic molecules at relatively high temperatures, as they have much lower fusion and decomposition points than inorganic compounds.

5.4.4.2 TEMPERATURE GRADIENTS

Even if energy is necessary for promoting chemical reactions, the temperatures of some actual hydrothermal fluids may attain up to 400°C (Von Damm 2013; James et al. 2014), which are excessively high for organic molecules. It is an immense problem, considering that these high temperatures could have existed in some environments during the Archean (Shibuya et al. 2010). However, as explained in sections above, such temperatures are not constant in time and space; high-temperature vents are commonly located in submarine areas at temperatures nearing 0°C, which implies the occurrence of strong thermal gradients. *In situ* studies at present-day hydrothermal vent systems demonstrate the existence of such gradients: just 15 cm around the hydrothermal vents temperature drops at least 30°C from the vent (Chevaldonné et al. 1991; Bates et al. 2010). The spatial variability of the temperature, associated with the turbulent mixing of the fluids in this type of environments, could considerably increase the stability of the organic molecules.

However, temperature is not the only variable that may present broad gradients, such is also the case of pressure, pH, Eh, ionic concentration, mineralogy, etc. Such gradients, besides representing an undeniable fact in natural hydrothermal systems, could also have contributed to increase the stability of organic molecules. Recently, attention has been paid to gradients in the experimental field and some attempts have been made indeed.

A first approximation is to estimate the half-life of molecules at different temperatures. Levy and Miller (1998) demonstrated that at 100°C, nucleobases have short half-lives ($t_{1/2} \approx 1$ year for A and G, $t_{1/2} \approx 12$ years for U, and $t_{1/2} \approx 19$ days for C). However, the half-lives of same molecules at 0°C leapt various orders of magnitude, to the point that all of them presented values in the order of 10^6 years. In other experiments, Larralde et al. (1995) tested the stability of sugars and found that the stability ribose increased from 73 min at 100°C to 44 years at 0°C. Such experiments can only encourage working with temperature gradients, ideally in congruence with those determined in natural examples.

The design and use of flow reactors brought a new perspective in the field, as they permit the generation of thermal

TABLE 5.4.3
Some Relevant Experiments in Prebiotic Chemistry Simulating Physicochemical Conditions of Hydrothermal Vents

Type of Study	Variables Used (Ω)	Description of the Experiments	Organic Molecule Used	Mineral	Main Findings	Reference
Decomposition	T	Solutions of amino acids (AAs) sealed in Pyrex glass	Ala, Arg, HCl, Asp, Cys, N.A. Glu, Gly, His, HCl, HyPro, Ile, Leu, Lys, HCl, Met, Phe, Pro, Ser, Thr, Tyr, Val		Interconversion of amino acids (i.e., methylamine from glycine; ethylamine from alanine; glycine, alanine, and ethanolamine from serine, etc.). There is an order of relative thermal stability at temperatures between 216°C and 280°C: (1) Asp, Thr, Ser, Arg, HCl; (2) Lys-HCl, His-HCl, Met; (3) Tyr, Gly, Val, Leu, Ile; (4) Ala, Pro, Hyp, Glu.	Vallentyne (1964)
Decomposition	T	Amino acid in water solutions	Glu, PCA (pyroglutamic acid)		Kinetic parameters	Povoledo and Vallentyne (1964)
Decomposition	T	Hydrolysis and decomposition of biomolecules in solutions at 250°C (pH = 7, potassium phosphate buffer).	Free amino acids, nucleic N.A bases, peptide bonds, phosphodiester bonds		The t _{1/2} of peptide bonds on alanine oligomers is close to 7 min. A fast breakdown of other oligomers (Ala-Asp and Glu-Ala). Short half-life for proteins (1.08 s for (Ala) ₃).	White (1984)
Decomposition	T, P	Amino acid decomposition (6 h of incubation at 250°C and 260 bar).	Ala, Arg, Asp, Glu, Gly, N.A. His, Ile, Leu, Lys, Met, Phe, Ser, Thr, Tyr, Val		Amino acids are drastically affected by high temperature and pressure. Some amino acids are almost quantitatively transformed or decomposed (Asp, Glu, Ser, Thr, Cys, Trp); apolar amino acids as well as His, Lys, Arg and Phe are partially degraded.	Bernhardt et al. (1984)
Decomposition	T, P, pH	Decomposition of solutions of amino acids at 250°C, 265 atm, and pH = 7.	Ala, Leu, Ser, Asp	N.A.	Leu t _{1/2} is 15–20 min; Asp (<1 min), and Ser (few minutes) decomposed more rapid than Leu; Ala is more stable than Leu. Gly is produced during the heating experiment.	Miller and Bada (1988)
Decomposition	T, P, M	Amino acid and oligomers at high temperatures, at both high and low pressure.	Gly, Di-Gly, L-Ala, L-Glu	Magnetite	Dipeptide hydrolysis and amino acid decomposition have a first-order rate law. Magnetite accelerates the decomposition.	Qian et al. (1993)
Decomposition	T, P, M	Kinetics of thermal decarboxylation of aqueous solutions of acetic acid and sodium acetate (335°C and 355°C) in contact with surfaces as potential catalysts. Different pressures were used.	Acetic acid and sodium acetate	Quartz, fused quartz, calcite, natural pyrite, titanium oxide, Au, Ca-montmorillonite, Fe- montmorillonite, hematite, synthetic pyrite, and magnetic.	The decarboxylation of acetic acid and acetate catalyzed by the cleavage of the C-C bond, while the acetate molecule is adsorbed onto a surface. Oxidation of acetic acid occur with hematite and defected magnetite.	Bell et al. (1994)
Decomposition	T, P, M, pH	Amino acids, at high temperatures (240°C), buffered solutions (pH = 7).	Ala, Gly + Leu, ethylamine	Quartz-fayalite-magnetite mixture	Amino acids are irreversibly destroyed by heating at 240°C. Equilibrium thermodynamic calculations are not applicable to organics under submarine vent conditions.	Bada et al. (1995)
Decomposition	T	Determination of half-lives of sugars (aldopentoses and aldohexoses).	Ribose	N.A.	Ribose t _{1/2} are very short (73 min at pH 7.0 and 100°C and 44 years at pH 7.0 and 0°C). The other sugars also have short half-lives (2-deoxyribose, ribose 5-phosphate, and ribose 2,4-bisphosphate).	Larralde et al. (1995)
Decomposition	T, redox	Decomposition at pH 4–8 and, temperatures from 40°C to 120°C. Amino acids at different temperatures, controlling the	Ala, bAla, aABA, Asp, Glu, Gly, Leu, Ser, Val	N.A.	The decomposition rate is lower in high hydrogen fugacity environments.	Kohara et al. (1997)

Some Relevant Experiments in Prebiotic Chemistry Simulating Physicochemical Conditions of Hydrothermal Vents

Type of Study	Variables Used (Ω)	Description of the Experiments	Organic Molecule Used	Mineral	Main Findings	Reference
Decomposition	T, pH	Half-lives of nucleic bases at 100°C and pH = 7.	Adenine, Guanine, Cytosine, Uracil	N.A.	At 100°C the half-lives for nucleobases are very short, half-For A is 1 yr, G is 0.8 yr, U is 12 yr, and T is 56 yr. C has half-life of 19 days. At 0°C, the half-life of A is 6×10^5 yr, G is 1.3×10^6 yr, U is 3.8×10^8 yr, and T is 20×10^8 yr.	Levy and Miller (1998)
Decomposition	T, P, M, redox	Stability of amino acids, under redox buffered hydrothermal conditions; 200°C and 50 bar in Teflon-coated autoclaves.	Ala, Asp, Leu, Ser	Pyrite-pyrrohite-magnetic Gly, and Ala were formed, from Ser. Decomposition rates of Leu, Ala and Asp lower in experiments containing the PPM assemblage.		Andersson and Holm (2000)
Decomposition	T, P	Influence of P (22.2 and 40.0 MPa). and T (250°C, 300°C, 350°C, 374°C, 400°C) in the processes.	Gly	N.A.	Formation of Di-Gly, Tri-Gly (traces), diketopiperazine and a 433 Da product. P and T influence both dimerization and decomposition. Maximum dimers formation at 350°C–375°C 22.2 and 40 MPa.	Alargov et al. (2002)
Decomposition	T, P	High temperature (200°C–340°C) and high pressure (20 MPa), in a continuous-flow tubular reactor.	Ala, Asp, Leu, Phe, Ser	N.A.	Degradation rates Asp> Ser>Phe>Leu>Ala. Two main reaction paths: <i>deamination</i> (Asp) to produce ammonia and organic acids, and <i>decarboxylation</i> to produce carbonic acid and amine. Production of glycine and alanine from serine.	Sato et al. (2004)
Decomposition	T, P	Hydrothermal reaction kinetics. Followed by a custom-built spectrophotometric reaction cell. <i>In situ</i> observations.	Asp	Reactor type. Non-inert (Ti-0.4/Au reactor) Inert reactor (Au reactor).	The reaction kinetics of Asp is complicated, and highly dependent on experimental conditions (P, T, catalytic surfaces).	Cox and Seward (2007a)
Decomposition	T, P	Hydrothermal reaction kinetic. A custom spectrophotometric reaction cell was constructed. <i>In situ</i> observations. Experiments performed at 120°C–165°C and 20 bar.	α -Ala, β -Ala, Gly	N.A.	Under certain hydrothermal conditions, α -Ala, Gly, and β -Ala undergo dimerization and cyclization reaction pathways.	Cox and Seward (2007b)
Decomposition	T, P	Decomposition of the amino acids sub- and supercritical water. The effect of T (250°C–450°C), and residence time (2.5–35 s), P (34 and 24 MPa), and reactant concentration (1.0% and 2.0%, w.v.).	Ala, Gly	N.A.	Decarboxylation and amino acid deamination reactions were proposed for both molecules. Ala is decomposed in lactic acid and ethylamine. Gly is decomposed in methyamine	Klingler et al. (2007)
Decomposition	T, M	The effect of iron oxide and sulfide minerals on decomposition reactions of amino acids.	Nva, Ala	Iron oxide and sulfide minerals. Mineral assemblage hematite-magnetic-pyrite (HMP) and pyrite-pyrrohite-magnetic (PPM).	Nva decomposes by (1) decarboxylation followed by oxidative deamination, and by (2) deamination directly to valeric acid. Ala decomposes in acetic and propionic acids, CO ₂ and NH ₃ . Minerals accelerated decomposition rates. Decomposition is faster in presence HMP than PPM. Surface catalysis and production of dissolved sulfur compounds are probably responsible of the decomposition.	McCollom (2013)

Some Relevant Experiments in Prebiotic Chemistry Simulating Physicochemical Conditions of Hydrothermal Vents

Type of Study	Variables Used (Ω)	Description of the Experiments	Organic Molecule Used	Mineral	Main Findings	Reference
Decomposition	T, M	Role of relevant minerals and mineral mixtures in the thermal behavior of an amino acid (200°C–250°C).	Gly	Mineral matrices: montmorillonite, nontronite, kaolinite, salts, artificial sea salt, gypsum, magnesite, picritic basalt, and three samples that simulate the Martian regolith.	Glycine intercalated in some phyllosilicates was well protected against thermomeleanoïd, survived unaltered or been transformed into the cyclic dipeptide (DKP) and linear peptides up to $(\text{Gly})_6$.	Dalai et al. (2017)
Decomposition	T, P, M, redox	Decomposition of aspartate (200°C and 15.5 bars in gold capsules) with and without a mineral product of serpentinization, and at reducing conditions (NH_4Cl and $\text{H}_2\text{[aq]}$)	Aspartate	Brucite	The reaction products vary significantly depending on the reaction conditions. Fluids including just aspartate formed: fumarate, maleate, malate, acetate, and succinate and glycine (both in traces). Under reducing conditions, the main product was succinate and amino acids glycine, α -alanine, and β -alanine.	Estrada et al. (2017)
Stability	T, M_d	The thermal stability of amino acids in seafloor hydrothermal systems is tested.	Ala, Asp, Gaba, Glu, Gly, Leu, Met, Ser.	Carbonaceous ooze. Calcite, with minor amounts of quartz and huntite and traces of illite, smectite and chlorite.	The upper limit temperature for the stable presence was 150°C and 200°C. AAs cannot be synthesized or survive at temperatures higher than 250°C.	Ito et al. (2006)
Stability	T, pH	Reactions of amino acids under subcritical water conditions (220°C–290°C).	Ala, Arg, Asp, Cys, Glu, Gly, His, Ile, Leu, Lys, Met, Phe, Pro, Ser, Thr, Tyr, Val.	N.A.	A decrease in the overall stability in amino acids mixtures. Most of the amino acids decompose at acidic and near-neutral pH, stable at basic pH.	Abdelmoez et al. (2007)
Stability	T, pH, M	Evaluation of the thermal stability of amino acids under alkaline hydrothermal conditions (an aqueous solution of NaCl and Na_2CO_3) at elevated temperature (100°C–300°C).	Ala, Arg, Asp, Bala, Gaba, Glu, Gly, His, Ile, Leu, Lys, Met, Or, Phe, Pro, Ser, Thr, Tyr, Val	Siliceous ooze	Compared with decomposition at neutral conditions, the decomposition rates are lower under alkaline conditions.	Yamaoka et al. (2007)
Stability	T, P, redox	Stability of adenine under hydrothermal conditions, at 300°C under fugacities of CO_2 , N_2 , and H_2 .	Adenine	Iron	The gases improve the stability of adenine. The concentration of adenine decreased rapidly during the first 24 h of the experiment, then kept decreasing slowly. Adenine was still present in the hydrothermal solution after ~200 h.	Franiatte et al. (2008)
Stability	T, M	Effect of the mineralogical and chemical properties of host sediments on the thermal stability of amino acids.	Ala, Arg, Asp, B-Ala, Gaba, Glu, Gly, His, Ile, Leu, Lys, Met, Phe, Pro, Ser, Thr, Tyr, Val	Siliceous ooze: silica minerals (mostly quartz and minor opaline silica); moderate amounts of calcite and minor amounts of smectite and illite. Montmorillonite Saponite (synthesized).	Amino acids protected from decomposition by amorphous silica and silicate minerals via adsorption and/or binding. The optimal temperature for amino acids was below 150°C. Amino acids are more stable at higher temperatures when associated with silicates.	Ito et al. (2009)

Some Relevant Experiments in Prebiotic Chemistry Simulating Physicochemical Conditions of Hydrothermal Vents

Type of Study	Variables Used (Ω)	Description of the Experiments	Organic Molecule Used	Mineral	Main Findings	Reference
Stability	T, P, pH	Ionization constants of nucleic bases at 250°C and 7.2 MPa	Adenine, Uracil	N.A.	Uracil and adenine decomposition occurred by one-step and two-step processes. Phosphate buffer solution enhances the stability of nucleic acid bases.	Balodis et al. (2012)
Stability	T, pH, redox	The effects of temperature (25°C, 150°C, 200°C, and 250°C) pH (6 and 10) and redox state (1.3 mM aqueous H ₂) of hydrothermal fluids. Reaction times from 3 to 36 min. Amino acids.	Glu	N.A.	Glutamic acid at high-temperatures cyclizes and forms pyroglutamate. The formed products (succinate, formate, carbon dioxide, and ammonia) depend on the temperature, pH, and the redox state.	Lee et al. (2014)
Oligomerization T, M		Gly, Phe, Tyr	(Ni,Fe)S surfaces.		The formation of oligopeptides was pH dependent. Di peptide formation (L-Phe, L-Tyr, D,L-Tyr and Gly).	Huber and Wächtershäuser (1998)
Oligomerization T, P, pH, M		Gly+Ala	CuCl ₂		Exponential growth of the products, as a consequence of previous cycles formation, function as templates for the next cycle. At least six different oligopeptides were detected; Ala-Gly, Gly-Ala, Ala-Ala, Gly-Ala-Ala, Ala-Ala-Ala, Ala-Ala-Ala-Ala.	Ogata et al. (2000)
Oligomerization T, pH, S _f		AMP	N.A.		Synthesis of oligonucleotides in the absence of condensing agents.	Ogasawara et al. (2000)
Oligomerization T		Oligomerization in a flow reactor (temperature gradient from 110°C to 0°C at pH 3). Dissolved ZnCl ₂ Amino acid solution heating at different temperatures (200°C–350°C) in a supercritical flow reactor. The stability of some amino acids (α - and ω -amino acids) under hydrothermal conditions was explored.	Gly	N.A.	Oligomers, up to tetra-Gly, formed at 200°C–350°C. No glycine oligopeptides were produced at 400°C. α -Amino acids and glutamic acid exhibited higher stability than other α -amino acids.	Islam et al. (2003)
Oligomerization T		Hydrothermal stability of alanine oligopeptides.	(Ala) ₃ , (Ala) ₄ , (Ala) ₅	N.A.	Small excess of oligopeptides longer than the starting ones. Elongation of (Ala) ₄ and (Ala) ₅ was possible in Ala excess. Elongation is competitive with degradation.	Kawamura (2005)
Oligomerization T		Amino acid solution heating at different T (160°C, 220°C, and 260°C).	Gly		Peptide synthesis (di-Gly, tri-Gly) is favored in hydrothermal fluids. Rapid recycling of products from cool into near-supercritical fluids will enhance peptide chain elongation.	Lemke et al. (2009)
Oligomerization T		In a hydrothermal microflow reactor, the synthesis of oligopeptide-like molecules at 250°C–310°C.	Glu, Asp		Synthesis of oligopeptide-like molecules of length up to 20-mers from Glu and Asp.	Kawamura and Shimahashi (2008)
Oligomerization T, pH		Dimerization rate of glycine, the effects of pH (ranging from 3.1 to 10.9) and temperature (120°C, 140°C, 160°C, and 180°C) were tested.	Gly	N.A.	Dimerization increases at basic pH (7–10). The dimerization rate increases with temperature (150°C). Gly dimerizes most under alkaline pH (~9.8) at about 150°C.	Sakata et al. (2010)

Type of Study	Variables Used (Ω)	Description of the Experiments	Organic Molecule Used	Mineral	Main Findings	Reference
Oligomerization	T	The production of phosphodiester bond and formation of mononucleotides capable of base pairing after hydration-dehydration cycles (85°C).	AMP, UMP	N.A.	The cycles of hydration and dehydration drive the synthesis of ester bonds. Oligomers resembling RNA are synthesized. Some of the products have properties suggesting secondary structures, including duplex species stabilized by hydrogen bonds.	DeGuzman et al. (2014)
Oligomerization	T, M, pH	The effect of elemental composition, pH, presence of clay, doping with small organic compounds, ribonucleotide activation on RNA oligomerization.	AMP, Imidazole-activated AMP (ImpA)	Iron-sulfide synthesized chimney's.	Nucleotide oligomerization—for both the activated and unactivated nucleotide—can occur in synthetic alkaline hydrothermal chimneys. Generation of oligomers (up to 4 units) with imidazole-activated ribonucleotides.	Burcar et al. (2015)
Synthesis	T, M	Heating of NH_4HCO_3 solution with C_2H_2 , H_2 and O_2 (produced <i>in situ</i>).	Acetylene	Calcium carbide. Calcium.	Amino acids (Gly, Ala, Asp, Glu, Pro, Ser, Leu, Ile, Lys, Val, Thr) and amines formed at 200°C–275°C, no formation at <150°C.	Marshall (1994)
Synthesis	T	Formation of lipids through Fischer-Tropsch-type synthesis of aqueous solutions.	Formic acid or oxalic acid	N.A.	Heating at 175°C for 2–3 days, lipid compounds from C_2 to $>\text{C}_{35}$ (n-alkanols, n-alkanoic acids, n-alkenes, n-alkanes and alkanones).	McCollom et al. (1999)
Synthesis	T, P, M	Reactivity of organic acids and acid anions (325°C, 350 bars) in the presence of the mineral assemblages.	Acetic acid, sodium acetate, valeric acid	(1) Hematite + magnetite + pyrite (HMP). (2) Pyrite + pyrrhotite + magnetic (PPyM) (3) Hematite + magnetic (HM)	Acetic acid and acetate decompose by decarboxylation and oxidation. Reactions are catalyzed by minerals: magnetite promotes decarboxylation; hematite promotes oxidation. The oxidation reaction is much faster. Valeric acid decomposed faster than acetic acid under similar conditions.	McCollom and Seewald (2003b)
Synthesis		Decomposition of formic acid and formate and the production of formate from CO_2 reduction (175°C–260°C). Experiments conducted in gold-TiO2 reactors	Formic acid and formate	Hematite, Magnetite. Serpentinitized olivine, Ni-Fe alloy	Minerals had no effect on the stability of formic acid or formate. The quantity of formate in hydrothermal fluids could be controlled by an equilibrium with dissolved CO_2 at the oxidation state and pH of the fluid.	McCollom and Seewald (2003a)
Synthesis	T, P, M	Conversion of CO_2 into organic compounds in hydrothermal conditions (300°C and 30 MPa), N-bearing molecules, to synthesize ammonia, at different T (200°C, 70°C, and 22°C).	CO_2 and H_2	Cobalt-bearing magnetite.	Formation of CH_4 , C_2H_6 , and C_3H_8 , but also $n\text{-C}_4\text{H}_{10}$ and $n\text{-C}_5\text{H}_{12}$.	Ji et al. (2008)
Synthesis	T, M		Dinitrogen, nitrate	Fe and Ni metal, awaruite ($\text{Ni}_{80}\text{Fe}_{20}$) and tetrataenite ($\text{Ni}_{50}\text{Fe}_{50}$), alloys bearing Fe and Ni.	Nitrite and nitrate are converted to ammonium rapidly. The reaction of dinitrogen is slower. Reduction is strongly temperature-dependent. Metals were more reactive than alloys.	Smirnov et al. (2008)
Synthesis	T	Amino acids synthesis in function of temperature, heating time, starting material composition and concentration.	NH_4HCO_2	Amino acids synthesized (Gly, Ala, Asp, Glu, Ser) from simple precursors under submarine hydrothermal systems conditions. Degradation is privileged in such conditions. Synthesis at lower temperatures.	Aubrey et al. (2009)

Some Relevant Experiments in Prebiotic Chemistry Simulating Physicochemical Conditions of Hydrothermal Vents

Type of Study	Variables Used (Ω)	Description of the Experiments	Organic Molecule Used	Mineral	Main Findings	Reference
Synthesis/ Precipitation	T, M	Pyrophosphate synthesis in inorganic precipitates simulating hydrothermal chimney structures in thermal and/or ionic gradients.	FeCl ₂ ·4H ₂ O, Na ₂ S·9H ₂ O, K ₂ HPO ₄ , Sodium silicate solution (Na ₂ O/26.5% SiO ₂),	N.A.	Poi was synthesized. Iron-rich membranes with incorporated phosphates were generated.	Barge et al. (2014)
Cycling	T, S	Laboratory simulation of hydrothermal pools under cycles of hydration and dehydration at 85°C in an atmosphere of CO ₂ and monovalent salts	Na-acetyl phosphate Mixtures of AMP and UMP	N.A.	1:1 are cycled in the presence of monovalent salts, a polymerization reaction yields a product with	Da Silva et al. (2015)
Absorption	T, M	Adsorption–desorption experiments at 80°C for 10 days.	Lys	Na-smectite (smectite (>90%), a small amount of cristobalite (<10%) and traces of calcite and quartz.	Thermal treatment originates stronger smectite–lysine binding, by H bonds between NH ₃ ⁺ lysine groups and smectite basal O atoms.	Cuadros et al. (2009)
Microsphere formation	T, P	Aqueous solution with amino acids (Gly, Ala, Val and Asp) in glass tubes, heated at 200°C, 250°C, 300°C, and 350°C, at 134 atm, buffered (pH 7.2).	Gly, Ala, Val, Asp	N.A.	Formation of microspheres at temperatures above 250°C. Polar Yanagawa and Kojima (1985)	
Reaction	T	Decarboxylation of an amino acid solution as a function of pH.	α -Ala	N.A.	Arrhenius parameters were determined. The addition of KCl resulted in a reduction of the decarboxylation rate.	Li et al. (2002)
Reactivity	T, M	Pyruvate reactions in presence of transition-metal sulfide minerals, at moderate temperatures (25°C–110°C).	Pyr	Pyrrohotite, troilite, arsenopyrite, pyrite, marcasite, sphalerite, chalcocite	Amino acids and fatty acids were formed. Formation of lactate, Novikov and propionate, and alanine, among others.	Novikov and Copley (2013)
Concentration	T, M	To test if channels within the mineral could act as act as natural Clusius–Dickel thermal diffusion column and increase local amphiphile concentrations.	Oleic acid	Borosilicate microcapillaries.	Microcapillaries act as a thermal diffusion column and concentrated the molecule. Vesicle formation.	Budin et al. (2009)
Mineral precipitation	T, pH	Raman spectroscopy to study ancient hydrothermal iron sulfide formation (growth temperatures from 40°C to 80°C).	N.A.	Aqueous alkaline solutions containing bisulfide and silicate injected into iron (II) solutions.	Formation of mackinawite and greigite iron sulfide phases. Mackinawite was probably the dominant catalyst in ancient pre-biotic chemistry.	White et al. (2015)

Note: All amino acids are abbreviated according to the IUPAC indications.

Key: ABA = aminobutyric acid, Ala = alanine, AMP = adenosine monophosphate, Arg = arginine, Asp = asparagine, Cys = cysteine, Gaba = gamma-aminobutyric acid, Glu = glutamic acid, Gly = glycine, His = histidine, Hyp = hydroxyproline, Ile = isoleucine, Leu = leucine, Lys = lysine, Met = methionine, Nva = norvaline, Orn = ornithine, Phe = phenylalanine, Pyr = pyruvate, Ser = serine, Thr = threonine, Tyr = tyrosine, Val = valine.

(Ω) Variables used refer to: T = temperature, P = pressure, M = temperature, S = salts, redox estate, and pH.

gradients. The use of those equipment showed that it is not only possible for organic molecules to remain in these environments, but it is also feasible to form more complex molecules, such as oligomers. This was tested for amino acids that formed oligopeptides (Imai et al. 1999; Ogata et al. 2000; Islam et al. 2003); similarly, oligonucleotides were formed from the repeatedly circulation of nucleotides between hot and cold regions, even in the absence of condensation agents (Ogasawara et al. 2000). These experiments have been completed with theoretical approaches that suggest that thermal gradients in mineral pores could favour the accumulation of molecules (Braun and Libchaber 2002; Baaske et al. 2007; Mast et al. 2013; Niether et al. 2016).

5.4.4.3 REDOX STATE AND DISSOLVED GASES

Hydrothermal vents harbor a high diversity of chemical species. Currently, some of these dissolved species in hydrothermal fluids are the fuel for microbial communities thriving in these environments (Martin et al. 2008). It has been proposed that the wide availability of gases and/or dissolved elements (CO_2 , H_2S , H_2 , CH_4 , NH_3 , Co, Fe, Mg, SO_4^{2-} , and Mn) (Tivey 2007; Martin et al. 2008) in hydrothermal systems could have been the basis of the first metabolic routes (Wächtershäuser 1990; Russell and Martin 2004; Martin et al. 2008). Certainly, dissolved chemical species in these environments may have promoted or inhibit the reactivity of organic molecules.

More recently, several research groups have delved into the effect of various geochemical variables on the stability of organic molecules. In general, the experiments suggest that the geochemical variables are intrinsically related to the fate of the organic molecules. That implies that in these environments small changes in environmental conditions could have promoted chemical changes. Investigations (Kohara et al. 1997) and (Lee et al. 2014) showed that the decomposition rate of some amino acids (*i.e.*, glycine, glutamic acid, and alanine) was much slower in environments with high hydrogen fugacity. In other experiments, the decomposition of amino acids decreases under buffered conditions, as the pyrite-pyrrhotite-magnetite system acts as a redox buffer (Andersson and Holm 2000). However, the redox condition also affects the decomposition pathways. There are two possible decomposition reactions of amino acids under hydrothermal conditions: *deamination* to produce ammonia and organic acids, and *decarboxylation* to produce carbonic acid and amines (Sato et al. 2004). It has been shown that some amino acids (*i.e.*, glycine and alanine) may preferably undergo dimerization and then cyclization reactions, instead of decomposition, depending on the experimental conditions (mineral surface, temperature, residence time, and redox state; (Cox and Seward 2007b, 2007c). In addition, depending on temperature and pressure, there may be a selection of the decomposition mechanism (Klingler et al. 2007).

Experiments with nitrogenous bases (Franiatte et al. 2008) showed that under an atmosphere containing CO_2 , N_2 , and H_2 , adenine was present after ≈ 200 hours of

heating at 300°C . On the other hand, the decomposition reactions (*e.g.*, dehydrogenation) may depend on the redox state of the system.

5.4.4.4 pH GRADIENTS

There is a great debate about the role of proton gradients in the origin of life, as the electrochemical gradients across the membranes could have boosted metabolism (Jackson 2016; Lane 2017). It is very feasible that the pH values in hydrothermal vent systems could also be involved in the chemical behavior of organic molecules. On-site measurements showed that hydrothermal fluids at high temperatures (*e.g.*, $>350^\circ\text{C}$) and with acidic pH (close to 5) change their pH toward neutrality when they come in contact with oceanic water (Ding et al. 2005). Similarly, theoretical studies explain that it is possible to have a gradient of up to 6 pH units (that is, six orders of magnitude) at a micrometric scale in hydrothermal vents (Möller et al. 2017). Experimentally, Sakata et al. (2010) showed that dimerization of glycine is most efficient at alkaline pH (≈ 9.8) due to differences in dissociation states of the molecule (*i.e.*, Gly^\pm and Gly^- fractions are approximately equal at this pH). Also, the decarboxylation of alanine is three times higher in pH values where the zwitterion predominates, although the presence of dissolved ions (*i.e.*, KCl) reduces it (Li et al. 2002).

5.4.4.5 EXPERIMENTS THAT INCLUDE MINERALS

One of the most important characteristics of hydrothermal vents is their high mineralogical diversity. The broad diversity of minerals in hydrothermal springs of any type could be a crucial parameter in the formation and production of complex organic molecules in prebiotic experiments (Colín-García et al. 2016). The role that minerals could have played in prebiotic reactions is complex but can be envisioned as follows: (1) catalysts of reactions, both decomposition and formation of more complex species, (2) templates where organics can organize and constitute more complex molecules, (3) protective agents, sheltering molecules from decomposition in the media, and (4) concentrating agents—the concentration of organics in contact with solids increases and some organic reactions can be promoted. The specific role that minerals play depends on variables including: chemical composition of minerals and their impurities, solubility of minerals, redox potential in the environment, pH, temperature, ionic force, and, of course, the characteristics of the organic molecule. Minerals affect at different degrees the thermal decomposition of organics; actually, many experiments have been performed in order to specifically understand the effect of minerals on the chemical reactions related to prebiotic chemistry experiments (Table 5.4.3).

In order to evaluate the effect of the mineralogical and chemical properties of host sediments on the thermal stability of amino acids (Ito et al. 2006) reported almost full decomposition of amino acids (90.1% at 200°C and 99.7% at 300°C) in experiments including calcareous sediments and

NaCl solutions. Also, they suggested that the temperature roof for having stable amino acids probably varies between 150°C and 200°C (Ito et al. 2006). Later, the same group demonstrated that at the very same conditions siliceous ooze served as a better protection for amino acid than calcareous sediments (Ito et al. 2009). Yamaoka et al. (2007) also studied the effect of siliceous ooze in the decomposition of amino acids, but under alkaline hydrothermal conditions (by enrichment of Na₂CO₃ and volatile gases). They found that decomposition is inhibited in alkaline conditions and, even more, amino acids remained even after heating for 240 hours at 300°C. Dalai et al. (2017) investigated how minerals and mineral mixtures change the formation of a black water-soluble thermal polymer (“thermomelanoid”) of glycine. When the experiment was carried out in the presence of phyllosilicates, these minerals precluded the formation of the polymer; instead, glycine remained unaltered or was even transformed to the cyclic dipeptide diketopiperazine (DKP) or polymerized up to Gly6.

It has also been tested the role of sulfides in prebiotic reactions. Novikov and Copley (2013) demonstrated that pyrite favors the synthesis of amino acids and fatty acids from pyruvate (an important precursor for organic molecules and already synthesized under simulated hydrothermal vent conditions). Qian et al. (1993) showed that magnetite increases the decomposition of amino acids at high pressures and temperatures. In addition, the presence of mineral substrates (*e.g.*, iron oxides and sulfides) accelerates the decomposition rates of some amino acids (norvaline; McCollom 2013).

A series of experiments (McCollom and Seewald 2003a) showed that minerals such as hematite, magnetite, serpentinized olivine, and NiFe alloy had little effect on the stability of some species (formate and formic acid, the simplest organic acid, and acid anion present in natural waters). However, minerals influenced both the pH and concentration in CO₂ of fluids, and, in turn, dissolved CO₂ determined the amount of formate that was present. Acetic acid and acetate (intermediates in metabolism) decompose rapidly in the presence of minerals containing metal ions (*e.g.*, calcium- and iron-bearing montmorillonite, pyrite, hematite, and magnetite) as they act as catalysts in the decarboxylation reaction (Bell et al. 1994).

Stereoselectivity is also promoted by minerals. Fuchida et al. (2017) heated (at 120°C) DL-alanine in presence of olivine and water to investigate the formation of the diastereoisomers of diketopiperazine (DKP). Olivine was an efficient catalyst to form DKP and determined the preferential formation of one of these dipeptides.

Studies that included other types of variables demonstrated that minerals can also have a representative role in the behavior of organic molecules. For example, the presence of dissolved ions may favor the protection of amino acids against thermal decomposition, probably due to the formation of complexes with dissolved ions (*e.g.*, Ca²⁺ and Mg²⁺) that, in turn, increase their sorption onto mineral surfaces (Dalai et al. 2017). Likewise, thermal treatment from a hydrated phase can favor the concentration of amino acids in clays due to the increase in hydrogen bonds between the tetrahedron

bed and the amino group of the amino acid (Cuadros et al. 2009). Also, the stability of formate and formic acid could be affected more by dissolved CO₂ contents and the pH of the fluid than by the presence of some minerals (*e.g.*, hematite, magnetite, and serpentine; McCollom and Seewald 2003b).

5.4.5 SUMMARY OF RELEVANT GEOLOGICAL AND MINERALOGICAL ASPECTS FOR EXPERIMENTAL STUDIES WITH REGARD TO PREBIOTIC SYNTHESIS

Physicochemical variables such as temperature, pressure, composition of solutes in aqueous brines or supercritical fluids, pH, and Eh are obvious key factors that control prebiotic synthesis. In addition, the role of minerals in prebiotic chemistry is acknowledged nowadays as no lesser factor (see the previous sections; Schoonen et al. 2004; Cleaves et al. 2012). The broad variety of factors that have an influence on prebiotic chemistry come from an even broader variety of natural environments (Figures 5.4.5 through 5.4.8, which stretch far more generously than those visible in deep submarine VMS-type hydrothermal vents, either acidic or alkaline (see Table 5.4.2). In other words, many natural settings interesting as models for prebiotic studies can be found outside VMS-type hydrothermal vents.

Natural systems keep resisting experimental simplifications but also have a great potential for furnishing new possibilities for experimental patterns. It is in such spirit that we may now summarize from the above the following variables and “situations,” as it were, in order to direct future experimental endeavors as much close to nature as possible.

1. Physicochemical gradients: temperature gradients, pH gradients, Eh gradients, salinity gradients, ionic force gradients, pCO₂ gradients, and O₂ and S₂ fugacity gradients (virtually all hydrothermal systems in early sections of this paper). All natural hydrothermal systems show strong natural variations (Hazen and Sverjensky 2010) in all these cases with respect to (A) upwelling hydrothermal fluids themselves, and (B) the contrast between them and the environment they may encounter (whether it is a rock, air, seawater, a lake, or a puddle). As consequence, the value distribution of all variables may behave fractally across space and time—for instance, temperature decreases and pH increases from the central to the peripheral vents in VMS and SEDEX mounds, but they also do so in the lifetime of a particular vent and as the whole hydrothermal system wanes. The most obvious differences that arise for a given variable when comparing two or more types of hydrothermal systems have to do with how extreme is the range of variation of a given physicochemical variable, as such general ranges overlap in all the types of systems considered hereby. For example, all ranges of temperatures in Table 5.4.2 are those of

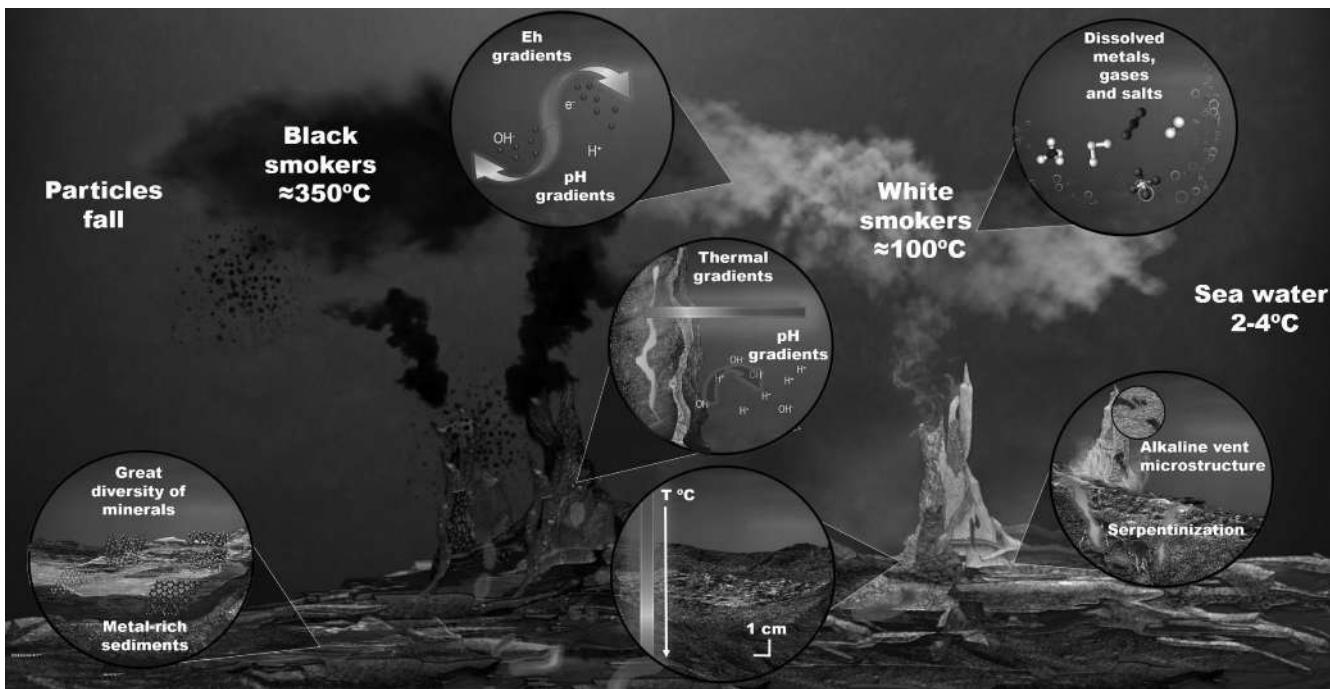

FIGURE 5.4.5 Representation of structures, processes, and gradients of key variables on the seafloor in association with hydrothermal systems of the volcanogenic massive sulfide (VMS) type, as of [Figure 5.4.1](#).

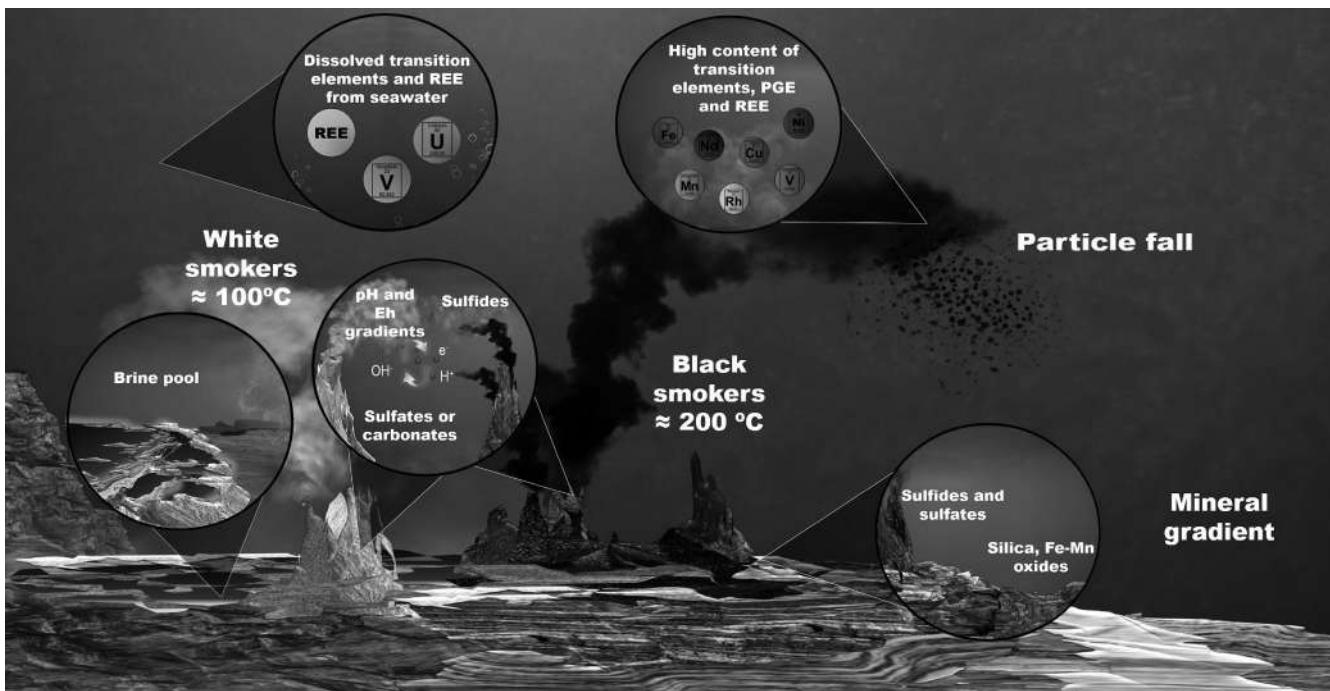

FIGURE 5.4.6 Representation of structures, processes, and gradients of key variables on the seafloor in association with hydrothermal systems of the sedimentary-exhalative (SEDEX) type, as of [Figure 5.4.2](#).

typical stages of mineral deposition (ore associations in particular), but the general variation of temperature stretches down to the environmental temperature for each case (~0°C in deep seawater and ~25°C in continental systems). In addition, all the (paleo-) hydrothermal systems considered in this paper have

a multi-episodic behavior, which means that each hydrothermal pulse has physicochemical characteristics that may differ greatly from those of preceding or later pulses.

2. Mineralogical gradients across a mineral deposit or compositional gradients within the same mineral

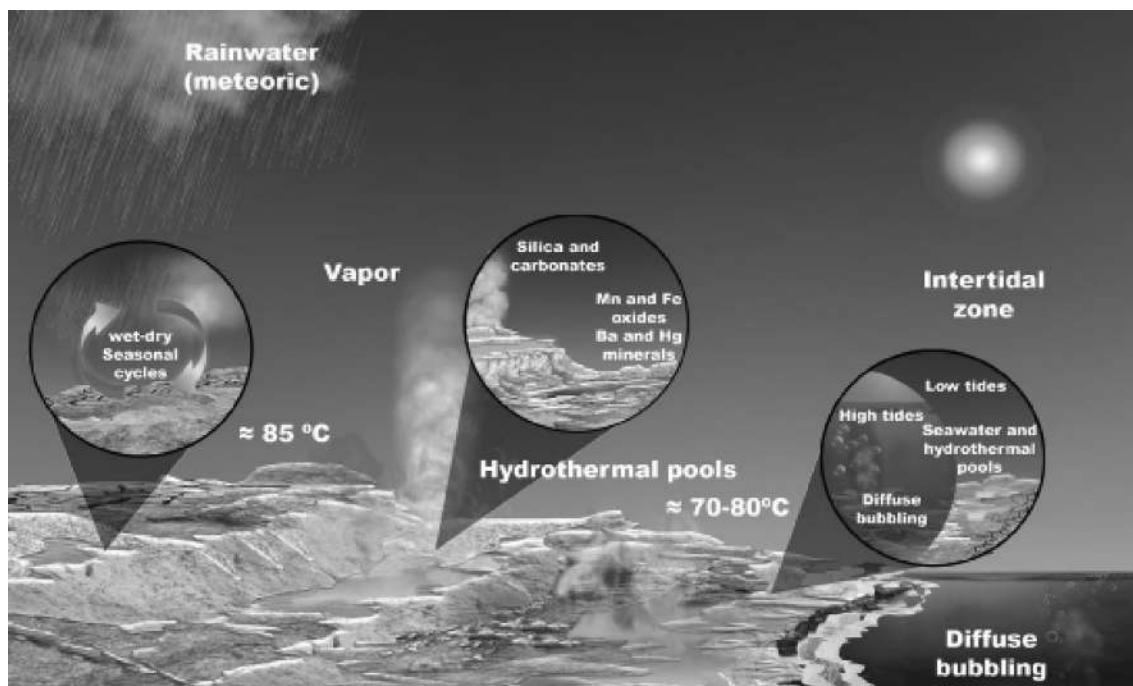

FIGURE 5.4.7 Representation of structures, processes, and gradients of key variables in shallow submarine to subaerial hydrothermal systems that occur during early stages of continental rifting, as of [Figure 5.4.3](#).

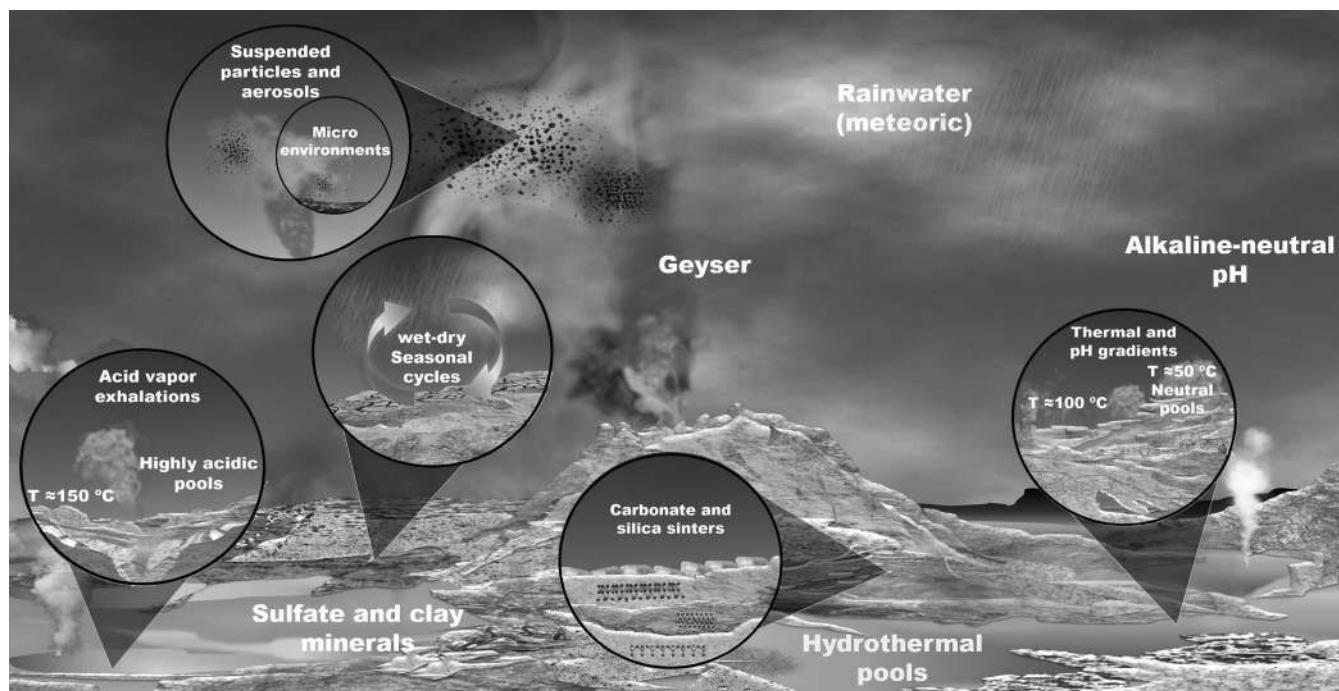

FIGURE 5.4.8 Representation of structures, processes, and gradients of key variables on the surface in association with active geothermal fields and epithermal deposits, as of [Figure 5.4.4](#).

(virtually all systems). Most hydrothermal systems share minerals from about the same mineralogical hierarchical categories (silica, carbonates, sulfates, sulfides, clay minerals, etc.), but the distribution of such minerals may vary among different types of hydrothermal systems and even among different

vents of the same system. Strong mineralogical contrast may occur at very variable stretches, from millimeters to meters, even fractally in the same deposit (*e.g.*, within the internal banding of a single mineralized chimney and on the surface from core to rim of venting in a VMS mineralized vent). There

- is no straightforward explanation for such variation, which is multifactorial in nature. It may even happen that high-temperature fluids cross low-temperature mineral associations and vice versa. Additionally, minerals show natural variations in composition that may vary among different types of hydrothermal systems (*i.e.*, sphalerite may attain very different Fe contents) and even down to crystal scale.
3. Grain-size gradients (virtually all systems). Ever since their formation, crystals may naturally vary between coarse-grained to cryptocrystalline, even into amorphous phases. This is an important aspect for experimental matters because as grain size decreases, the overall specific surface of a mineral aggregate increases. Also, the grain size of a mineral aggregate can be relatively homogeneous or inhomogeneous. Grain size may be highly variable since the very moment in which a mineral aggregate is deposited, but grain sizes can be greatly modified during the life span of a hydrothermal system. Indeed, minerals can be “ground” by fracturing and deformed by diapiric ascent or slope sliding; the grain size of a mineral may increase due to thermal recrystallization (or replacement by another mineral), and gels and amorphous phases may eventually crystallize. However, these processes do not necessarily occur during the life span of a hydrothermal system, and these are issues that need to be addressed case by case.
 4. Occurrence of silica and/or Fe-Mn oxide gels, or colloidal phases (VMS, shallow subaqueous systems, epithermal, black shales, SEDEX, Algoma-type BIF). Can the presence of silica and other inorganic species from gels have any role in the oligomerization of organic species? It has been demonstrated that amino acids interact with the surface of silica by different mechanism (Rimola et al. 2013 and reference therein). Moreover, once adsorbed, amino acids react to give DKP cyclic intermediates, which constitute a full research area, the study of the thermal transformations of amino acids catalyzed by silica (Rimola et al. 2013 and reference therein).
 5. Occurrence of liquid interfaces with highly contrasting physicochemical characteristics. Such is the case of the interfaces among submarine brine pools, less saline hydrothermal fluids, and even less saline and cooler seawater (VMS and SEDEX); among some of these and hot molten sulfur (VMS and submarine volcanoes); or between two aqueous fluids with contrasting salinities, which will not mix easily on the continental surface (geothermal/epithermal). The experimental work concerning prebiotic synthesis is generally carried out between a liquid phase with dissolved organic molecules and a solid phase, which is the most common situation in natural hydrothermal systems. However, it is yet to be tested whether

some of the situations described previously may have a role in prebiotic chemistry.

6. Seasonal gradients for water supply (epithermal and other continental systems) or invasion/retreat of seawater upon low and high tides twice a day (shallow subaqueous systems). These gradients imply the variation in time of water availability either by (A) seasonality of meteoric recharge that may not compensate the evaporation of puddled water, or (B) the occurrence of puddles in intertidal areas filled with upwelling hydrothermal fluids and variable amounts of seawater. The relevance and potential of fluctuations in wet/dry or hydration/dehydration cycles for prebiotic synthesis have been already pointed out by Damer and Deamer (2015).
7. Occurrence of diffuse bubbling (epithermal, shallow subaqueous systems, including exceptionally shallow VMS and SEDEX systems) or aerosols with or without the occurrence of minute mineral particles alongside them in association with geysers, mud pots, or phreatomagmatic eruptions (geothermal/epithermal and other subaerial to shallow submarine/sublacustrine hydrothermal manifestations). It has been demonstrated that in bubbles and aerosols, many chemical reactions occur, and both types of interfaces represent heterogeneous microenvironments. Bubbles become more stable as they adsorb dissolved materials, thus concentrating these; afterward, the stabilized bubbles that contain organics act as nucleation sites for larger bubbles. This mechanism increases the concentration of organics (Lerman 2010) that could react to form more complex molecules.
8. Transition metals, which are available in aqueous solution elsewhere in all the hydrothermal systems described in the previous sections, may be effective catalysts for abiotic reactions that are involved in prebiotic synthesis by means of natural gases at temperatures $\leq 200^{\circ}\text{C}$ (Horita 2001).

5.4.6 FINAL CONSIDERATIONS

Hydrothermal systems in oceanic (submarine) or continental settings (subaerial, sublacustrine) may have played an important role in the synthesis of organic compounds in the early Earth. In order to understand the role of the various geological environments in prebiotic chemistry, a multidisciplinary approach is necessary, which includes chemistry and geology. There are many environments, both ancient and recent, that can be called hydrothermal. Although many experiments have been conducted to simulate the conditions of the most conspicuous environments (mostly VMS-type systems, both white and black smokers), little effort has been devoted to understanding the possible contributions to organic synthesis stemming from other likely hydrothermal environments. In this work, the possible role of other hydrothermal environments is highlighted, provided that their characteristics

also provide physicochemical variables, a broad variety of minerals, and a natural variability that could have been relevant in the synthesis of organic molecules from inorganic compounds. In order to contribute to a consensus on whether the participation of hydrothermal environments to chemical evolution was constructive or destructive, it is necessary to design more accurate experiments that combine not only the known physicochemical variables, but also their gradients in space and time. In this sense, recent literature in this matter increasingly aims at reproducing physicochemical conditions that are closer to natural gradients than earlier work. Although multivariable approaches to prebiotic chemistry are hard to manage, they will surely prove to be worthwhile endeavors, especially those that get as close as possible to the natural diversity of hydrothermal systems. In addition, the approach on which this paper relies provides many possibilities for conducting experiments that use heterogeneous interfaces of many kinds that would be firmly based on actual natural hydrothermal systems.

5.5.1 INTRODUCTION

Prebiotic reactions have been studied in different media. These include reactions in the aqueous medium at normal temperature and pressure, such as in the prebiotic soup; reactions in the gas phase, such as in the interstellar space; reactions in the solid state, such as on asteroids and meteorites; and reactions in the aqueous systems under high pressures and temperatures, such as in the hydrothermal vents (e.g., Miller and Orgel 1974; Mason 1991; Holm and Anderson 2000; Hazen et al. 2002; Shaw 2006; Martin et al. 2008; Braakman 2013). In this chapter, prebiotic reactions in such media are discussed, with the exception of the gas phase, which is addressed in [Section IV](#) of this handbook.

Water is a commonly assumed prebiotic reaction medium on the early Earth. This assumption is based on other underlying assumptions. First, since life, as we know it, is based on water, it is then assumed that the pre-biological reactions, to be prebiotically feasible, need to occur in water. Second, even though some prebiotic organic materials may have been formed in the gas or solid phases within the solar system, upon their delivery to the early Earth, they would eventually end up in the prebiotic soup and primordial oceans. As a consequence, prebiotic chemists have focused mostly on the syntheses of the water-soluble organic compounds. The latter are typically small molecules, generally five carbon atoms or less, which have hydrophilic groups, such as hydroxyl, carboxyl, and amino. In addition, charged organic compounds, such as salts of carboxylic acids (carboxylates), of phenols (phenolates), and of amines (amine salts), are also water-soluble, providing

that the hydrophobic portion of these salts is not disproportionately large (e.g., Solomons and Fryhle 2013). Examples of water-soluble organic compounds that are prebiotically relevant include simple sugars, polyols, amino acids, and alcohols. These water-soluble compounds can react in water. Such reactions are classical prebiotic in-water reactions. The choice of the water-soluble chemicals has limited the synthetic options under prebiotic conditions, since most organic compounds are either insoluble in water or are only poorly soluble (Kolb 2014). Also, it has been assumed that non-aqueous solvents, which are commonly used in organic syntheses, such as aliphatic and aromatic hydrocarbons, ethers, and alcohols, were not available on the prebiotic Earth as pools of liquids. They could be found only in relatively small amounts as compared with the large bodies of water. This has also created a problem for the prebiotic chemists, since they could not tap to the wealth of the chemical synthetic pathways that have been developed for the non-aqueous organic chemistry.

In the introductory chapter of this handbook, [Chapter 1.1](#), the multidisciplinary and interdisciplinary nature of astrobiology was discussed. It was shown that astrobiology, as a field of science, clearly benefits from the input of other disciplines. Relatively recently, a new subfield of chemistry has been developed, that of green chemistry, and most relevant for this chapter, green organic chemistry (e.g., Lancaster 2002; Ahluwalia 2012; Zhang and Cue 2012; Kolb 2016). Within this subfield, numerous chemical syntheses that occur under the green (environmentally safe) conditions have been reported

(e.g., Ahluwalia 2012). These include organic reactions in water, including superheated water, without solvent (“solventless”), and in the solid state, as reviewed in the recent book by Kolb (2016). These new developments have been recently applied to prebiotic chemistry (e.g., Kolb 2010, 2012, 2014, 2015). These are reviewed in this chapter.

5.5.2 ORGANIC REACTIONS “ON WATER” AND THEIR PREBIOTIC POTENTIAL

It has been known for quite some time that many organic compounds that are not soluble in water are still capable of reacting in water. Such organic reactions occur in the heterogeneous system, comprising a suspension or an emulsion of organic compounds in water. Initially, such reactions were viewed as a curiosity and as an exception. However, after a number of examples have been discovered, they became a subject of an extensive study (e.g., Rideout and Breslow 1980; Breslow 1991, 2006). Such heterogeneous reactions were termed “on water” reactions. They are distinct from “in water” reactions, which occur in solution, and are thus homogenous.

The importance of these “on water” reactions grew, as they were shown to be extremely efficient (often giving quantitative yields), quite specific, and accelerated in the presence of water, as compared with the organic solvents. Many such reactions have been studied as green chemistry reactions (e.g., Liu and Wang 2010; Kolb 2016). The discovery of the mechanism of such reactions removed them from the category of unexplained exceptions (e.g., Rideout and Breslow 1980; Breslow 1991, 2006; Lindström 2002; Narayan et al. 2005; Purrung et al. 2008; Chanda and Fokin 2009; Manna and Kumar 2013).

The mechanism of these “on water” reactions and their acceleration are briefly reviewed here. For a detailed coverage, which is beyond the scope of this chapter, the reader is directed to the literature in the field (e.g., Rideout and Breslow 1980; Breslow 1991, 2006; Otto and Engberts 2000; Lindström 2002, 2007; Klijn and Engberts 2005; Narayan et al. 2005; Sarma et al. 2006; Purrung et al. 2008; Shapiro and Vigalok 2008; Chanda and Fokin 2009; Manna and Kumar 2013; Kolb 2014, 2016).

The mechanism can be conveniently explained on a classical example of Diels-Alder reaction. This reaction is a cycloaddition reaction between a diene and a dienophile, which results in the formation of carbon-carbon bonds and the six-membered cyclic compound (Solomons and Fryhle 2013). In the past, this reaction was typically performed in organic solvents. However, when Diels-Alder reaction was attempted between two water-insoluble components, anthracene-9-carbinol (a diene) and *N*-ethylmaleimide (a dienophile), the cycloaddition product formed rapidly (Figure 5.5.1) (work by Breslow and co-workers; see Kolb [2016] and references therein for a review) (e.g., Breslow 1991; Kolb 2016). Since various water-insoluble dienes and dienophiles are potential prebiotic compounds, the discovery that Diels-Alder reaction may be performed in water makes it prebiotically feasible.

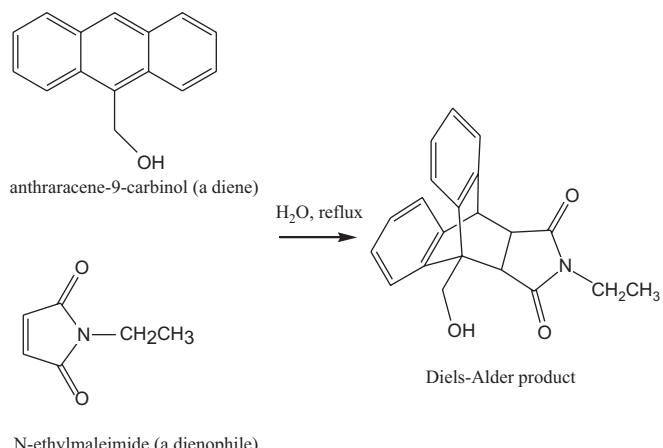

FIGURE 5.5.1 Diels-Alder “on water” reaction between anthracene-9-methanol and *N*-ethylmaleimide, which yields the Diels-Alder adduct.

This reaction’s success in water was explained by a hydrophobic effect in which the water-insoluble reactants are pushed toward each other in an attempt to escape water. A close proximity of the reactants that is thus achieved allows for an efficient molecular orbital overlap between the diene and dienophile. This is shown conveniently on a simpler example of a diene and dienophile (e.g., Solomons and Fryhle 2013) in Figure 5.5.2.

Such an overlap results in a faster and more selective reaction. The operation of the hydrophobic effect is supported by the effect of various salts on the reaction (e.g., Kumar 2001). Some salts cause an increase in the hydrophobic effect and the reaction rates (e.g., LiCl, NaCl, KCl, NaBr, MgCl₂, CaCl₂, and Na₂SO₄). Some other salts decrease both (e.g., guanidinium chloride, LiI, and ClO₄⁻). Additives other than salts may also influence hydrophobic interaction (e.g., urea, ethanol, as anti-hydrophobic) (see Kolb [2016] and the references therein for a review). These findings would have an immediate applicability to the prebiotic soup model, since pure water as

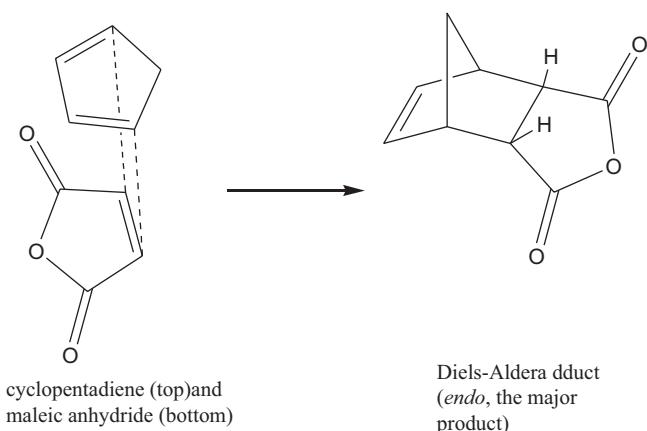

FIGURE 5.5.2 Orbital overlap in Diels-Alder reaction between cyclopentadiene and maleic anhydride, which results in the major product, which is *endo*.

its medium is unrealistic, while the presence of salts, including amino acids and small polar molecules, is expected.

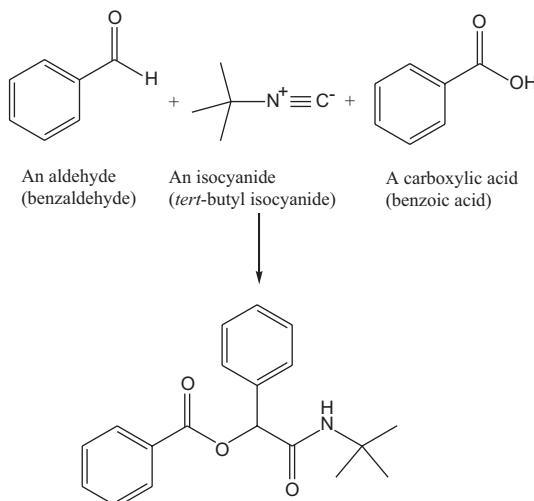

Performing the Diels-Alder reaction "on water," as opposed to the organic solvents, may result in a very large increase of the reaction rate, for example, more than 10,000 times (Otto and Engberts 2000). Although the Diels-Alder reaction in organic solvents shows an intrinsic selectivity toward the *endo* product, water enhances this selectivity further. This may be attributed to the difference in stability of the transition states for the *endo*, as opposed to the *exo* isomer in water. Hydrophobic effects are assumed to favor stabilization of the *endo* transition state, since it is more compact. In contrast, the transition state for the *exo* product is more extended. A concise explanation is that "hydrophobic packing" favors the *endo* product.

Before the discovery of the "on water" reactions, the reactions between water-insoluble starting materials in the aqueous media have not been examined by the prebiotic chemists, even when the starting materials were prebiotically feasible. Many such reactions exist, in addition to the already mentioned Diels-Alder reaction. Examples include 1,3-dipolar cycloadditions, Claisen rearrangement, Passerini and Ugi reactions, nucleophilic substitution reactions, and nucleophilic opening of three-membered rings, among others (Chanda and Fokin 2009). Although numerous "on water" reactions have been reported, they cannot be automatically assumed to be prebiotically relevant. Only a limited number of the "on water" reactions can be classified as potentially prebiotic at this time, by virtue of their starting materials when they are prebiotically feasible. For the cases in which they are not, modification of the starting materials to fit prebiotic criteria is possible in principle but has not been studied in most cases.

In addition to Diels-Alder reaction, which has a broad synthetic utility and a possible prebiotic relevance, some multicomponent "on water" reactions (e.g., Chanda and Fokin 2009; Huang et al. 2012; Kolb 2016) are prebiotically promising (e.g., Kolb 2014). The multicomponent reactions typically occur fast and give a single product of high purity, in an almost quantitative yield (e.g. Prrung and Sarma 2004). One such example is the Passerini reaction, which is a three-component reaction. Some multicomponent reactions have more components, for example, even seven (Huang et al. 2012). Multicomponent reactions are an ideal type of prebiotic reactions, since they give a clean product, and thus, the common problem of prebiotic chemistry, namely an intractable mixture of products, is avoided. The Passerini reaction is described next.

The ease by which this reaction occurs and the purity of its single product are so outstanding that this reaction is now introduced in the undergraduate organic laboratory (e.g., Hooper and DeBoef 2009; Williamson and Masters 2011) as an example of a green "on water" reaction. This reaction also has a prebiotic potential. An example of the Passerini reaction is shown in Figure 5.5.3.

Figure 5.5.3 shows the structures of three components, an aldehyde (benzaldehyde), an isocyanide (*tert*-butyl isocyanide), and a carboxylic acid (benzoic acid). The categories of these compounds are all prebiotically feasible, since these or similar compounds have either been found on the meteorites, such as

The Passerini reaction product (benzoic acid, *tert*-butylcarbamoyl-phenyl-methyl ester)

FIGURE 5.5.3 The Passerini three-component reaction between an aldehyde (benzaldehyde), an isocyanide (*tert*-butyl isocyanide), and a carboxylic acid (benzoic acid), which results in a single product (*tert*-butylcarbamoyl-phenyl-methyl ester of benzoic acid).

Murchison (e.g., Schmitt-Kopplin et al. 2010, 2014) or could be reasonably easily synthesized by the known simulated prebiotic reactions (e.g., Miller and Orgel 1974; Mason 1991). The product itself, *tert*-butylcarbamoyl-phenyl-methyl ester of benzoic acid, is a solid product, which forms rapidly in water. The reaction is very fast, which is also prebiotically desirable, since side reactions of the components with other compounds that may be present in the prebiotic soup may be avoided. The Passerini reaction can build prebiotic chemical diversity easily, without side products, when the derivatives of the starting materials are employed.

Recently, Sutherland and his co-workers have successfully applied multicomponent reactions to various aspects of prebiotic synthesis of nucleotides and their components, which were previously notoriously difficult. In some applications, they have used the isocyanide chemistry that was modeled by the multicomponent Ugi reaction (related to the Passerini reaction), in which an isocyanide, an aldehyde, and ammonium chloride were reacted (Mullen and Sutherland 2007). Their work continues and is a highly successful application of multicomponent reactions, such as a chemoselective assembly of purine precursors in water (Powner et al. 2010) and potentially prebiotic Passerini-type reactions of phosphates (Sutherland et al. 2008), among others. These contributed to a new modus operandi of prebiotic chemistry (Powner and Sutherland 2011) and an outstanding advancement of the prebiotic chemistry synthetic tools.

5.5.3 ORGANIC REACTIONS IN SUPERHEATED WATER AND THEIR PREBIOTIC SIGNIFICANCE

Various prebiotically significant reactions have been studied under the simulated hydrothermal conditions in the past (Orgel 2004). The impetus for such studies was that the

hydrothermal vents are rich in life, despite high pressures and temperatures. As one example, components of the citric acid cycle have been synthesized under these conditions (Orgel 2004). Since hydrothermal vents provide both chemicals and energy sources, they are considered as localities that are hospitable for the emergence of life on Earth and on other bodies in the solar system that may harbor such vents.

The subject of hydrothermal vents and the origin of life has been reviewed (e.g., Holm and Anderson 2000; Hazen et al. 2002; Orgel 2004; Martin et al. 2008; Padgett 2012; Sojo et al. 2016) and is further updated in [Section V](#) of this handbook.

Organic chemistry under hydrothermal conditions has been studied extensively (Avola et al. 2013), including feasibility of biochemical reactions and metabolic cycles under these conditions (Braakman 2013). Organic chemical possibilities in superheated water were systematically explored (Savage 1999; Katritzky et al. 2001; Siskin and Katritzky 2001; da Silva 2007; Liotta et al. 2007; Savage and Rebacz 2010; Kruse and Dinjus 2012). Many organic reactions in superheated water not only are prebiotically feasible but also offer clear prebiotic advantages (Kolb 2015). Examples of such reactions are shown in [Section 5.5.3.2](#), after a brief review of the properties of superheated water in [Section 5.5.3.1](#).

5.5.3.1 PROPERTIES OF SUPERHEATED WATER

In this subsection, properties of water and how they change when water is superheated are briefly reviewed (Li and Chan 2007; Kolb 2016). Water is capable of making hydrogen-bonded networks, owing to the large electronegativity difference between oxygen and hydrogen. Oxygen has lone electron pairs, and it acts as a hydrogen-bond acceptor, while partially positive hydrogen behaves as a hydrogen-bond donor. The resulting hydrogen-bonded networks are responsible for the relatively high boiling point of water, among other properties. [Figure 5.5.4](#) depicts such a network.

Water exhibits high polarity, which is reflected in its high dielectric constant (78.4 at 25°C). Water dissociates to proton (H^+ , which hydrates to H_3O^+) and hydroxide (OH^-) ions. Since concentrations of both acidic protons and basic hydroxide ions are the same, water is neutral. The ionic product of water ($K_w = [H^+] [OH^-]$) is very small (10^{-14} at room temperature). This means that the concentrations of both protons and hydroxide ions are very small ($10^{-7} M$).

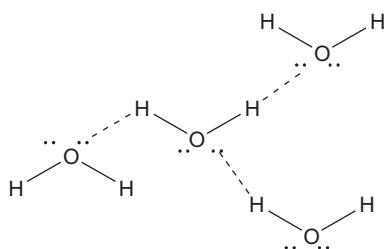

FIGURE 5.5.4 Hydrogen-bonded network of water molecules, which are presented as their Lewis structures.

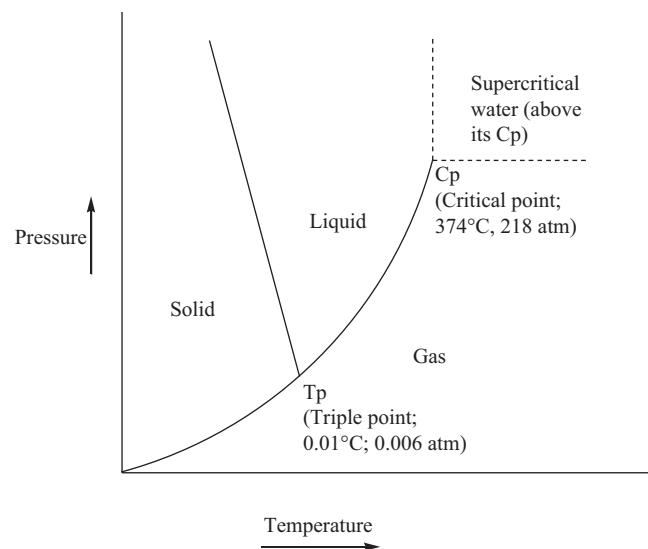

FIGURE 5.5.5 Phase diagram of water (simplified, on a free scale).

These properties of water are dramatically changed when water becomes superheated. A simplified phase diagram for water is shown in [Figure 5.5.5](#). It includes the areas of superheated water.

The points that are labeled on the diagram are T_p (triple point) and C_p (critical point). The T_p is the unique pressure and temperature condition where all three phases (solid, liquid, and gas) coexist (0.01°C; 0.006 atm). At the C_p (374°C; 218 atm), the boundary line between the liquid and gas phases terminates, and these two phases become indistinguishable and form a single phase. The region in the phase diagram between the dashed lines, which start at the C_p , shows the supercritical fluid phase. The supercritical water (SCW) is a single uniform phase at and above the C_p . The high temperatures of superheated water are achieved in conjunction with an increase in pressure. The superheated water region also includes the near-critical water (NCW), at temperatures of 200°C–300°C, and the upper critical solution temperature (UCST), above which the organic substrate and water are miscible in all proportions (Liotta et al. 2007). The term high-temperature water (HTW) is also used, for water above its normal boiling point (100°C; 1 atm) (Savage and Rebacz 2010).

Properties of water, such as density, dielectric constant, and K_w , differ between water at the ambient conditions (25°C; 1 atm) and the HTW and SCW. This is shown in [Table 5.5.1](#).

The values from [Table 5.5.1](#) show that the HTW, at 250°C and 50 atm, has decreased values of density and dielectric constant but has a substantially increased value of K_w , as compared with water at the ambient conditions. For the SCW at 400°C, these properties vary with pressure. For example, the SCW at 250 atm shows a dramatic decrease in K_w as compared with water at the ambient conditions, while at 500 atm, the K_w is substantially increased.

The increased value of K_w of the HTW under specific conditions means that water becomes more acidic (and basic) than the ambient water. This is quite significant for the reactions that require acid (or base) catalysis. While at the ambient

TABLE 5.5.1
Properties of Superheated Water as Compared with Water at Ambient Conditions

Property	Ambient Water	High-Temperature Water	Supercritical	Water
Temperature (°C)	25	250	400	400

Li (Ed.), pp. 331–361, Wiley-VCH, Weinheim, Germany, 2010; Kolb, V.M., *Green Organic Chemistry and Its Interdisciplinary Applications*, CRC Press/Taylor & Francis, Boca Raton, FL, 2016.

conditions an external catalyst needs to be added, in HTW, the H⁺ (or OH⁻) provided by the heated water may be sufficient. When the water is cooled, the ambient ion concentrations are restored, thus representing a self-neutralizing catalytic medium (Liotta et al. 2007). Such *in situ* catalysis is highly significant for prebiotic chemistry, as it facilitates reactions without an externally added catalyst.

As the temperature is increased from 25°C to 300°C, under these near-critical conditions, water loses ca. 55%–60% of its hydrogen-bonding network (Liotta et al. 2007). In addition to reducing the number of hydrogen bonds per water molecule, the increase in temperature also reduces the persistence of hydrogen bonds, as they form and break at faster rates. This leads to the shorter hydrogen-bond lifetime (Savage and Rebacz 2010).

The increase in temperature is accompanied by a decrease of the dielectric constant. The value of the dielectric constant

for the NCW at 300°C is ca. 20, which represents a 75% reduction from the value for the ambient water (Liotta et al. 2007). Significantly, this value for the dielectric constant corresponds most closely to a moderately polar solvent, such as acetone (dielectric constant of 21.4 at 25°C). This enables enhanced solubility of nonpolar organic species in NCW (Liotta et al. 2007). This is of a high significance for prebiotic chemistry. It means that the organic compounds that are not water-soluble will become so in the superheated water.

5.5.3.2 PREBIOTIC POTENTIAL OF ORGANIC REACTIONS IN SUPERHEATED WATER

A large variety of organic reactions have been reported to occur in superheated water (Savage 1999; Katritzky et al. 2001; Siskin and Katritzky 2001; Akiya and Savage 2002; da Silva 2007; Li and Chan 2007; Kruse and Dinjus 2012; Avola et al. 2013). Possibilities also exist for new reaction pathways, since the reaction mechanism sometimes is changed in superheated water. Some such reactions were recently reviewed as potentially prebiotic (Kolb 2015). They include some common reactions that could be used for the synthesis of more complicated molecules. They are shown in Table 5.5.2.

Chemical equations for some of the reactions from Table 5.5.2 are shown in Figure 5.5.6.

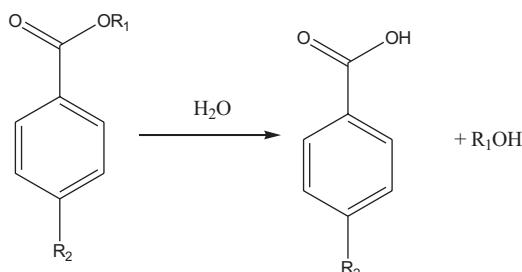

The reactions in superheated water that are shown represent just a small number of the reactions that are known to occur successfully in this medium and that have a prebiotic potential. However, the great wealth of the reaction possibilities in superheated water is virtually unexplored by prebiotic chemists. The reactions that are shown here illustrate two important points. The first is that the reactions that have been impossible to perform under commonly simulated prebiotic conditions can now be added to the prebiotic synthetic repertoire. Examples include Friedel-Crafts and other reactions that require acid/base catalysis. For example, traditional chemistry uses Lewis acid catalysts, such as AlCl₃, for the Friedel-Crafts reaction, but such a catalyst

would fall apart in water. The superheated water provides H^+ catalyst intrinsically and self-neutralizes upon cooling. The second is that hydrothermal vents provide a medium that is capable of producing rich organic chemistry, based on a myriad of the reactions that have been successfully performed in this medium. Prebiotic chemists need to get fully acquainted with these reactions and should add them to the prebiotic synthetic toolbox.

5.5.4 SOLVENTLESS AND SOLID-STATE REACTIONS, AND THEIR PREBIOTIC POTENTIAL

5.5.4.1 GENERAL

Solventless and solid-state reactions may have been critical for the formation of organic compounds that are found on the meteorites, such as the Murchison meteorite, which is a carbonaceous chondrite. Meteorites are believed to be one of the sources of organic compounds on the early Earth (Shaw 2006; Longstaff 2015; Kwok 2016, 2017). A large number of organic compounds has been identified on the Murchison meteorite and is getting larger with better analytical techniques. For example, Schmitt-Kopplin et al. (2010, 2014) reported tens of thousands of different molecular compositions on the Murchison meteorite, by an application of ultra-high-resolution analytical methods, which combine state-of-the-art mass spectrometry, liquid chromatography, and nuclear magnetic resonance. Classes of organic compounds found on the Murchison meteorite include aliphatic and aromatic hydrocarbons, carboxylic acids, hydroxyl carboxylic acids, dicarboxylic acids, carboxamides, amino acids, aldehydes, ketones, alcohols, amines, purines and pyrimidines, nitrogen heterocycles, sulfonic acids, and phosphonic acids, among many others. Since water on asteroids was available only sporadically, chemical pathways in the absence of water need to be examined. Solid-state and solventless conditions have been proposed for chemical reactions on asteroids and the resulting meteoritic chemistry (Kolb 2010, 2012), as well as for general prebiotic chemistry (Kolb 2014).

Solventless reactions occur without solvent, as the term indicates. This term is popular in the green chemistry literature. Such reactions occur when two or more solid compounds are mixed. Solid compounds act as impurities to each other. The impurities become incorporated into the crystalline lattice of a pure compound and cause a breakup of the regular crystalline pattern, which results in the lowering of the melting point. In some instances, the melting point is lowered to the extent that melting of the mixture occurs. When this happens, chemical reactions may proceed in the melted state, thus eliminating the need for the solvent. Such reactions are known as solventless (e.g., Raston and Scott 2000; Cave et al. 2001; Raston 2004; Kolb 2016). Solid-state reactions occur when the solid compounds are mixed but do not melt. However, a very small amount of melted material may occur at the interface of the solids that are mixed, which is not visually observable, unless the product is colored. This blurs the division between solventless and solid-state reactions (Rothenberg et al. 2001; Kolb 2016). Other variations exist. For example, when a

liquid and a solid component come in contact, the suspension may become reactive. Sometimes, a gas-solid reaction is successful. All of these scenarios could be fruitful on asteroids (Kolb 2010, 2012, 2014).

The asteroids are presumably rich in organic compounds, as deduced by the analysis of Murchison and similar carbonaceous chondrite meteorites that originate from them. While some of these compounds may be potentially reactive toward each other, some others may not be. However, the unreactive compounds could act as chemically inert additives to the potentially reactive mixture of compounds and could lower the melting points of such mixtures to cause their melting. This would enable the reactions to occur in the melted state. The temperature estimates on the asteroids are in a range from 25°C to 100°C. This is consistent with the conditions of aqueous alterations and is friendly to the organic reactions and preservation of the organic compounds. The heat to maintain this temperature range could be provided by the radioactive processes or impacts (Kolb 2010, 2012).

5.5.4.2 EXAMPLES OF PREBIOTICALLY RELEVANT SOLVENTLESS AND SOLID-STATE REACTIONS

Major types of organic reactions, such as oxidations; reductions; eliminations; substitutions; condensations; cyclizations; rearrangements; and formation of carbon-carbon, carbon-oxygen, and carbon-nitrogen bonds, can occur as solventless or in the solid state (Toda 1993; Toda 1995; Raston 2000; Tanaka and Toda 2000; Cave et al. 2001; Rothenberg et al. 2001; Raston 2004; Tanaka 2009; Kolb 2016). These reactions often occur rapidly and are quite efficient.

In the reported studies, both terms "solventless" and "solvent-free" are used. In this section, the terms are used as given by the authors of the study, to facilitate the literature searches by the key words.

Experimental procedures for solvent-free reactions (Tanaka 2009) generally involve just mixing of the reactants. Such a procedure is prebiotically feasible. This is also the case for many solid-state reactions (e.g., Toda 1993, 1995; Kaupp 2005). If a catalyst is needed, the reaction needs to be explored with the catalysts that were available on the early Earth. This is possible in principle. For example, a non-prebiotic acidic catalyst could be substituted with a naturally occurring acidic clay.

Selected examples of solventless and solid-state reactions that are of prebiotic interest are given here. More examples are given by Kolb (2012, 2014).

One such reaction is the formation of ethers in the solid state, from the solid mixture of alcohols in the presence of an acid catalyst. Ethers with the appropriate structures could be used as membranes for the primitive life. The precedent is found in some Archaea's membranes, which are ethers, in contrast to the esters, which are found in the lipid membranes of the majority of contemporary life (Kolb 2012 and the references therein). An example of a solid-state reaction of an alcohol to form an ether under the acid catalysis with *p*-toluenesulfonic acid (TsOH) (Toda et al. 1990) is shown in Figure 5.5.7.

Etherification of alcohols

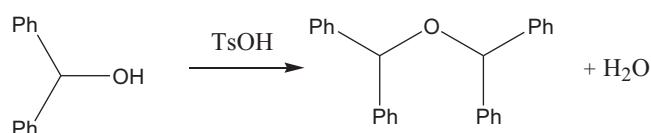

FIGURE 5.5.7 Solvent-free etherification of alcohols.

Alcohols are prebiotically feasible compounds. However, the corresponding ethers are difficult to make prebiotically in the aqueous solution, since water needs to be driven off during the condensation reaction, which is a dehydration. The solid-state etherification reaction provides a viable prebiotic path to the ethers. The TsOH could be substituted by a prebiotic acid catalyst, such as an acidic clay.

Another prebiotically significant reaction, a carbon-carbon bond formation by the oxidative coupling of a phenol (a naphthol) to a binol ([1,1'-binaphthalene]-2,2'-diol), occurs in the solid state (Tanaka 2009). It is shown in Figure 5.5.8.

Phenol itself can be synthesized under prebiotic conditions, from sodium bicarbonate (NaHCO₃) in water, with iron as a catalyst, under hydrothermal conditions (Tian 2007). The example from Figure 5.5.8 is especially significant. When a phenol (2-naphthol) undergoes the solid-state oxidative coupling with FeCl₃, it gives a binol ([1,1'-binaphthalene]-2,2'-diol), which is not planar, owing to the steric hindrance of the two hydroxyl groups. Instead, it is twisted, and thus asymmetric, which makes it chiral (Carey and Sundberg 2007). The binol forms in the reaction as a racemic mixture of two enantiomers. Under the prebiotic conditions, a possible enantiomeric enrichment may be achieved under the influence of the available chiral molecules or minerals (Kolb 2012, 2014).

Aldol-type condensation reactions, in which carbon-carbon bonds are made, play an important role in chemistry and biology (e.g., in the citric-acid cycle). Such reactions are thus of a great prebiotic importance (Kolb 2012, 2014). An example of aldol reaction in which the basic alumina is used as a catalyst, under solvent-free conditions, is shown in Figure 5.5.9.

The reaction is clean, since there is no cross-reactivity and a single product is obtained. The molecules of aldehyde are not reactive between themselves, since they cannot form the

Oxidative coupling of naphthols

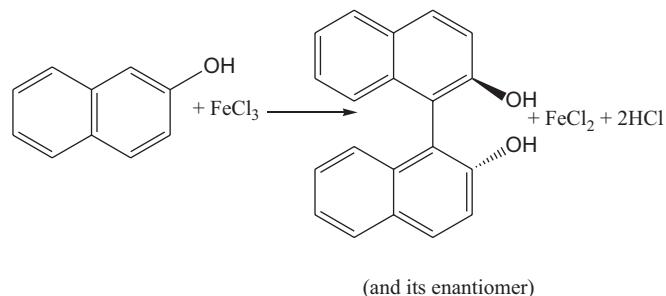

FIGURE 5.5.8 Solid-state oxidative coupling of a phenol (a naphthol) to a binol.

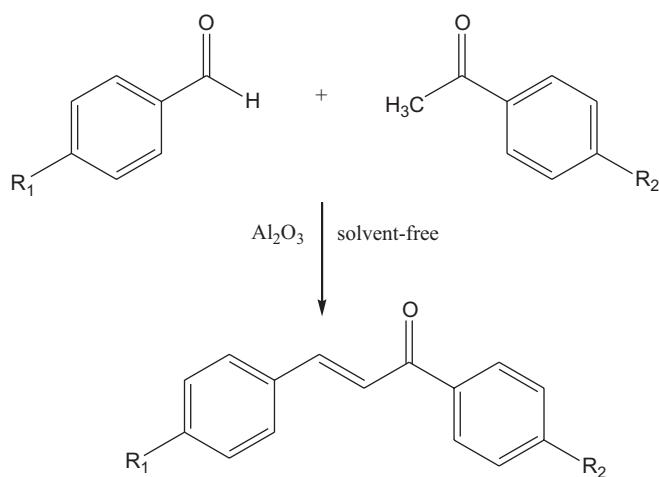

FIGURE 5.5.9 Solvent-free aldol condensation.

needed α -carbanion (enolate). The ketone molecules can form the α -carbanion, but the latter does not give the condensation product with other ketone molecules, owing to the unfavorable thermodynamics. Thus, the only reaction occurring is between the ketone carbanion and the aldehyde, to give the shown product. This example also shows that a belief that in prebiotic chemistry “everything reacts with everything else” can be misleading. Single products may be obtained, owing to the intrinsic limitations in the reactivities of the starting materials, as shown in this example (Kolb 2012, 2014).

Esterification is another general reaction of importance to the prebiotic chemistry (Kolb 2012, 2014). When the starting materials for this reaction, an alcohol and a carboxylic acid, react to give an ester, the equilibrium of the reaction does not favor the ester product. Thus, the equilibrium needs to be shifted toward the product. This can be accomplished by removing water or by using a strong acid catalyst with dehydrating properties, such as concentrated H_2SO_4 . Such requirements make esterification in the prebiotic soup infeasible. However, the solvent-free esterification, shown in Figure 5.5.10 (Tanaka 2009, p. 288), appears to be feasible (Kolb 2012, 2014).

This reaction requires perchlorates, which are found on Earth, especially under arid conditions, and also on Mars. MgSO_4 could act as a recyclable dehydrating agent (Kolb 2012, 2014).

Another important synthesis is that of the corroles, which are porphyrin analogues. They are important prebiotically, since they may serve as primitive enzymes, as they have a metal complexing site in the center of the molecule (Kolb 2012, 2014). A solventless synthesis of a corrole is shown in Figure 5.5.11 (Tanaka 2009).

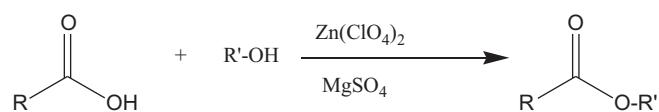

FIGURE 5.5.10 Solvent-free esterification.

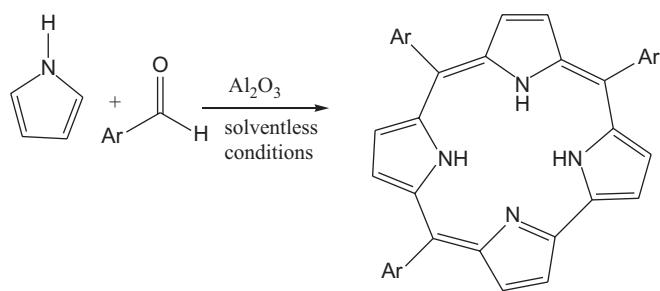

FIGURE 5.5.11 Solventless synthesis of a corrole by condensation of pyrrole and aldehyde.

This reaction occurs between pyrrole and an aromatic aldehyde, under solventless conditions, with Al_2O_3 as catalyst, to give a corrole product. A diversity of the structures of corroles can be achieved by employing differently substituted aromatic aldehydes (Kolb 2012, 2014).

As the final example, a synthesis of a macromolecule with a cavity is shown. It occurs readily by a cyclocondensation of resorcinol with an aldehyde under the solvent-free conditions (Tanaka 2009) (Figure 5.5.12).

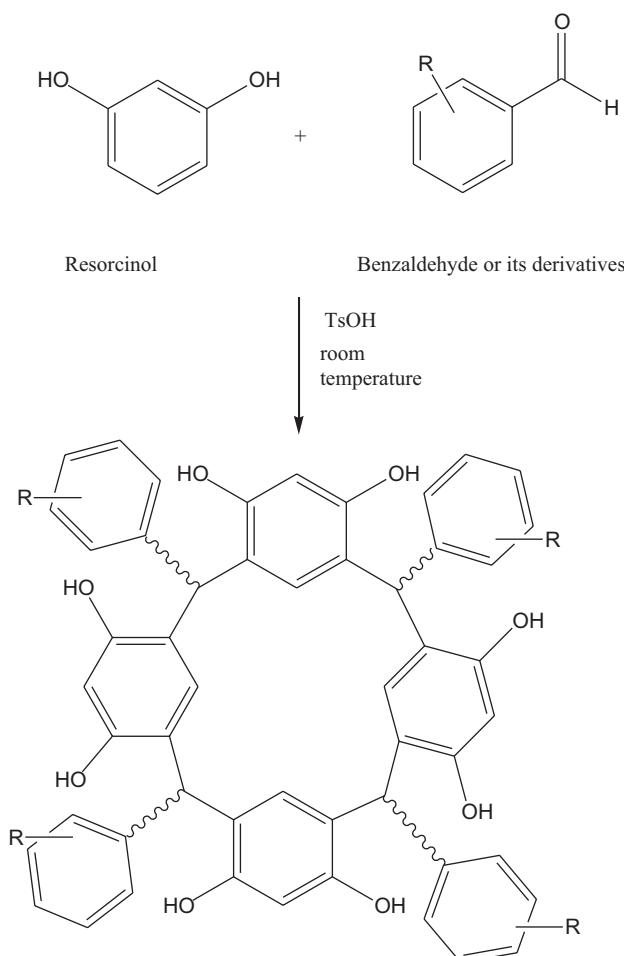

FIGURE 5.5.12 Solvent-free cyclocondensation of resorcinol and a benzaldehyde, which gives a macromolecule with a cavity.

This remarkable reaction occurs at room temperature. The large cavity inside the molecule could find some enzymatic role under the prebiotic conditions. The TsOH as a catalyst could be substituted with an acidic clay, which is prebiotically more feasible (Kolb 2012, 2014).

5.5.5 CONCLUSIONS

In this chapter, prebiotically feasible reactions "on water," under hydrothermal conditions, solventless, and solid-solid are reviewed. Such reactions expand the repertoire of prebiotic chemistry. Among "on water" reactions, Diels-Alder and Passerini multicomponent reactions are highlighted. Although the starting materials for "on water" reactions are not water-soluble, the reactions nevertheless occur smoothly, in a selective manner, and give high yields. Reactions in superheated water are also significant for prebiotic chemistry. Properties of superheated water, under certain conditions of temperature and pressure, enable water to dissolve organic compounds, since water changes its polarity and behaves as acetone. In addition, superheated water can also act as an acid/base catalyst, as its K_w changes. Solventless and solid-solid reactions are relevant to the chemistry on asteroids, in addition to the general prebiotic chemistry. Selected examples of the key organic reactions that occur under these conditions are shown. They include esterifications, etherifications, aldol-type condensations, and preparations of the large cyclic molecules. The latter could serve as primitive enzymes.

ACKNOWLEDGMENTS

Thanks are expressed to the Wisconsin Space Grant Consortium/NASA for their continuous support of my experimental work in prebiotic chemistry. Special thanks are due to my research students, who have performed experimental work, especially in the area of the "on water" and solid-state chemistry.

5.6.1 IMPLICATIONS OF HOMOCHIRALITY AND SELF-REPLICATION FOR THE ORIGIN OF LIFE

Homochirality of biomolecules, such as seen in L-amino acids and D-sugars, is not a mere phenomenon of life but one of the essential features of life. Left and right hands are mirror images and are not superimposable. In the same manner, L- and D-amino acids are mirror images and are not superimposable, that is, they are chiral compounds (Figure 5.6.1). In general, when a carbon atom has four different substituents or atoms, the carbon atom becomes a stereogenic (chiral) center and is termed an asymmetric carbon atom (Eliel and Wilen 1994).

Why is homochirality essential for life? Consider the situation of shaking hands. When two people use their right hands to shake hands, it is normal; however, if one uses the left hand and the other the right, the situation becomes very different. In peptides, for example, L-alanyl-L-alanine and D-alanyl-L-alanine are diastereomers and have different properties, such as melting points. Peptides and proteins are composed of L-amino acids by forming peptide bonds. If D-amino acids are irregularly incorporated, the conformation of the protein changes and the enzymes would not be able to exhibit their functions. DNA is

composed of D-deoxyribose and forms a helix. If L-deoxyribose is irregularly incorporated, the normal double helix structure would not be formed and the gene information would not be transferred. Thus, the homochirality of components is essential for living organisms and the origin of life.

Then, how did biomolecules become highly enantioenriched? How was the first chiral organic compound formed? It should be mentioned that usual chemical reactions using achiral reactants and without the intervention of any chiral factor afford a mixture with an equal ratio of D- and L-products, that is, racemates. Therefore, the origin of the chirality of organic compounds has been a subject of considerable attention for 170 years, ever since the discovery of molecular chirality by Pasteur (Gal 2008).

Several theories have been proposed as the origin of chirality of organic compounds (Weissbuch et al. 1984; Kondepudi et al. 1990; Inoue 1992; Bolli et al. 1997; Siegel 1998; Feringa and van Delden 1999; Ribó et al. 2001; Hazen and Sholl 2003; Mislow 2003; Pizzarello and Weber 2004; Raval 2009; Breslow and Cheng 2010; Weissbuch and Lahav 2011; Ernst 2012; Gellman et al. 2013; Gonzalez-Campo and Amabilino 2013; Saito and Hyuga 2013; Olsson et al. 2015; Miyagawa et al. 2017). However, because the enantiomeric excesses (ee) induced by the proposed mechanisms have been very low in

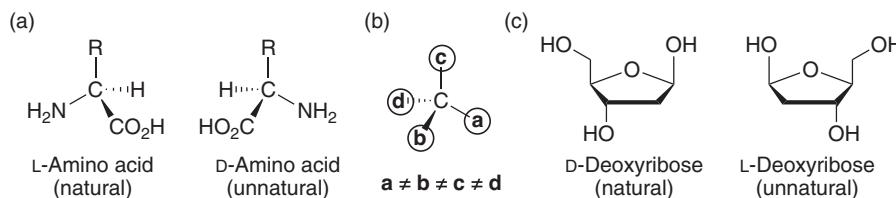

FIGURE 5.6.1 (a) General structure of L- and D-amino acids (R = CH₃; alanine). (b) The general structure of asymmetric carbon, i.e., C (carbon) with four different substituents (a ≠ b ≠ c ≠ d). (c) D-Deoxyribose (natural) and L-deoxyribose (unnatural) in nucleosides.

many cases, the amplification of low ee to high ee is necessary (Girard and Kagan 1998; Green et al. 1999; Zepik et al. 2002; Viedma 2005; Soloshonok et al. 2012; Soai et al. 2014a). In this chapter, we focus on asymmetric autocatalysis and the origin of homochirality. Asymmetric autocatalysis is a reaction in which a chiral product acts as a chiral catalyst for its own production (Figure 5.6.2) (Soai et al. 1995, 2000, 2014b, 2017; Shibata et al. 1999; Avalos et al. 2000; Todd 2002; Sato et al. 2003a; Soai and Kawasaki 2008; Bissette and Fletcher 2013). The process is a catalytic self-replication of a chiral compound. In the asymmetric autocatalysis of pyrimidyl alkanol in the addition of diisopropylzinc (*i*-Pr₂Zn) to pyrimidine-5-carbaldehyde, the ee amplifies from extremely low to >99.5% ee (the Soai reaction). Various chiral factors, such as circularly polarized light (CPL) and chiral inorganic crystals, trigger asymmetric autocatalysis and afford the product with high ee. Moreover, spontaneous absolute asymmetric synthesis without the intervention of any chiral factor has been achieved by the Soai reaction.

Self-replication, that is, automultiplication, at the individual and cellular levels is another essential feature of life. Self-replication at the molecular level has been examined (Sievers and von Kiedrowski 1994; Wintner et al. 1994; Lee et al. 1996; Ashkenasy et al. 2004, 2017). Asymmetric autocatalysis of pyrimidyl alkanol, that is, the Soai reaction, is unique in that the process is a catalytic self-replication of a chiral compound.

As to the theories of the origin of homochirality, mechanisms other than asymmetric autocatalysis, including crystallization with racemization, self-disproportionation by distillation, crystallization with abrasion (Viedma ripening), and amino acids in meteorites, have been reported. These are beyond the scope of this article, and readers are encouraged to consult the corresponding articles and reviews.

5.6.2 ASYMMETRIC AUTOCATALYSIS OF 5-PYRIMIDYL ALKANOL WITH AMPLIFICATION OF ENANTIOMERIC EXCESS: THE SOAI REACTION

Frank (1953) proposed a scheme of asymmetric autocatalysis without mentioning the actual chemical structure of compounds. We found in 1995, for the first time, the asymmetric autocatalysis with amplification of ee as a real chemical reaction in the enantioselective addition of *i*-Pr₂Zn to pyrimidine-5-carbaldehyde (Soai et al. 1995). After further investigation of the substituent effect, that is, by the introduction of a 2-alkynyl group at the 2-position of the pyrimidine ring (Shibata et al. 1999), the isopropylzinc alkoxide of 2-alkynyl-5-pyrimidyl alkanol **1** (Matsumoto et al. 2015a, 2016a) formed *in situ* acted as a practically perfect asymmetric autocatalyst during the course of enantioselective addition of *i*-Pr₂Zn to pyrimidine-5-carbaldehyde **2** (Figure 5.6.3). It has been demonstrated that 5-pyrimidyl alkanol **1** shows remarkable amplification of ee in the addition reaction of *i*-Pr₂Zn to aldehyde **2**, therefore, an initial slight enantiomeric imbalance, as low as approximately 0.00005% ee, was significantly amplified to nearly enantiopure (>99.5% ee) in only three consecutive asymmetric autocatalyses of **1** by the reaction between **2** and *i*-Pr₂Zn (Sato et al. 2003a). During these three consecutive reactions, the initial slight excess of the (*S*)-enantiomer **1** was automultiplied by a factor of *ca.* 630,000, whereas the slightly minor initial (*R*)-**1** was automultiplied by a factor of less than 1,000. Therefore, the significant asymmetric amplification of pyrimidyl alkanol **1** has been realized during its formation, without the intervention of any other chiral auxiliary.

5.6.3 MECHANISTIC INSIGHT OF THE ASYMMETRIC AUTOCATALYSIS OF PYRIMIDYL ALKANOL

The mechanism of this significant asymmetric amplification of pyrimidyl alkanol **1** has not yet been fully revealed. However, many research groups have contributed to understanding and gradually unveiling this unique amplification mechanism. The amplification mechanism is considered an analogy of the positive nonlinear effect in nonautocatalytic asymmetric reactions (Puchot et al. 1986; Kitamura et al. 1989), such as the dimer as a catalyst or a nonreactive reservoir (Figure 5.6.4).

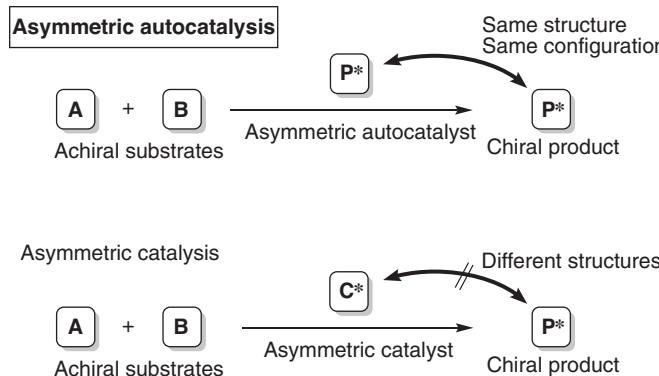

FIGURE 5.6.2 The concept of asymmetric autocatalysis in comparison with conventional asymmetric catalysis.

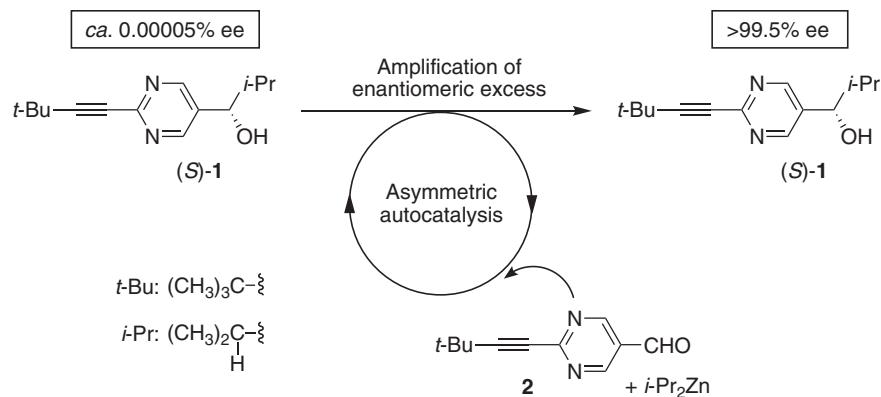

FIGURE 5.6.3 The Soai reaction. Asymmetric autocatalysis with significant amplification of ee from *ca.* 0.00005% ee to nearly enantiopure (>99.5% ee).

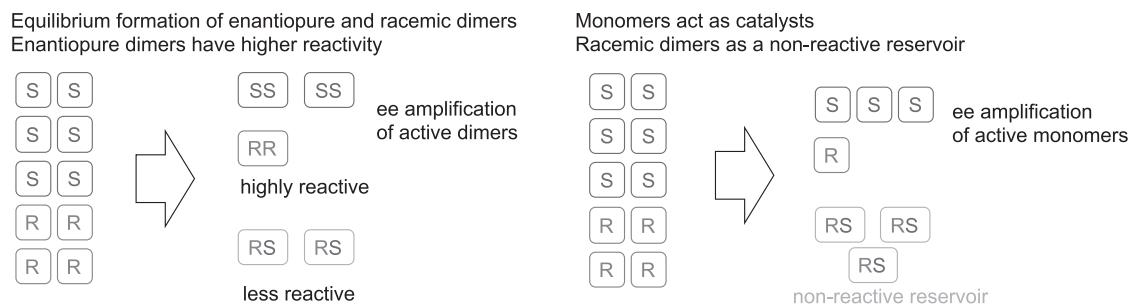

FIGURE 5.6.4 Amplification of ee via oligomerization and possible oligomer units.

In the asymmetric autocatalysis of pyrimidyl alkanol, the formation of higher oligomeric structures via Zn–O–Zn–O square (**Figure 5.6.5a**) and macrocyclic Zn–N coordination (**Figure 5.6.5b**) has been suggested. In early kinetic studies (Blackmond et al. 2001; Sato et al. 2001a, 2003b) and experimental observation of ee reaction profiles, the dimers appear to act as an actual catalyst rather than a nonreactive reservoir. Nuclear magnetic resonance (NMR) studies suggest an equilibrium between homochiral and racemic square dimers (Gridnev et al. 2004), and density functional theory (DFT) calculation studies suggest no significant stability difference between homochiral and heterochiral dimers (Gridnev and Brown 2004). According to these results and a more detailed kinetics study (Buono and Blackmond 2003), the reaction cycle in which an active catalyst dimer with two aldehydes afforded tetramer resting state and released two new active dimers was proposed by a DFT

calculation (Schiaffino and Ercolani 2008). However, recent studies on the reaction model suggest that the simple dimer catalyst model is not enough to explain the significant amplification of ee (Micheau et al. 2012). Furthermore, the existence of higher oligomer species via N–Zn coordination was also supported by NMR observations (Quaranta et al. 2010; Gehring et al. 2012).

We have recently observed the actual oligomeric structure of the asymmetric autocatalyst by using single-crystal X-ray diffraction analysis (Matsumoto et al. 2015a, 2016a). Crystallization of both enantiopure and racemic pyrimidyl alkanol **1** with an excess amount of $i\text{-Pr}_2\text{Zn}$ afforded the tetrameric structure of the isopropylzinc alkoxide of alkanol **1**. In this tetrameric structure, two zinc alkoxides form a square dimer by the Zn–O–Zn–O structure, and the two dimers are bridged by pyrimidine ring coordination to the alkoxide Zn atom of each other to form a 12-membered macrocyclic

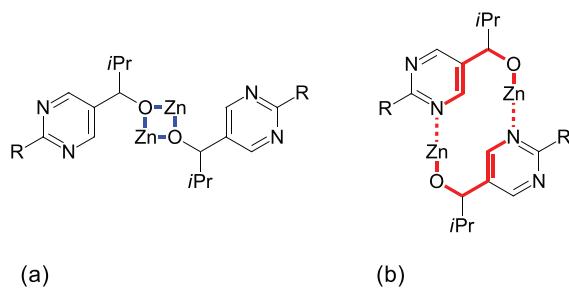

FIGURE 5.6.5 Planar description of dimeric structures of asymmetric autocatalyst with (a) Zn–O–Zn–O square and (b) macrocyclic Zn–N coordination.

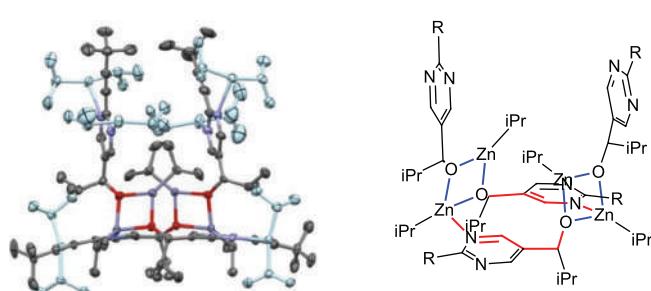

FIGURE 5.6.6 Single-crystal X-ray structure of the isopropylzinc alkoxide of the enantiopure asymmetric autocatalyst.

structure (Figure 5.6.6). In the presence of an almost stoichiometric amount of *i*-Pr₂Zn, the one-dimensional oligomeric structure was obtained by further formation of the macrocyclic structure of Zn–O–Zn square dimers. These results also support the involvement and importance of higher-order oligomer structures for the significant asymmetric amplification and spontaneous symmetry breaking.

5.6.4 ASYMMETRIC AMPLIFICATION INDUCED BY CHIRAL COMPOUNDS IN CONJUNCTION WITH ASYMMETRIC AUTOCATALYSIS

Asymmetric autocatalysis of 5-pyrimidyl alkanol **1** can significantly enhance the slight enantiomeric imbalance. Therefore, if the initial asymmetry of the autocatalyst **1** could be introduced by chiral compounds other than the autocatalyst **1**, it can be expected to obtain pyrimidyl alkanol **1** with detectable ee by the subsequent significant asymmetric amplification during autocatalytic formation of **1** by the reaction between aldehyde **2** and *i*-Pr₂Zn. The absolute configuration of **1** should be controlled by the absolute handedness of the originally used external chiral factor; thus, it has been found that various chiral compounds, even those whose asymmetric induction power is assumed to be weak, can act as chiral initiators of asymmetric autocatalysis (Soai et al. 2014a).

Meanwhile, propylene oxide is known as the first interstellar chiral compound, found in the Sagittarius B2 star-formation region (McGuire et al. 2016). The enantioselective addition of *i*-Pr₂Zn to pyrimidine-5-carbaldehyde **2** was examined using (*S*)- and (*R*)-(+)propylene oxide with low to high ee as a source of chirality (Figure 5.6.7) (Kawasaki et al. 2004). When the addition of *i*-Pr₂Zn to pyrimidine-5-carbaldehyde **2** was conducted in the presence of (*R*)-(+)propylene oxide with 97% ee, (*S*)-5-pyrimidyl alkanol **1** with 96% ee was obtained after the asymmetric autocatalysis with amplification of ee. By contrast, in the presence of (*S*)-(−)propylene oxide with 97% ee, oppositely configured (*R*)-**1** with 94% ee was formed. Even when propylene oxide with low (2–3%) ee was utilized, the same stereochemical relationship could be observed, that is, the (*R*)-(+) isomer with only 3% ee and (*S*)-(−)-isomer with 2% ee were found to serve as chiral initiators in the asymmetric autocatalysis, producing (*S*)-**1** and (*R*)-**1** with high ee, respectively. Thus, the chiral interstellar chiral

compound propylene oxide, acting as the source of chirality, is correlated with highly enantioenriched 5-pyrimidyl alkanol **1** via the asymmetric autocatalysis with amplification of ee. Styrene oxide also is a chiral initiator of asymmetric autocatalysis (Kawasaki et al. 2004).

It should also be mentioned that extraterrestrial amino acids detected in meteorites often exhibit enantioenrichments (Cronin and Pizzarello 1997). This shows that space is a candidate for the place of origin of homochirality. In fact, the Rosetta spacecraft of the European Space Agency (ESA) with a probe was launched to perform the *in situ* analysis of chirality of amino acids on a comet (Mygorodska et al. 2015).

The existence in space of polycyclic aromatic hydrocarbons (PAHs) has been discussed (Tielens 2005). For example, fullerenes have been detected in meteorites (Becker et al. 1994) and the planetary nebula (Cami et al. 2010). Helicenes are chirally relevant to PAHs with right- and left-handed helical structures, and the asymmetric photosynthesis of [6]helicine has been reported by irradiation with CPL, followed by oxidation (Kagan et al. 1971). We have reported that chiral [6] and [5]helicenes acted as highly efficient chiral inducers in the enantioselective synthesis of a pyrimidyl alkanol **1** by the addition of *i*-Pr₂Zn to pyrimidine-5-carbaldehyde **2** in combination with asymmetric autocatalysis (Figure 5.6.8) (Sato et al. 2001b). It should be noted that the asymmetric induction using chiral hydrocarbons without heteroatoms as a catalyst or ligand would be a challenge from the synthetic point of view.

When pyrimidine-5-carbaldehyde **2** was treated with *i*-Pr₂Zn in the presence of (*P*)-(+)-[6]helicine, after the amplification of ee by asymmetric autocatalysis, (*S*)-alkanol **1** was formed in 95% ee. On the other hand, (*M*)-(−)-[6]helicine induced the production of (*R*)-**1** with 93% ee. Even if the ee values of (*P*)-(+) and (*M*)-(−)-[5]helicenes were lowered to *ca.* 0.13% and 0.54% ee, asymmetric autocatalysis afforded (*S*)- and (*R*)-**1** with the same stereochemical relationships, respectively. (*P*)-(+) and (*M*)-(−)-[5]helicenes also gave (*S*)- and (*R*)-**1**, respectively. Therefore, one of the PAHs, [6] and [5]helicenes could also act as an origin of chirality of asymmetric autocatalysis. 1,1'-Binaphthyl (Sato et al. 2002) and finite single-wall carbon nanotube molecules (Hitoguti et al. 2014) can also be utilized as chiral inducers for asymmetric autocatalysis.

Since the pioneering work by Miller (1953), it has been demonstrated that racemic amino acids could be synthesized

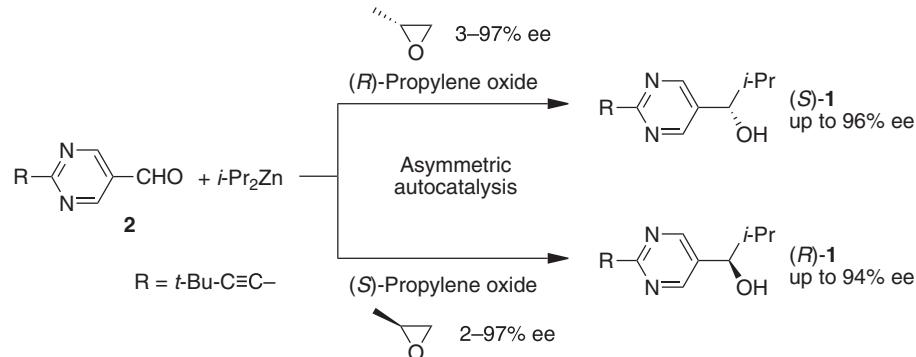

FIGURE 5.6.7 Highly enantioselective synthesis induced by propylene oxide in conjunction with asymmetric autocatalysis.

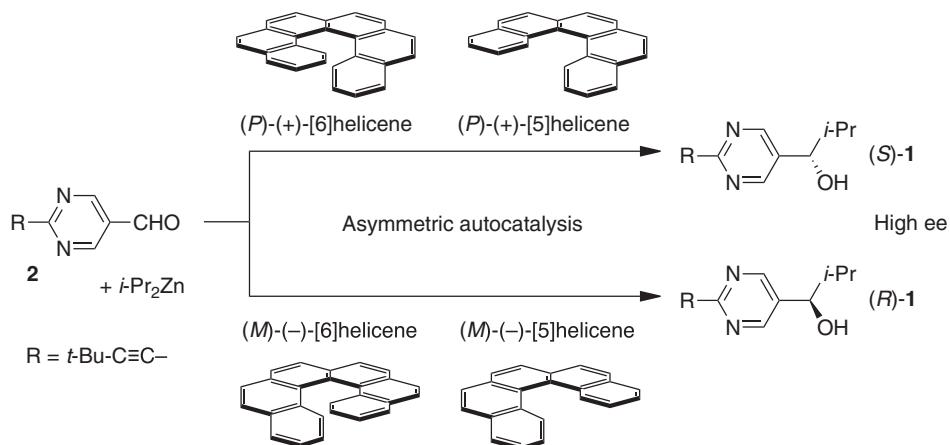

FIGURE 5.6.8 Asymmetric autocatalysis triggered by [6] and [5]helicenes with helical chirality.

under primitive earth conditions with an electric discharge (Miller and Urey 1959). Formation of amino acids and asymmetric induction by irradiation with CPL (Meierhenrich et al. 2005) have also been reported under simulated interstellar conditions (Bernstein et al. 2002; Munoz Caro et al. 2002). Furthermore, enantiomeric enrichment of amino acids was detected in a meteorite (Cronin and Pizzarello 1997; Engel and Macko 1997). Thus, in combination with a suitable amplification pathway, that is, asymmetric autocatalysis, highly enantioselective synthesis induced by the prebiotic amino acids becomes an important approach toward understanding the origin of biological homochirality, such as in L-amino acids.

We have demonstrated the asymmetric autocatalysis induced by enantioenriched proteinogenic amino acids (Shibata et al. 1998; Sato et al. 2007). When asymmetric autocatalysis was initiated in the presence of L-alanine with high ee, the production of (S)-5-pyrimidyl alkanol **1** with 92% ee was observed, whereas D-alanine gave (R)-alkanol **1** with 90% ee (Figure 5.6.9). Further investigations were conducted using alanine with low ee. When L-alanine with ca. 10% ee was used as the chiral initiator, the (S)-alkanol **1** with 94% ee was obtained. Even when the ee of L-alanine was as low as ca. 1% and ca. 0.1% ee, (S)-**1** was produced with high ee. On the other hand, asymmetric autocatalysis in the presence of D-alanine with low ee (ca. 10%, 1%, and 0.1% ee) gave oppositely configured (R)-**2**. Therefore, even if the enantiomeric

imbalance of alanine is as low as *ca.* 0.1% ee, it can work as the origin of chirality in asymmetric autocatalysis to give a large amount of highly enantioenriched organic compound **1**.

Serine has been considered one of the prebiotic molecules (Ring et al. 1972), and a chiral effect in the formation of the aggregate has been reported (Nanita and Cooks 2006). It has also been reported that the crystallization of racemic serine from aqueous sulfuric acid gives chiral crystals of DL-diserinium sulfate monohydrate that contain an equimolar amount of D- and L-serine with (*P*)- or (*M*)-crystal chirality. We have demonstrated that the chiral crystal formed from racemic serine can induce initial ee toward the autocatalyst **1** by the reaction between **2** and $i\text{-Pr}_2\text{Zn}$ to initiate the asymmetric autocatalytic amplification of ee (Figure 5.6.10) (Kawasaki et al. 2011a). Thus, the enantioselective addition of $i\text{-Pr}_2\text{Zn}$ to **2** was conducted in the presence of enantiomorphs of racemic serine as a heterogeneous chiral source, because dissolution of the crystal of serine causes the disappearance of the chirality. As a result, the (*P*)-crystal of *rac*-serine induced the production and propagation of (S)-pyrimidyl alkanol **1** with 94% ee by asymmetric autocatalysis with amplification of ee. On the other hand, the reaction between aldehyde **2** and $i\text{-Pr}_2\text{Zn}$ in the presence of (*M*)-crystal afforded (R)-**1** with 95% ee. The ee value was achieved to be greater than 99.5% ee by an additional round of asymmetric autocatalysis. Therefore, highly enantioselective synthesis was achieved utilizing the crystal chirality, including racemic serine.

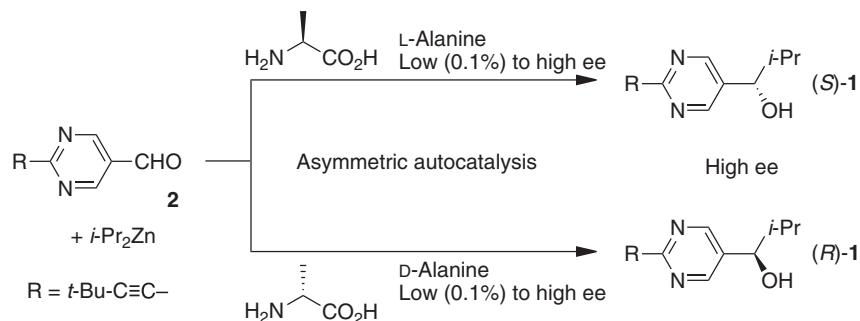

FIGURE 5.6.9 L- and D-Alanine-induced asymmetric autocatalysis to give (S)- and (R)-5-pyrimidyl alkanols **1** with high enantiomeric purity.

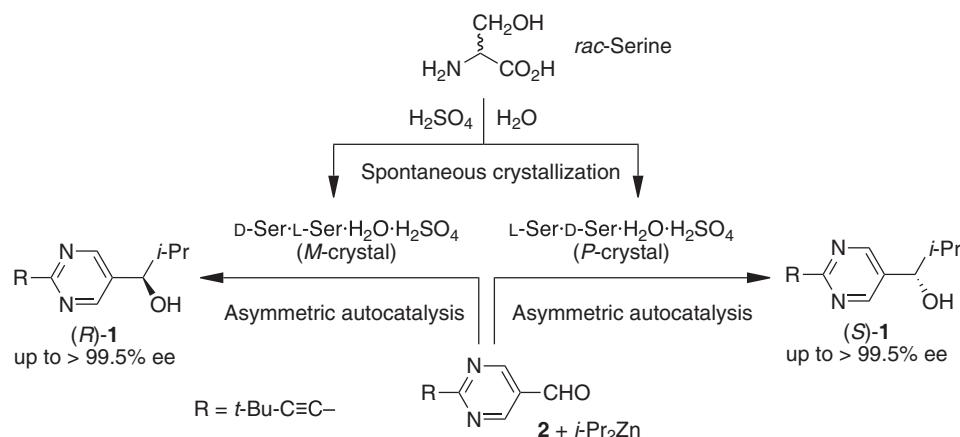

FIGURE 5.6.10 Asymmetric autocatalysis initiated with a chiral crystal of racemic serine.

5.6.5 ENANTIOSELECTIVE SYNTHESIS INDUCED BY CIRCULARLY POLARIZED LIGHT

The occurrence of strong CPL in the infrared region is observed in the star-formation region of the Orion nebula (Bailey et al. 1998). As investigated previously, left (*l*)- and right (*r*)-handed CPL is an external chiral physical force to induce ee in chiral compounds (Kagan et al. 1971; Balavoine et al. 1974; Bonner and Rubenstein 1987; Suarez and Schuster 1995). Thus, CPL has been proposed as a possible candidate for the origin of chirality. However, the degree of ee induced by irradiation with CPL is usually too small to be associated with overwhelming enantioenrichment in the compounds found in nature because of the very small anisotropy factors of organic compounds. The irradiation by CPL of racemic organic compounds such as leucine induces enantioenrichment with only *ca.* 2% ee (Inoue 1992). The correlation between these low ee and the homochirality of bioorganic compounds has not been clear. Therefore, we examined the direct irradiation by CPL of the racemic asymmetric autocatalyst **1** (Figure 5.6.11). Direct irradiation of **rac-1** by *l*-CPL and the subsequent asymmetric autocatalysis afford highly enantioenriched (*S*)-alkanol **1** with >99.5% ee. By contrast, irradiation with *r*-CPL gives (*R*)-**1** with >99.5%

ee. The overall reaction provides the first direct correlation of the handedness of CPL with that of an organic compound with significantly high ee.

5.6.6 ASYMMETRIC AUTOCATALYSIS TRIGGERED BY ISOTOPICALLY CHIRAL COMPOUNDS AND ISOTOPOMERS OF METEORITIC AMINO ACIDS

Many apparently achiral organic molecules may be chiral by considering the randomly labeled isotopes in the enantiotopic moiety. However, it is extremely difficult to recognize the chirality arising from the isotopic substitution because the chirality originates from the small difference between the numbers of neutrons in the atomic nuclei. We have reported asymmetric autocatalysis triggered by the chiral isotopomers arising from carbon isotope ($^{12}\text{C}/^{13}\text{C}$) substitution (Figure 5.6.12) (Kawasaki et al. 2009a). The carbon isotope chirality induces enantioselectivity in asymmetric autocatalysis; therefore, enantiomerically amplified alkanol **1** can be obtained with chirality corresponding to that of the carbon isotope substitution. This is the first example of such a chiral effect, that is, asymmetric induction by chiral compounds arising from the substitution of carbon isotopes ($^{12}\text{C}/^{13}\text{C}$).

On the other hand, the simplest achiral α -amino acid, glycine, was detected in the coma of a comet (Sandford et al. 2006; Altweig et al. 2016) and was also synthesized under prebiotic conditions (Miller 1953). Moreover, in addition to achiral glycine and α -methylalanine (Pizzarello and Huang 2005), L-enriched chiral α -methyl-substituted amino acids were identified in meteorites as deuterium-enriched forms (Engel and Macko 1997). We focused on the hydrogen isotope chirality in the apparently achiral meteoritic amino acids. When one of the hydrogen atoms of the methylene group of glycine or one methyl group of α -methylalanine is enantiomerically deuterated, these compounds become chiral because of the deuterium substitution. Thus, asymmetric

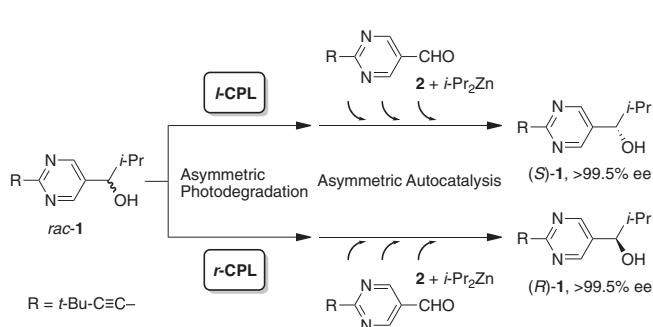

FIGURE 5.6.11 Asymmetric autocatalysis initiated by direct irradiation with CPL.

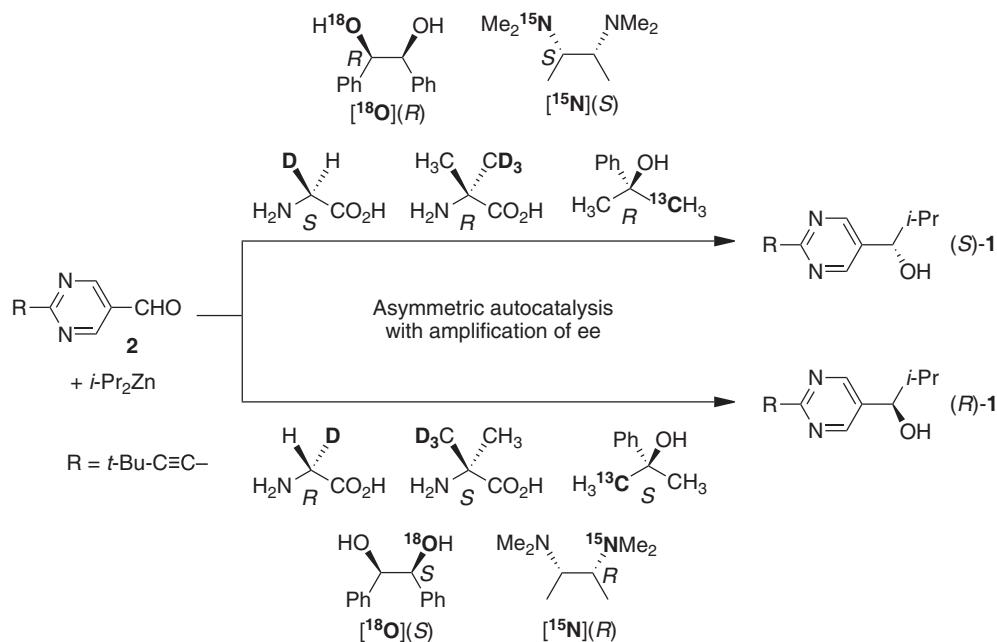

FIGURE 5.6.12 Asymmetric autocatalysis triggered by the chiral isotopomers with hydrogen (D/H), nitrogen ($^{15}\text{N}/^{14}\text{N}$), carbon ($^{13}\text{C}/^{12}\text{C}$), and oxygen ($^{18}\text{O}/^{16}\text{O}$) isotope substitution.

autocatalysis triggered by chiral meteoritic amino acids would become one approach toward the extraterrestrial origin of biological homochirality.

We have asymmetrically synthesized the isotopomers of glycine- α -d and α -methyl- d_3 -alanine, which were used as chiral initiators in asymmetric autocatalysis (Figure 5.6.12) (Kawasaki et al. 2009b). When $i\text{-Pr}_2\text{Zn}$ was reacted with aldehyde **2** in the presence of (S)-glycine- α -d, (S)-**1** with high ee was obtained. In the presence of (R)-glycine- α -d, on the other hand, (R)-**1** was formed after the asymmetric autocatalysis. Further investigations show that α -methyl- d_3 -alanine also acts as a chiral source in asymmetric autocatalysis with amplification of ee. We have reported that the partially deuterated α -methylalanine derivatives could also work as highly efficient chiral triggers for asymmetric autocatalysis (Kawasaki et al. 2011b).

Nitrogen isotope (^{15}N) enrichment was also reported in the meteoritic organic compounds (Engel and Macko 1997). We have demonstrated that the chiral nitrogen isotopomer of a diamine can also act as a chiral trigger for asymmetric autocatalysis to afford highly enantioenriched alkanol **1** with the corresponding absolute configurations to that of N^2,N^2,N^3,N^3 -tetramethyl-2,3-butanediamine containing nitrogen isotope ($^{14}\text{N}/^{15}\text{N}$) chirality (Figure 5.6.12) (Matsumoto et al. 2016b). The addition of $i\text{-Pr}_2\text{Zn}$ to pyrimidine-5-carbaldehyde **2** in the presence of $[^{15}\text{N}](S)$ -diamine afforded (S)-alkanol **1**. By contrast, (R)-alkanol **1** was obtained from the reaction initiated with $[^{15}\text{N}](R)$ -diamine. The ee was amplified to $>99.5\%$ ee by a further asymmetric autocatalytic reaction by using the obtained pyrimidyl alkanol **1**. In addition, asymmetric autocatalysis

has enormous power to discriminate and amplify the chirality of the isotopomers with $^{18}\text{O}/^{16}\text{O}$ substitutions (Kawasaki et al. 2011c; Matsumoto et al. 2013).

As described, the present results should increase the implications of chiral isotopomers in the study of the origin of biological chirality.

5.6.7 ASYMMETRIC AUTOCATALYSIS WITH AMPLIFICATION OF ENANTIOMERIC EXCESSES INITIATED WITH A CHIRAL CRYSTAL OF ACHIRAL NUCLEOBASES CYTOSINE AND ADENINE

Nucleobases are essentially achiral flat molecules and are considered to have existed on the prebiotic earth before the RNA world (Gilbert 1986). For example, cytosine could be efficiently synthesized from interstellar molecules, that is, hydrogen cyanide and cyanoacetylene (Robertson and Miller 1995; Shapiro 1999). The isolation of adenine from meteorites (Callahan et al. 2011) and prebiotic synthesis, that is, pentamORIZATION of hydrogen cyanide under prebiotic conditions (Oro 1960; Schwartz et al. 1982), has been reported. Therefore, the investigation of enantioselective synthesis based on crystal chirality arising from an achiral nucleobase is an important experimental approach to understanding the origins of both biological homochirality and life.

Cytosine crystallizes spontaneously from methanol into a chiral form (space group: $P2_12_12_1$) that exhibits either plus or minus Cotton effects in the solid-state circular dichroism (CD) spectra

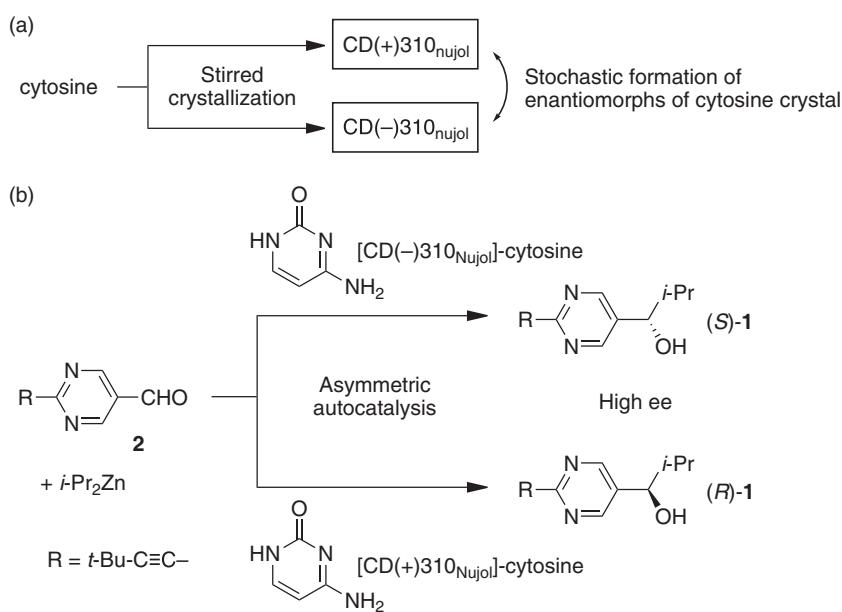

FIGURE 5.6.13 (a) Stirred crystallization of cytosine. (b) Highly enantioselective asymmetric autocatalysis induced by a spontaneously generated chiral crystal of achiral nucleobase cytosine.

at *ca.* 310 nm in Nujol. The enantiomorphs of cytosine can be obtained spontaneously using stirred crystallization (Figure 5.6.13a) (Kawasaki et al. 2008a). Chiral crystals of cytosine have been used as chiral initiators for asymmetric autocatalysis. In the presence of [CD(-)310_{Nujol}]-cytosine crystals, the reaction between aldehyde **2** and *i*-Pr₂Zn gives enantioenriched (*S*)-**1** in conjunction with asymmetric autocatalysis (Figure 5.6.13b). By contrast, [CD(+)]310_{Nujol}-cytosine crystals trigger the production of (*R*)-**1**. Furthermore, we have demonstrated the enantiospecific formation of chiral cytosine crystals by the dehydration of crystal water of achiral cytosine monohydrate under thermal and vacuum conditions (Kawasaki et al. 2010a; Mineki et al. 2013).

Crystallization of adenine from aqueous nitric acid produces adeninium dinitrate (adenine-2HNO₃) in enantiomorphic form (space group: *P*2₁;2₁). The chirality of adenine-2HNO₃ can be discriminated using solid-state CD analysis with Nujol (Mineki et al. 2012). Thus, one crystal exhibited a positive cotton effect at 250 nm ([CD(+)]250_{Nujol}-adenine-2HNO₃), while the other enantiomorph had a negative Cotton effect at the same wavelength ([CD(-)]250_{Nujol}-adenine-2HNO₃).

The enantiomorphs of adenine were subjected to the enantioselective addition of *i*-Pr₂Zn to pyrimidine-5-carbaldehyde **2** as a source of chirality (Figure 5.6.14). The reaction of **2**

with *i*-Pr₂Zn in the presence of finely powdered crystalline [CD(-)250_{Nujol}]-adeninium dinitrate resulted in the formation of (*S*)-5-pyrimidyl alkanol **1** with >99.5 ee after the asymmetric amplification. By contrast, with enantiomorphous [CD(+)]250_{Nujol}-adeninium dinitrate as the chiral initiator, the opposite (*R*)-**1** was obtained with >99.5% ee. The absolute configuration of the produced alkanol **1** with high ee obtained was controlled efficiently by the crystal chirality of the adenine salt in conjunction with asymmetric autocatalysis. Therefore, the crystal chirality of the prebiotic nucleobases cytosine and adenine can be responsible for the synthesis of nearly enantiopure organic compounds in conjunction with asymmetric autocatalysis.

5.6.8 ASYMMETRIC AUTOCATALYSIS WITH AMPLIFICATION OF ENANTIOMERIC EXCESSES TRIGGERED BY CHIRAL CRYSTALS COMPOSED OF ACHIRAL ORGANIC COMPOUNDS

In addition to cytosine and adenine, chiral crystallization of achiral compounds is not such a rare phenomenon (Matsuura and Koshima 2005; Pidcock 2005). Various chiral crystals of achiral compounds, such as the co-crystal of tryptamine and *p*-chlorobenzoic acid (Kawasaki et al. 2005), hippuric acid (Kawasaki et al. 2006a), benzil (Kawasaki et al. 2008b), tetraphenyl ethylene (Kawasaki et al. 2010b), benzene triester (Kawasaki et al. 2013), and ethylenediamine sulfate (Matsumoto et al. 2015b), act as chiral initiators in asymmetric autocatalysis (Table 5.6.1). These results clearly suggest that although the chiral induction of asymmetric autocatalysis by the chiral crystal is not specific to some crystal, the crystal chirality of achiral compounds has efficiently worked as a chiral trigger of homochirality in conjunction with asymmetric autocatalysis.

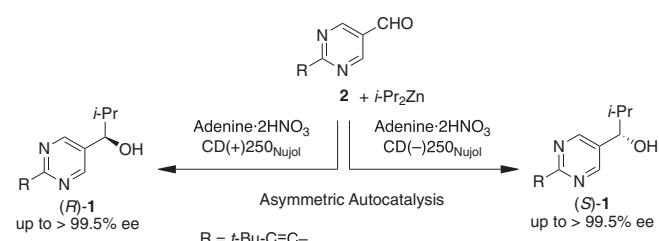

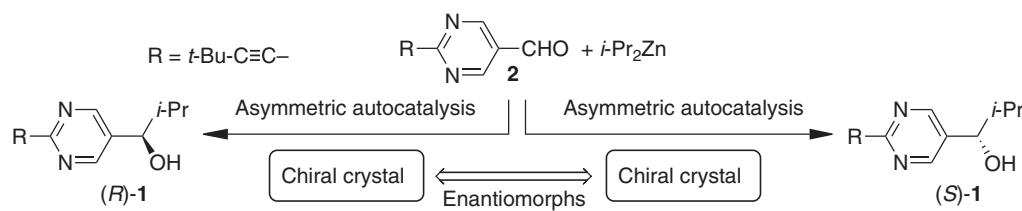

FIGURE 5.6.14 Asymmetric autocatalysis induced by a chiral crystal of adeninium dinitrate.

5.6.9 ASYMMETRIC INDUCTION BY THE CHIRAL SURFACE OF MINERALS

Chiral minerals provide effective environments for the discrimination of chiral molecules. Their possible roles in the origin of biological homochirality have been discussed previously (Hazen 2004). In the earth's crust, there is a wide variety of chiral minerals that could serve as accessible chiral surfaces in the prebiotic evolution of chiral organic molecules. However, only a very small asymmetric induction has been reported in the asymmetric adsorption of chiral compounds on quartz (Bonner et al. 1974). We have reported asymmetric autocatalysis triggered by *d*- and *l*-quartz. When pyrimidine-5-carbaldehyde **2** was treated with *i*-Pr₂Zn in the presence of *d*- and *l*-quartz powder, (*S*)- and (*R*)-**1** with a high enantioenrichment were obtained in conjunction with asymmetric autocatalysis (Figure 5.6.15) (Soai et al. 1999). In addition, chiral ionic crystals of sodium chlorate (Sato et al. 2000) and sodium bromate (Sato et al. 2004) also act as chiral triggers of asymmetric autocatalysis of 5-pyrimidyl alkanol **1**.

Cinnabar is a chiral mineral of mercury(II) sulfide. Recently, we have demonstrated that enantiomeric *P* and *M* crystals of cinnabar act as chiral triggers for asymmetric autocatalysis to afford (*R*)- and (*S*)-enantiomers of **1**, respectively (Figure 5.6.15) (Shindo et al. 2013). When pyrimidine-5-carbaldehyde **2** was treated with *i*-Pr₂Zn in the presence of cinnabar, which had right-handed *P*-helicity, (*R*)-pyrimidyl alkanol **1** was obtained in 88% ee and 87% yield. By contrast, in the presence of the (*M*)-HgS, the opposite enantiomer of (*S*)-**1** was isolated in 92% ee and 91% yield. Almost enantio-pure (*S*)- and (*R*)-**1** with >99.5% ee were obtained by applying consecutive asymmetric autocatalysis.

Meanwhile, the chiral enantiotopic surface of achiral minerals has also been considered an origin of chirality. Therefore, increasing attention has been focused on two-dimensional surface chirality. Hazen reported the enantiomer-selective adsorption of racemic amino acids on the enantiotopic faces of the achiral mineral calcite (CaCO₃) (Hazen et al. 2001). Certain metal surfaces, such as artificially prepared Cu(643),

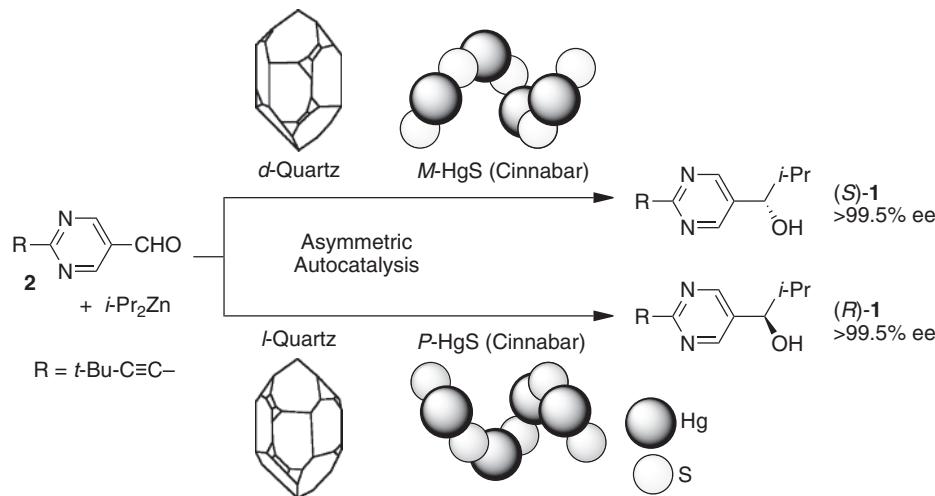

FIGURE 5.6.15 Enantioselective synthesis of 5-pyrimidyl alkanol **1** on the chiral surface of the chiral minerals quartz and cinnabar in conjunction with asymmetric amplification by asymmetric autocatalysis.

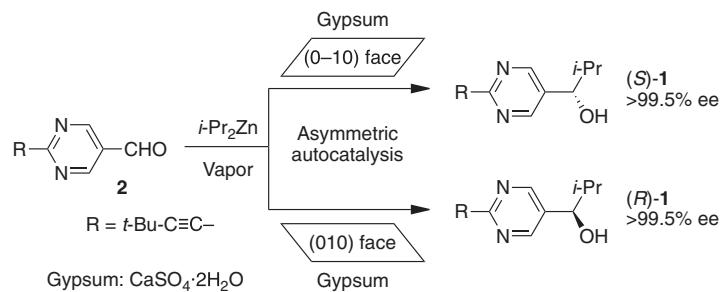

FIGURE 5.6.16 Enantioselective synthesis on the enantiotopic face of achiral gypsum in combination with asymmetric autocatalysis.

become enantiotopic. Enantiomer-selective desorption and decomposition have been reported on these enantiotopic metal surfaces (Gellman et al. 2013).

We have demonstrated that the chiral (010) and (0-10) surfaces of achiral mineral gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) could act as chiral environments to induce asymmetry in the asymmetric autocatalysis (Figure 5.6.16) (Matsumoto et al. 2017). On the (0-10) surface of gypsum, the reaction of adsorbed aldehyde **2** with *i*-Pr₂Zn vapor afforded alkanol **2** in the (*S*)-configuration. On the other hand, (*R*)-alkanol **1** was obtained through the reaction on the opposite (010) face. The ee values of pyrimidyl alkanol **1** could increase to >99.5% ee during further asymmetric autocatalysis with significant amplification of ee. It is considered that the slightly imbalanced *Re* and *Si* face orientations of aldehyde **2** on the enantiotopic (010) and (0-10) faces of gypsum are the origins of asymmetric induction.

5.6.10 SPONTANEOUS ABSOLUTE ASYMMETRIC SYNTHESIS: AMPLIFICATION OF THE FLUCTUATION OF ENANTIOMERIC EXCESSES BY ASYMMETRIC AUTOCATALYSIS

The reaction of achiral substrates forming enantioenriched products without the intervention of any chiral factor has been defined as spontaneous absolute asymmetric synthesis

(Mislow 2003). Spontaneous absolute asymmetric synthesis has been proposed as one of the origins of homochirality. However, it is widely accepted that common reactions without using a chiral factor always give a 1:1 mixture of two enantiomers, that is, a raceme. Based on statistics, the numbers of the two enantiomers fluctuate. As described in the preceding section, the Soai reaction can amplify extremely low ee to >99.5% ee. We have reported asymmetric autocatalysis of (*S*)- and (*R*)-alkanols during the reaction of pyrimidine-5-carbaldehyde and *i*-Pr₂Zn without adding any chiral substance (Soai et al. 1996) in the mixed solvent including diethyl ether (Soai et al. 2003) and in the presence of achiral silica gel (Kawasaki et al. 2006b) (Figure 5.6.17). Further investigations on spontaneous absolute asymmetric synthesis revealed that reactions in the presence of achiral amines spontaneously afforded pyrimidyl alkanol **1** with either (*S*)- or (*R*)-configurations (Suzuki et al. 2010). An approximately stochastic distribution for the formation of either (*S*)- or (*R*)-5-pyrimidyl alkanol **1** was observed, for example, formation of *S* 19 times and *R* 18 times for the 37 experiments (Soai et al. 2003). The fluctuation of ee produced spontaneously and stochastically in the initial stage of the addition of *i*-Pr₂Zn to achiral pyrimidine-5-carbaldehyde **2** forming racemic alkanol **1** can be amplified to a detectable value during the asymmetric autocatalysis. This stochastic behavior in the formation of (*S*)- and (*R*)-**1** fulfills one of the conditions necessary for spontaneous absolute asymmetric synthesis.

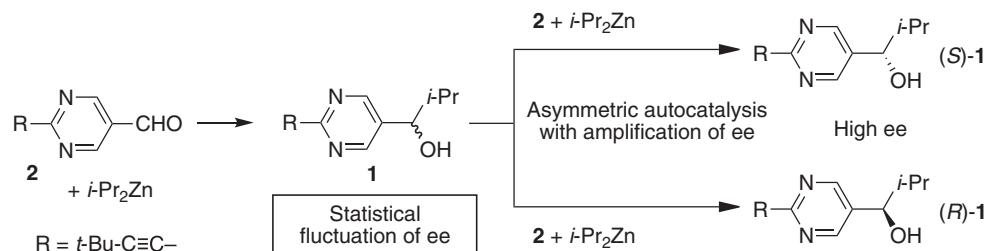

FIGURE 5.6.17 Spontaneous absolute asymmetric synthesis: amplification of the statistical fluctuation of ee in the initially forming racemic asymmetric autocatalyst.

5.6.11 ASYMMETRIC AUTOCATALYSIS AS A CHIRALITY SENSOR OF METEORITE SAMPLES

As mentioned above, asymmetric autocatalysis is a highly sensitive reaction to discriminate the chirality of a variety of materials, including chiral compounds such as isotopomers and chiral surfaces of minerals. In addition, without the addition of chiral materials, asymmetric autocatalysis affords (*S*)- and (*R*)-**1** with high ee in almost the same probability by the amplification of stochastic enantiomeric imbalances at the beginning of the reaction.

Thus, we have used asymmetric autocatalysis to determine the chirality inside a meteorite, that is, the autocatalytic reaction was repeatedly performed in the presence of meteorite samples (Kawasaki et al. 2006c). As a result, we could determine that chirality remains in Murchison and Allende powders after extraction with water and solvents in addition to the Murray kerogen-like insoluble organic materials (IOM) after demineralization. On the other hand, the Murray IOM samples after hydrothermolytic treatment (IOM-H) gave both (*S*)- and (*R*)-pyrimidyl alkanol **1** in equal probability, that is, stochastic results were obtained, which indicates the absence of chiral elements in the IOM-H sample. Chirality is not found in Murchison powders from which all organic components had been removed by O₂ plasma at low temperature. These results provide a powerful approach to detect the extraterrestrial origin of chirality.

5.6.12 SUMMARY

As described, we have shown that 5-pyrimidyl alkanol is a highly enantioselective asymmetric autocatalyst in the reaction between *i*-Pr₂Zn and pyrimidine-5-carbaldehyde, with significantly large amplification of ee from extremely low (*ca.* 0.00005% ee) to a nearly enantiopure state (>99.5% ee) without the assistance of any other chiral auxiliary. Chiral compounds such as interstellar chiral propylene oxide and chiral isotopomers of meteoritic amino acids can act as chiral initiators of asymmetric autocatalysis to afford enantioenriched alkanol with a handedness corresponding to that of chiral initiators. The spontaneous absolute asymmetric synthesis was realized in the formation of enantioenriched pyrimidyl alkanol; therefore, stochastic imbalance of the initially forming racemate

could also be asymmetrically amplified. Furthermore, various sources of chirality, such as CPL, chiral crystals of achiral nucleobases, and enantiotopic surfaces of achiral mineral gypsum, have been directly correlated with nearly enantio-pure pyrimidyl alkanol using asymmetric autocatalysis. The asymmetric autocatalysis of 5-pyrimidyl alkanol, that is, the Soai reaction (Pályi et al. 2012), is a unique reaction leading to overwhelming enantioenrichments, as observed in biological compounds such as L-amino acids and D-sugars. According to the new definition of life proposed by Carroll, the Soai reaction is the simplest form of life, that is, a self-amplifying autocatalytic reaction (Carroll 2009).

5.7.7 Plausibility and Interrelationships of Key Prebiotic Chemical Pathways—Ammonia and the Central Importance of Hydrogen Cyanide	357
Endnote	358
References.....	358

5.7.1 BACKGROUND

I last reviewed the subject matter of this chapter in 2006 (Schwartz 2006). That paper included a historical survey of previous literature, in which the topic of phosphorus and its place in biology and prebiotic chemistry was addressed, which of course is still appropriate and recommended as background. Much attention was placed in that review on what was referred to as the “phosphorus problem.” It is useful to summarize that issue briefly by considering the possible geological sources of phosphorus, which must be the starting point for any discussion of prebiotic chemistry involving the element (see Table 5.7.1).

With the possible exception of schreibersite (a special case to be discussed later), all of the calcium-containing minerals listed in the table share a common property. The low equilibrium concentrations of phosphate, which might be liberated in aqueous solution (and especially in the presence of the many other possible terrestrial sources of Ca^{2+} or other alkaline earth metals), lead directly to a potential problem for prebiotic chemistry, first recognized by Addison Gulick (1955). In 2006, I described a number of possible solutions for this problem.

These included the possible volatilization of P_4O_{10} from apatite at high temperatures to produce condensed phosphate (Yamagata et al. 1991), the corrosion (hydrolysis reactions) of meteoritic schreibersite to produce phosphite and other products (Pasek and Lauretta 2005), and the consequences of reduction of phosphate to phosphite by lightning strikes, either in volcanic dust clouds or to the ground (De Graaf and Schwartz 2000). The conclusion reached then is summarized here:

“A variety of pathways now are available as possible solutions for what this author used to refer to as the ‘phosphate problem’.

The ‘problem’ seems to have evolved gradually into the less perplexing one of having to decide which of several possible mechanisms are most likely to have operated on the primitive Earth.” (Schwartz 2006). The purpose of the present note is to update the previous review and add some more recent data. First, however, it seems necessary to summarize some *older* data. Perhaps because of misplaced modesty, combined with enthusiasm for newer ideas, an earlier hypothesis of mine (which in retrospect still seems quite attractive) was not covered in the previous review and will be discussed briefly here.

5.7.2 PHOSPHORYLATION WITH APATITE: UREA, AMMONIUM CHLORIDE, AND AMMONIUM OXALATE

It was demonstrated (Lohrmann and Orgel 1971) that mixtures of urea and ammonium chloride were effective in solubilizing and activating hydroxylapatite as a source of phosphate for the phosphorylation of nucleosides. To introduce a personal note here, I should comment that I met Leslie Orgel for the first time at the Third International Conference on the Origin of Life, at Pont-à-Mousson, France, which was held in 1970. I had presented a talk entitled “Phosphate: Solubilization and Activation on the Primitive Earth” (Schwartz 1971), which was a theoretical study of the possible role of simple complexing agents that strongly bind calcium (Schwartz and Deuss 1971), of which the prime example is oxalic acid ($\text{H}_2\text{C}_2\text{O}_4$). During the break, Orgel (to whom I was introduced by Sid Fox) remarked that he and Lohrmann thought they had “solved the problem.” The paper to which he was referring was soon published (Lohrmann and Orgel 1971); it reported that mixtures of urea, ammonium chloride, and various inorganic phosphates, including hydroxylapatite,

Major Phosphate Minerals and Their Occurrences

Fluorapatite	$\text{Ca}_5(\text{PO}_4)_3\text{F}$	Common Accessory Mineral in Terrestrial Igneous Deposits (see Figure 5.7.1)
Hydroxyapatite	$\text{Ca}_5(\text{PO}_4)_3(\text{OH})$	Terrestrial sedimentary deposits such as phosphorites
Francolite	$\text{Ca}_5(\text{PO}_4)_{2.5}(\text{CO}_3)_{0.5}\text{F}$	Terrestrial sedimentary deposits such as phosphorites
Schreibersite	$(\text{Fe}, \text{Ni})_3\text{P}$	Meteorites
Whitlockite	$\text{Ca}_6(\text{Mg}, \text{Fe})(\text{PO}_4)_6\text{PO}_3\text{OH}$	Meteorites
Chlorapatite	$\text{Ca}_5(\text{PO}_4)_3\text{Cl}$	Meteorites

could phosphorylate nucleosides, and thus, these conditions clearly solubilized the phosphate. Urea is indeed an indisputably plausible prebiotic molecule, but so is ammonium oxalate, since both urea and ammonium oxalate are products of the oligomerization of HCN (Ferris et al. 1978). Additionally, prebiotic oxalate could have been formed by a number of mechanisms. It had been established that oxalic acid can be generated photochemically from CO_2 and formic acid (Getoff 1962), and later, it was reported that oxalic acid was formed by irradiation of bicarbonate solution (Draganic et al. 1991). (For review of related literature, see Chittenden and Schwartz 1981).

Later experiments indeed demonstrated that phosphorylation of nucleosides by fluorapatite (Figure 5.7.1) occurred as a result of the evaporation of dilute solutions containing ammonium oxalate and that inclusion in the reaction mixture of the products of cyanogen hydrolysis was even more effective than oxalate alone (Schwartz et al. 1975). Cyanogen (C_2N_2) is a convenient stand-in for HCN, as it is available in cylinders and produces a similar set of hydrolysis products after reaction in water (particularly oxalate and urea).

5.7.3 PHOSPHORYLATION WITH STRUVITE

It was later argued (Hanschuh and Orgel 1973) that, in the presence of concentrations of ammonium ion greater than 0.01 M, struvite ($\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$) could precipitate rather than apatite, which could lead to the possibility of loss of ammonia upon heating to generate condensed phosphate and/or phosphorylate nucleosides. This proposal runs into several difficulties. The difficulty of maintaining an atmosphere on the primitive earth containing significant amounts of ammonia has been pointed out (Abelson 1966; Ferris and Nicodem 1972; Kuhn and Atreya 1979; Levine et al. 1982), so it is far from clear whether struvite would actually ever be precipitated on the prebiotic earth. (Also see the discussion in Section 5.7.7 on the plausibility of prebiotic chemical pathways and their interrelationships). The relevance of struvite has also been questioned more recently. It has been argued, on the basis of theoretical calculations, that struvite would not have been abundant on the earth (Gull and Pasek 2013). The same paper reports the results of some model phosphorylations (of glycerol and of choline chloride), which are somewhat unclear in their applicability, since they compare struvite to monetite (an acidic calcium phosphate, CaHPO_4), rather than apatite, and are conducted in the *presence of water*. The most interesting property of struvite, if formed, would be its activity in phosphorylation reactions under *drying conditions* (Hanschuh et al. 1973). Such conditions are, by the way, crucial to the effectiveness of ammonium salts of phosphoric acid in phosphorylation reactions; heating leads to loss of ammonia and generates an acidic phase.

5.7.4 PHOSPHORYLATION STARTING WITH SCHREIBERSITE

The meteoritic phosphide mineral schreibersite was proposed as a possible starting point for prebiotic phosphorus chemistry (Pasek and Lauretta 2005). The hydrolysis reactions of this mineral (“corrosion” in the terminology of Pasek and Lauretta) lead to the formation of a number of interesting reduced phosphorus oxyacids, including phosphite. It has been established that phosphite is not only more soluble than phosphate as an alkaline earth salt (Schwartz 2006) but also more reactive (De Graaf and Schwartz 2005). More recently, evidence has been presented that carbonate samples from the Archean limestone deposits from Coonterunah, Australia, show the presence of phosphite, as determined by extraction and ^{31}P NMR studies (Pasek et al. 2013). This appears to be the first direct evidence supporting the hypothesis that meteoritic schreibersite might have had a role in prebiotic chemistry and is a very exciting result.

On the other hand, another report (Britvin et al. 2015) makes a similar claim but is essentially irrelevant. The abstract states: “The results of the present study *could* [emphasis added] provide a new insight on the terrestrial origin of natural phosphides—the most likely source of reactive prebiotic phosphorus at the times of the early Earth.”

Unfortunately, the deposit studied (the Hatrurim Formation near the Dead Sea in Israel and Jordan) is a recent formation, and the authors discuss a possible metamorphic event that occurred in the formation between 2 million and 4 million years ago. It is clear that this formation might serve as a *model* for a prebiotic event (which may be what the authors intended to say), but the inference is an analogy rather than evidence for a historical process. In the past several years, however, a number of other publications have appeared that considerably strengthen the case for schreibersite in prebiotic phosphorus chemistry.

5.7.5 PHOSPHORYLATION IN DEEP EUTECTIC SOLVENT SYSTEMS

Deep eutectic solvent (DES) systems have been studied as a medium for phosphorylation (Gull et al. 2014; La Cruz et al. 2016), with application to reactions on the surfaces of synthetic schreibersite samples, and have been proposed to be prebiologically plausible:

“Deep eutectic solvents arise spontaneously by evaporation of water, and hence these may be formed merely by the drying down of solutions on minerals.” (La Cruz et al. 2016).

For example, evaporation of water solutions containing urea and choline chloride are said to lead to the formation of a 2:1 urea and choline chloride eutectic, in which phosphorylation studies have been conducted. It would be convincing if experiments had actually demonstrated the plausibility of DES systems, but while these papers suggest that this has been established, a little investigation does not support this inference. For example:

“We believe that these reactions may be prebiotically relevant. The DES system we employed here has shown significance for other biochemical reactions and from the prebiotic perspective, as eutectic melts of urea and choline can form spontaneously by drying these mixtures (Austin and Waddell 1999; Miller 1953; Miller and Schlesinger 1993)...” (Gull et al. 2014).

Some of these citations are rather strange. Austin and Waddell merely report the synthesis of “choline like molecules” such as ethanolamine and N-methylethanolamine. Work by Miller (1953) does not appear to be relevant here. The inference in the above citation is therefore rather carelessly drawn. I do not necessarily question the possible importance of DES systems—such systems might possibly arise through the evaporation of aqueous solutions containing these two organic compounds—but this simple mechanism has not yet been demonstrated. Published data are available for the urea–choline chloride phase diagram (Morrison et al. 2009), but it is not clear what effect water would have on the system, nor whether a 2:1 urea–choline chloride phase would be formed in this way, since a urea–water eutectic is also possible (Durickovic et al. 2009); the combination would lead to a more complex case. Actual experiments need to be conducted.

5.7.6 PHOSPHORYLATION IN UREA–AMMONIUM FORMATE–WATER

A better case has been made for the urea–ammonium formate–water (UAFW) eutectic system (Burcar et al. 2016). Although these results are intriguing, here too, the argument is not clear-cut. In an elaborate series of experiments in which (among other factors studied) the eutectic system was partially reformed by addition of water and re-evaporation, hydroxyapatite, struvite, and several other phosphates were used to phosphorylate nucleosides. However, questions remain. For example, what would the results have been if other starting conditions had been used? In all the experiments described, a 1:2 starting ratio of urea to ammonium formate was used (the eutectic composition). The suggested plausibility of this system really depends on uncertainties, such as this, being clarified. It would be valuable to determine the full phase diagram for the three-component UAFW system.

5.7.7 PLAUSIBILITY AND INTERRELATIONSHIPS OF KEY PREBIOTIC CHEMICAL PATHWAYS—AMMONIA AND THE CENTRAL IMPORTANCE OF HYDROGEN CYANIDE

As summarized earlier, the solubilization and activation of terrestrial phosphate minerals seems to require, or at least is greatly stimulated by, the participation of products of hydrogen cyanide oligomerization. Stanley Miller (1953), in his iconic work on amino acid synthesis from reduced gas mixtures, was the first to identify HCN as an important precursor in the process (Miller 1957). John Oró went a considerable step further by demonstrating that adenine was a minor product of the extended oligomerization of HCN (Oró 1960).¹

In an extremely thorough study by Robert Sanchez, James Ferris, and Leslie Orgel (1967), the necessary conditions to permit the oligomerization of HCN were described. Hydrogen cyanide in water will oligomerize in mildly alkaline solution if present at a concentration substantially greater than 0.01 M. At concentrations greater than 0.1 M, polymerization reactions are more important than hydrolysis, and reaction to produce tetramer and higher oligomers is rapid. A plausible mechanism for concentrating HCN solutions was already known to be freezing, which produces a highly concentrated solution (74.5 M!) of HCN in the form of a eutectic phase (Coates and Hartshorne 1931). This remarkable effect (shown in modified form as Figure 5.7.2) may have had a crucial influence in prebiotic chemistry (Sanchez et al. 1966). Perhaps, it is reasonable to suggest the possibility that such low-temperature conditions may have been *required* to permit the concentration of HCN in a eutectic phase and to have permitted key synthetic processes to occur. A related problem is that of ammonia availability for prebiotic chemistry. While synthesis of HCN (as well as C₂N₂) has been shown to occur in less highly reduced and therefore more plausible

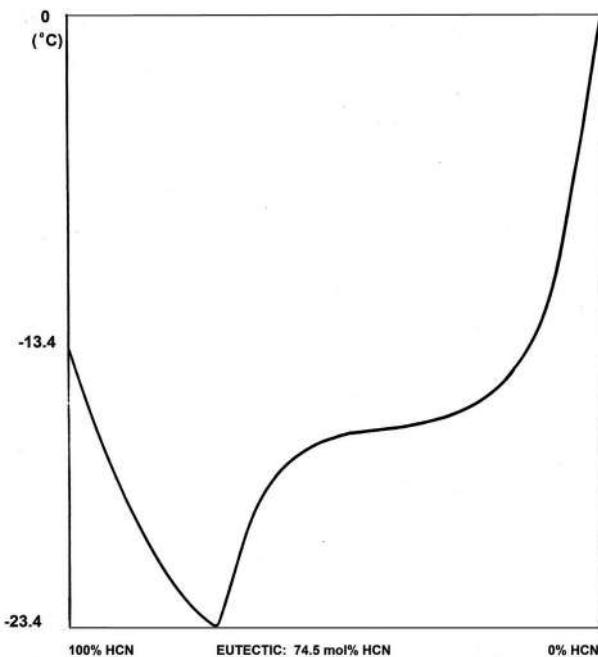

FIGURE 5.7.2 The HCN–water eutectic. This melting point diagram is originally from Coates and Hartshorne and has been redrawn, modified, and simplified to emphasize the portion of the diagram above the eutectic point. (For the original diagram, see: Coates, J.E. and Hartshorne, N.H., *J. Chem. Soc.*, 657–665, 1931.)

methane-nitrogen atmospheres (Toupane et al. 1975), the problem of ammonia stability complicates the question.

The susceptibility of ammonia to photolytic destruction is potentially an extremely serious problem for prebiotic chemistry, which has probably not been appreciated widely enough (Ferris and Nicodem 1972; Kuhn and Atreya 1979; Levine et al. 1982). Henderson-Sellers and Schwartz pointed out that a possible prebiotic source of ammonia (photochemical generation on natural minerals), which was not considered by Ferris and Nicodem, might have contributed to a steady-state concentration of ammonia (ammonium ions) sufficient to have permitted prebiotic chemistry to occur (Henderson-Sellers and Schwartz 1980). The cycling of HCN through the hydrosphere (via hydrolysis) must have constituted another such source. In fact, it seems obvious that such cycling was indispensable to the origin of life, an idea that has been expressed before: “Alternatively, we may suppose that cyanide never reached a concentration approaching 10^{-2} M but that nitrogen was constantly recycled through the oceans in the form of cyanide” (Sanchez et al. 1967).

The lesson seems to be clear; prebiotic chemical cycles were not only finely tuned but intricately *interdependent*.

ENDNOTE

¹ Incidentally, after spending some years trying to sort out the complexities of the pathways of HCN oligomerization (Voet and Schwartz 1983), I am less enthusiastic than Leslie Orgel was, when he remarked that the formation of a complex structure such as adenine by such a

simple reaction was a *remarkable* result (Orgel 2004). It certainly was an *important* result but should now be viewed against a background of the enormous complexity, which this reaction system produces. I am reminded of a remark attributed to Harold Urey, who—when asked what he expected from Miller’s planned experiment—answered “Beilstein” (Wills and Bada 2000). Beilstein is the classical compendium of all known organic molecules and at the time would have amounted to more than 500 volumes.

5.8.1 INTRODUCTION

The element phosphorus (P) is critical to life as we know it. On the modern Earth, phosphorus is often the limiting reagent in an ecosystem (Karl and Björkman 2014), and a phosphorus-limited system will continue to reproduce and grow until exhausting the available phosphorus (Benitez-Nelson 2000). On the other extreme, if there is an abundance of phosphorus in an area, the organisms will continue to reproduce and consume other available nutrients. Often, this abundance leads to algal blooms that can exhaust the oxygen and cause eutrophication (Smayda 2008). To maintain a healthy ecosystem, a source for phosphorus must be available, and the source must not overwhelm the ecosystem with an overabundance of phosphorus. The unique chemical characteristics of phosphorus, including its structure and geochemical abundance, make it well suited as a key nutrient. Given the strong limitation of available phosphorus in biology today, it seems plausible that phosphorus may have been a critical element for early organisms and the chemistry for the origin of life.

We note here a need for a distinction between “phosphorus”, “phosphorous”, “orthophosphate”, and “phosphate”. The element is termed “phosphorus”. Other than when referring to the acid, H_3PO_4 , “phosphorous” is typically a misspelling, except where it archaically refers adjectivally to bonding structures. We typically call C-C bonds “carbon bonds” instead of “carbonous bonds”. “Orthophosphate” typically refers to inorganic phosphate, often free in solution or bonded to minerals. “Phosphate” is a specific bonding structure of phosphorus, where phosphate forms four single bonds and one double bond, supported by varying resonance structures, to four oxygen atoms.

The structure of phosphate, and of similar compounds bearing P, O, and H, is shown in [Figure 5.8.1](#). In phosphate, the phosphorus has an oxidation state of +5. Phosphite, hypo-

phosphate, and hypophosphite are distinct phosphorus speciations where the phosphorus employs a different oxidation state (+3, +4, and +1 respectively) and the species are chemically distinct.

Living organisms depend on phosphorus as an essential macronutrient. For example, in the human body, phosphorus participates in nearly all biochemical functions and is crucial for bones and teeth, for the formation of high-energy compounds, as a buffer to maintain homeostasis, and in the synthesis of genetic material, phospholipids, and phosphoproteins. Approximately 80%–85% of the phosphate in the human body is in the form of orthophosphate as the mineral component of bone and teeth (Wang et al. 1992). The remaining phosphate is present in a variety of vital inorganic and organic compounds found in both intracellular and extracellular tissues. These compounds are involved in metabolism, structure, and genetic reproduction (Dorozhkin 2014). Prokaryotic organisms are similarly enriched in phosphorus with respect to dry weight (Lange and Heijnen 2001), despite lacking a calcium phosphate endoskeleton.

Nucleic acids are biochemical macromolecules that primarily store, synthesize, and transfer genetic material. Ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) are two nucleic acids, having backbones of sugars alternating with phosphates, used in all known life. These are orthophosphate diesters that are formed when an alcohol (including sugars) is linked to a phosphate by two bridging oxygen atoms ([Figure 5.8.2](#)). The bonds of these diesters are relatively low in energy and are ionized, giving the backbone of these important structures stability in aqueous environments while hindering their diffusion through the phospholipid cellular membrane (Nelson et al. 2008).

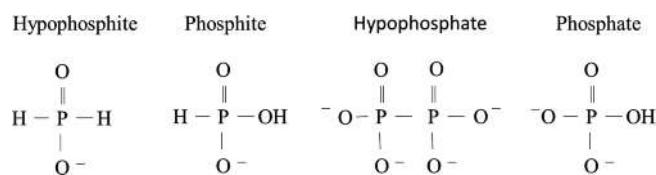

FIGURE 5.8.1 Phosphorus molecules consisting of H-P-O arrangements.

High-energy biochemical molecules store and deliver energy to chemical reactions needed by organisms. Many of the high-energy molecules are organic polyphosphates which transfer energy within the intermediaries of metabolism by breaking one of the phospho-anhydride or polyphosphate bonds by hydrolysis (reaction with water) yields energy and drives metabolism. The typical example of a metabolic phosphorylated molecule is adenosine triphosphate (ATP, Figure 5.8.2). It contains a high-energy anhydride bond between each phosphate group. The products formed when the terminal phosphate bond is broken are adenosine diphosphate (ADP) and a phosphate group. The ADP and the phosphate group are stabilized by the electrostatic repulsion of the positively charged phosphates and the negatively charged oxygen, and by the ionization and resonance of the products, and because the products have greater entropy than the reactants (Nelson et al. 2008). The phosphate group is then reattached to the ADP by phosphorylation, a condensation reaction, to reform the ATP.

One of phosphorus's properties that makes it indispensable to modern biochemical reactions is its ability to form two bonds while remaining ionized (Westheimer 1987). This ionization provides distinct advantages to specific biomolecules. For example, the molecule retains a charge even when bridging two organics, such as sugars in the primary nucleic acids RNA and DNA. The resulting ionization prevents diffusion of the nucleic acid out of the cell membrane, itself composed of a bilayer of phospholipids. This compartmentalization by phospholipids helps to give local stability to RNA and DNA, which store central genetic material. The charge also prevents hydrolysis of the bonds by water or hydroxide, giving the nucleic acids additional stability in either basic or neutral solutions. This resulting stability gives the individual bonds half-lives estimated as millions of years and results in nucleic acids (which are millions of nucleotides long) requiring only yearly repair (Benner 2004). The ionization also

enhances dissolution of phosphorylated organics in water, as the negative charge on the phosphorylated organic increases the interactions with the polar solvent—water—and increases the solubility of the phosphorylated organics (Pasek and Kee 2011). As many biochemical molecules rely on water for transportation, increased solubility increases the number of available biomolecules for catalysis (Pasek et al. 2017).

Organophosphates lack stereochemical handedness, conferring a structural trait that makes phosphorus indispensable for biology; phosphate is achiral. In RNA, the two oxygen share the charge via resonance with no resulting stereoisomers. As life is selective when it comes to chirality, this achirality is especially pertinent. Therefore, it is difficult to replace organophosphates as many of the suggested replacement molecules are chiral or induce a handedness when linking the nucleotides (Westheimer 1987).

To summarize, phosphorus is a key biologic element due to several of its unique properties. It plays a role in biological structure as phosphate biominerals (bone) and phospholipid cell membranes and is an important structural element in nucleic acids, the key genetic material of all life as we know it. It is important to metabolism as ATP, also known as the energy currency of life. The question is, “In which of these roles is phosphorus so critical that there is not much evidence of alternatives near the onset of life?” The next section seeks to address this question.

5.8.2 TOP DOWN AND BOTTOM UP APPROACHES FOR IDENTIFYING THE CRITICAL PHOSPHATE BIOMOLECULES

Historically, scientists have approached questions surrounding the origins of life in two ways, termed “top down” and “bottom up.” The “top down” approach falls principally in the field of biology. Biological researchers hope to gain insight into the fundamental features of life—what it did and where it lived—by using their knowledge of modern organisms—their biochemical pathways, environmental habitats, and core genetic material—to address what life might have looked like at the very start of modern biology. Such an approach has been immensely successful and has provided the key data that led to the RNA world insight (Woese 1967; Orgel 1968; Pace and Marsh 1985; Gilbert 1986).

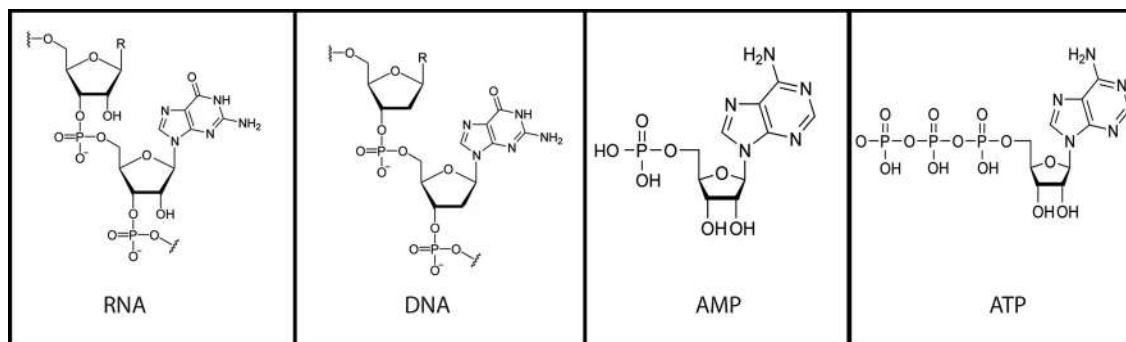

FIGURE 5.8.2 Examples of key phosphorylated biomolecules.

The “bottom up” approach is typically in the realm of chemists, including biochemists, geochemists, and cosmochemists who seek to define the simple chemical reactions that may have led to the components of modern life. Such information may include prebiotic reactions that lead to sugars, the competition and selection of polymers, and the environmental conditions leading to organic reactions of interest (Oró 1961; Ferris et al. 1968; Mizuno and Weiss 1974; Krishnamurthy et al. 2000; Ricardo et al. 2004). As such, researchers take knowledge of the world/solar system, before the onset of life, and try to find a plausible route to making a simple, plausible biochemistry.

Typically, how and when phosphates first became part of life has been explored using the bottom up approach. Researchers use a combination of geochemistry and biochemistry, with the goal of forming organophosphates molecules. However, a “top down” approach may be beneficial because it allows us to elucidate the fundamental chemical services of phosphorus and phosphate, to review the various roles of phosphorus in biology, and to seek places where phosphate has possible substitutes in order to constrain the places where nothing but phosphate will work. These phosphate-essential biomolecules can then be the targets of the bottom up approach for chemical synthesis.

Constraining the biomolecules in the top-down approach involves answering four questions. A “no” to all of the questions points to a molecule with a deeper, fundamental requirement for phosphorous in life: (1) Is the biomolecule used by only a portion of modern organisms? (2) Are there replacements for the phosphorous in modern biochemistry that work well enough? (3) Are there any indications that there were alternatives to the phosphorous in early life? (4) Are there routes that might be imagined on early Earth that lead to the replacement of phosphorous compounds by less stable but easier-to-build compounds?

First, we investigate phosphate as a biomineral. The phosphate mineral apatite makes up the internal supporting structure of vertebrate organisms, as bones and teeth, and is produced by some brachiopods and protists as a biomineral (Omelon et al. 2013) and by one group of plants as a deterrent against herbivores (Ensikat et al. 2016). In addition to apatite, there are many other phosphate biominerals, including struvite ($\text{NH}_4\text{MgPO}_4 \cdot 6\text{H}_2\text{O}$), brushite ($\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$), and vivianite ($\text{Fe}_3(\text{PO}_4)_2 \cdot 8\text{H}_2\text{O}$), most of which are produced as waste products by microbes.

The use of apatite as a biomineral is limited to a few branches of Eukarya and other organisms produce many other biominerals. For example, various mollusks, echinoderms, and arthropods produce calcite and aragonite. Also, iron oxides and sulfides, carbonates, and silica are used extensively to support cell structure and are produced by organisms as a waste mineral. Other researchers identify bioapatite as a young (~550 million years ago) biogenic mineral with an origin dependent on the chordate life cycle. We can conclude biomineralization is not a phosphorus-dependent function.

Second, we investigate are the phospholipids. Phospholipids make up the cell membranes of nearly all modern life. Phospholipids are composed of either two long-chain fatty

acids (carboxylic acids) or two ethers linked to a glycerol molecule. On one end of the glycerol molecule is a phosphate, which itself may be a diester, linking to an ethanolamine, choline, or similar molecule.

In contrast to biominerals where phosphates are one of many, organophosphates are the major variety of cell membrane lipid, thus fulfilling the first criteria for our top-down approach. However, with respect to phosphorous, biology explores variations in lipid chemistry more than it does metabolism and nucleic acids. Many lipids do not involve phosphate at all, including the sphingolipids, the sulfolipids, and the aminolipids. Both the sphingolipids and aminolipids are used to supplement phospholipid chemistry, but the sulfolipids can completely replace them. This replacement tends to occur most commonly in those environments where phosphate is limited (Van Mooy et al. 2009). The synthesis of phospholipids requires dissolved phosphate, glycerol, and fatty acids to condense, and, though the membranes formed are robust, simple fatty acids also form membranes. To this end, lipids appear to not require phosphate as part of cell membranes. However, if given the “choice,” most biochemical systems do appear to preferentially make phospholipids, pointing to a greater utility in biochemistry.

Phospholipids are beneficial to cells, and replacement of phosphate is done only out of necessity. The preference for phospholipids likely is a result of their stability and of the stability of the membranes they form. However, prebiotic chemists have proposed that if less stability can be tolerated in a tradeoff for ease of formation, then simple fatty acids were likely precursors of phospholipids. Thus, our criterion 4 suggests that phospholipids were post-origin phosphorylated biomolecules. There are advantages of using phospholipids, but those advantages were likely evolutionarily selected.

Third, we investigated the metabolites. The most critical of these in biochemistry today is the molecule ATP. It is the dominant energy currency for all life as we know it: storing energy during catabolism and releasing energy during anabolism. It is the most widespread nucleotide in this role, although other nucleotide triphosphates (guanosine triphosphate, uridine triphosphate, and cytosine triphosphate) also have minor roles in metabolism, primarily in sugar transfer and protein synthesis. In contrast, ATP is used in nearly all biochemical reactions requiring an energy input.

This use is universal, hence fulfilling our criterion 1. All organisms require phosphate—as ATP—in their metabolic processes. Some metabolic processes require GTP, UTP, or CTP instead, but these are much less common than ATP-requiring processes. Aside from ATP, each of these nucleotide triphosphates tends to serve a specific metabolic role (e.g., glycosylation), and not one is as widespread as ATP.

In life today, ATP is generated primarily by a proton gradient and a molecular machine, the enzyme ATP synthase. The proton gradient is formed through metabolic processes as organisms dump protons outside of their cell membranes (or organelles within cell membranes that do the same). Then, these protons are slowly let back in and, in the process, drive a mechanical enzyme that sticks phosphate on ADP to make ATP.

The reverse process is called a proton pump and trades chemical energy for pushing protons (H^+) out of a cell. This process is generally powered by ATP (breaking down to form ADP); however, there are a suite of enzymes that break a much simpler molecule—pyrophosphate—down to phosphate. These enzymes are not widespread, and the use of an alternative molecule to ATP—that of pyrophosphate—is limited to this main role thus far (Baltscheffsky 1967; Baltscheffsky and Baltscheffsky 1995).

The assembly of two phosphates forms pyrophosphate. Continuing to build up phosphates yields a biopolymer termed polyphosphate. Polyphosphates have an energy potential similar to that of ATP but are composed exclusively of phosphate. Polyphosphates are ubiquitous in cells, where they serve as phosphate and energy reservoirs. Organisms, when both energy and phosphate are in abundance, turn ATP into polyphosphate and then transfer the polyphosphate into small cellular sacks called vacuoles. From these vacuoles, polyphosphate can then be extracted and the energy can be recovered by transferring a phosphate to ADP to make ATP when either energy or phosphate is required to maintain cellular function. Many scientists have argued that polyphosphate is ancient and possibly a precursor to ATP in metabolic processes (Kornberg 1995; Achbergerova and Nahalka 2011). The main issue with polyphosphates is that they are highly ionized and sometimes less soluble than the nucleotide triphosphates. In modern life, they do not participate in metabolism without the ATP intermediate.

Our second criterion is that there be no replacements that work well enough. Indeed, modern biochemistry points to a uniqueness of phosphorus in biochemical metabolism. Nothing really substitutes for phosphorus in biochemical processes. Some molecular changes are possible, but even so, the dominant biomolecule driving metabolic reactions is ATP.

Our third criterion deserves close analysis. Recently, work by Goldford et al. (2017) pointed out that there exists a suite of reactions that they identified as being close to a “core” metabolism that does not rely on phosphate for the key steps. They postulated that this core was ancient and involved, in lieu of phosphates, molecules termed thioesters. Such a scenario had indeed been envisioned by others interested in prebiotic chemistry (De Duve 1991; De Duve and Miller 1991), who argued that sulfur could form high-energy bonds capable of metabolism for the origin of life. To this end, the replacement of phosphate in metabolism may have existed, and there is some evidence that alternatives to phosphorylated biomolecules can perform the key roles of life (though not conclusively so). Several plausible prebiotic alternatives have been outlined, suggesting that our top-down perspective of the requirement of phosphate in metabolism falls somewhere around our criteria 3 and 4. Phosphate presently is required throughout all biological metabolism, but there may have been ancient ways around it.

The final major role of phosphorus in biomolecules is in nucleic acids. The two nucleic acids used by all life today are DNA and RNA, which differ in their sugar backbones by an oxygen (DNA has one less O on each sugar), and in their

nucleobases (uracil in RNA is replaced by thymidine in DNA). The phosphorus backbone comparatively remains unchanged in all nucleic acids. The DNA and RNA easily meet the first and second criteria in our top-down view of prebiotic chemistry: phosphorus is critical to all nucleic acids.

There is a slight exception to stating that *phosphate* is critical to all nucleic acids. In recent studies, Wang et al. (2007) demonstrated that, in lieu of phosphate, DNA in some bacteria consisted of a thiophosphate (SPO_3^{3-}) linker. This change was proposed to be due to an evolved defense mechanism that modifies existing DNA to make it less susceptible to attack by nucleic acid enzymes. Other alternatives to phosphate, such as arsenate (Wolfe-Simon et al. 2011), have not been definitively proven and, for reasons of chemical stability, are highly unlikely.

Biochemical reactions are all contingent on DNA and RNA, and, currently, there is no core biochemical pathway that doesn’t rely on these molecules, unlike metabolism and its potential non-phosphorus reactions (criterion 3). In this respect, a requirement for phosphorus in nucleic acids seems to be even stronger than the requirement for phosphorus in metabolic molecules. However, Hud et al. (2013) outlined an alternative view of nucleic acids and took a reductionist approach to nucleic acids, which they proposed to be composed of three parts: an ionized linker, trifunctional connector, and a recognition unit. These correspond to phosphate, ribose/deoxyribose, and nucleobases, respectively, in the context of RNA and DNA. Hud et al. (2013) postulated that each of these characteristic molecules could have been replaced at some point in early life, and hence, modern day nucleic acids are not representative of ancient nucleic acids. They provide the molecule glyoxylate as a potential substitute for phosphate in nucleic acids as an example of changing out the ionized linker (Bean et al. 2006).

In summary (Figure 5.8.3), a top-down approach highlights two sets of phosphorylated molecules that merit focus as goal molecules for a bottom-up approach: high-energy polyphosphates such as ATP or the simpler polyphosphates,

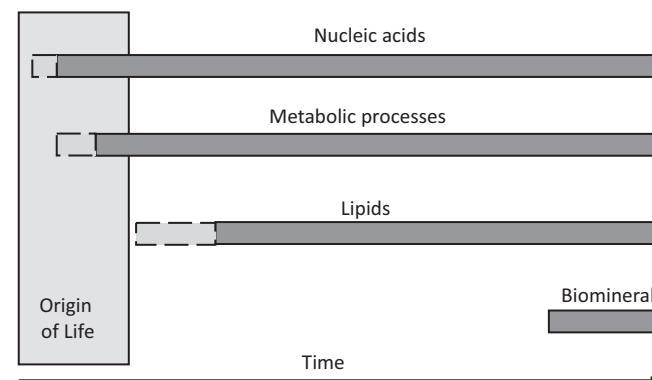

FIGURE 5.8.3 A top-down view of phosphorus in biology. The likely addition point of each major phosphorus-bearing molecule is shown, based on our criteria for inclusion. The “origin of life” block may be either a singular event or a continuum. Therefore, molecules shown starting within this box were potentially present at the origin of life (but not necessarily so, since the singular event may have been prior to the synthesis of these molecules).

and phosphorylated nucleic acids. Phospholipids are unlikely to have been critical in prebiotic chemistry, comparatively, and it is almost certain that phosphate biominerals were not part of the origin of life. Next, we investigate routes to forming nucleic acids and similar compounds.

5.8.3 THE PHOSPHORYLATION REACTION

A major goal of prebiotic chemistry is to find plausible, simple routes to forming the molecules that are presumed to have been important in the origin of life on the Earth. It is likely, though not proven, that organophosphates were in the suite of chemicals necessary for the origin of life. In the prior section, we identified the polyphosphates and nucleotides (or sugar/alcohol phosphates) as potential target molecules for prebiotic chemistry. To this end, finding a plausible route to forming these molecules merits closer review.

The phosphorylation reaction is simplified broadly as:

In this reaction, an organic compound, R^1OH , reacts with a phosphate, $R^2PO_3^{2-}$, to yield an organophosphate ($R^1-OPO_3^{2-}$), releasing the attached functional group of the reagent phosphate. This reaction has been left ambiguous, so that it encompasses most sample reactions that have been discussed in the literature (Keefe and Miller 1995; Pasek and Kee 2011; Pasek et al. 2017).

A variety of routes to perform this reaction have been proposed, all of which vary the conditions of this reaction to increase the yield of organophosphate product.

5.8.4 OVERCOMING THE ISSUES OF PHOSPHORYLATION

One major hurdle in the origin of life study is a problem termed “the water problem.” Unquestionably, all life as we know it now requires water. Water is also ubiquitous on the Earth, and water is assumed to have been readily available on the early Earth, due to its ubiquity in the solar system and throughout the universe. In a world where water would be abundant, a challenge arises: many reactions in prebiotic chemistry require a dehydration step. For instance, the formation of nucleotides requires a nucleobase bonding to a sugar that also bonds to a phosphate. Each of these steps releases

water. Furthermore, the polymerization of nucleotides to form nucleic acids occurs via a condensation reaction, as does the assembly of amino acids into polypeptides. Releasing water as a product is unfavorable in an aqueous solvent. This chemistry leads to a conundrum in the study of prebiotic chemistry: how to overcome the so-called “water problem.” To overcome this hurdle, researchers have employed different methods, including the use of condensing agents, high temperatures, reduced phosphorus minerals, and water-free (or low-water-activity) solvents. While researchers have had varying successes using different methods, not all of these routes would have been plausible on the early Earth.

One significant route to promoting phosphorylation reactions is in the use of condensing agents. Condensing agents have been utilized extensively in prebiotic chemistry, and their main action is by making R^1 in Reaction 1 a good leaving group when reacting with OH . Some of the condensing agents extensively studied have been cyanide-containing molecules and condensed phosphates. Dehydration reactions have been demonstrated in aqueous environments aided by the addition of condensing agents. Condensing agents, when added to the milieu, allow for a dehydration reaction to occur in a water solvent. One of the simplest condensing agents, cyanamide, has been demonstrated to aid in the phosphorylation of uridine (Lohrmann and Orgel 1968). Cyanogen has proven successful in aiding the phosphorylation of ribose (Halmann et al. 1969) by using the condensed phosphate trimetaphosphate (TMP). Urea has also been shown to aid in phosphorylation of uridine (Lohrmann and Orgel 1971; Osterberg et al. 1973).

A second route to promoting the phosphorylation reaction is through the addition of heat. In order to drive a condensation reaction in a water solvent, some have utilized heating nucleotides in the presence of phosphates to drive the reaction (Ponnamperuma and Mack 1965). Although this process afforded appreciable yields of nucleosides, the plausibility of the temperature used (160°C) is questionable on the surface of the early Earth and would lead to decomposition of compounds if they are left at these temperatures. Any researcher conducting a thermal experiment must take into account the temperature needed to overcome the activation barrier of the reaction and the temperature limit at which degradation of the products occurs too fast to be prebiotically plausible.

In lieu of activating the organic compound in the phosphorylation reaction (“energizing” R^1), phosphorylation can be promoted by activating the phosphate ion (“energizing” R^2),

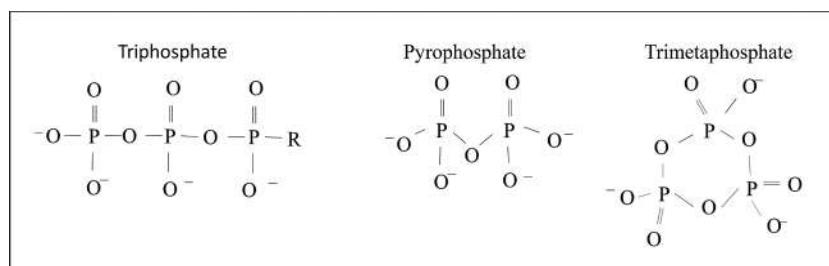

FIGURE 5.8.4 Examples of condensed phosphates that have been used as phosphorylating agents.

through the formation of a condensed phosphate (Figure 5.8.4). A condensed phosphate is one in which the phosphate anion is attached to a second phosphate anion (or more) via the oxygen. Condensed phosphates have been shown to phosphorylate nucleosides with appreciable yields (Chung et al. 1971; Krishnamurthy et al. 1999; Cheng et al. 2002). Trimetaphosphate and cyclic TMP have been utilized extensively by prebiotic chemists as both a condensing agent and a source for phosphorus. Krishnamurthy et al. (1999) demonstrated that TMP, when reacted with ammonia, yields amidotriphosphate, which then was able to phosphorylate glycoaldehyde under mild conditions in appreciable yields. In 2017, the Krishnamurthy group went on to demonstrate that diamidophosphate, derived from TMP, is able to phosphorylate nucleosides, fatty acids, sugars, and amino acids (Karki et al. 2017; Gibard et al. 2018). The results from this study showed not just phosphorylation of a single compound but also oligomerization of nucleotides to nucleic acids.

Although reactive phosphates and polyphosphates are able to provide chemists with a “one stop” route to phosphorylation, the availability of such phosphates outside of a laboratory is questionable. Keefe and Miller (1995) noted that the availability of such reactive phosphates on the early Earth is unlikely or limited to volcanic fumaroles (Yamagata et al. 1991). Hazen (2013), who has provided an extensive study of the mineralogy of the Hadean, has limited phosphate minerals to a few orthophosphate minerals (such as apatite, merrillite, and whitlockite) due to the absence of biology and a young Earth. Therefore, activated phosphate minerals that would have been geologically plausible on the early Earth would only have been found in a few niche settings (such as volcanic fumaroles and meteorites).

A specific route to activating phosphates is in the use of reduced-oxidation-state phosphorus compounds (Pasek and Lauretta 2005; Bryant and Kee 2006; Gull et al. 2015). Reduced-oxidation-state phosphorus species (bearing a formal charge on phosphorus less than the typical +5 oxidation state) and condensed phosphates have demonstrated the ability to phosphorylate organics. Gulick (1955) was the first to propose that phosphite minerals (oxidation state +3) may have been available in the Hadean Earth. He based his theory on a reducing atmosphere; however, the idea was abandoned by geochemists working at the time (Miller and Urey 1959). Pasek and Lauretta (2005) demonstrated that reduced-oxidation-state phosphorus compounds were common to meteorites and reacted to form a variety of intriguing phosphorus compounds. Specifically, the phosphide mineral schreibersite, $(\text{Fe}, \text{Ni})_3\text{P}$, is found in meteorites and may be a source of reactive phosphorus on the early Earth following the Late Heavy Bombardment (Pasek et al. 2013). Pasek and his coworkers demonstrated the formation of condensed reactive phosphates from the reaction of the mineral schreibersite with water. In addition, when these phosphide minerals are added to solutions of organic solutes, phosphorylation occurs at low yields (Gull et al. 2015), likely through a metaphosphate intermediate (Pasek et al. 2017).

The use of alternative solvents in condensation reactions has been studied for decades. This presents our final route to

phosphorylation, which is to minimize the activity of water (the product $\text{R}^2\text{-H}$ in our Reaction 1). Schoffstall (1976) first published a paper on the use of several solvents in place of water, demonstrating that only formamide had the capability of phosphorylating adenosine. This study used phosphate sources with questionable availability in the Hadean: KH_2PO_4 , polyphosphates, TMP, and ammonium phosphates. No phosphorylation was detected with the calcium phosphates. Saladino along with his coworkers also used formamide as an alternative solvent (Costanzo et al. 2007; Saladino et al. 2009, 2015). This research group found that formamide condenses to yield nucleobases and yields phosphorylated nucleotides. They have a caveat: at some point in time, life must have transitioned to a water-based solvent. The rebuttal to this work comes from Bada et al. (2016), arguing that a source of pure formamide on the early Earth was unlikely. Although formamide as an alternative solvent provides promising results, a prebiotic geological environment in which formamide could form and accumulate is problematic. Also, pure formamide is a hygroscopic compound; in water, formamide will rapidly undergo hydrolysis to form formic acid and ammonia.

Other water-free alternative solvents previously studied are the deep eutectic solvents of urea and choline chloride. Gull et al. (2014) showed that adding soluble phosphates and the nucleobases of adenine or uridine to this eutectic mixture results in phosphorylated products. While this method gives promising results in overcoming the challenges of a water solvent, the prebiotic relevance of choline chloride is questionable. More recent work in the use of alternative solvents has been explored by Burcar et al. (2016), using a low water-activity solvent of urea, ammonium formate, and water. Burcar and coworkers found that under mild heating, the three-component solvent mixture forms formamide in the solution and was able to demonstrate phosphorylation of nucleosides within this milieu. The compounds used—urea, ammonium formate, and water—all would have been available on the early Earth under a variety of environmental settings.

The above workarounds to the “water problem” demonstrate that the production of organophosphates in water is problematic, for much the same reason as condensation reactions as a whole are problematic. In this respect, the “phosphate problem” is a subset of the “water problem.” Water is difficult to form as a product of a chemical reaction when it is also the solvent. However, a second issue with phosphates also merits comments: the poor solubility of phosphate under many geochemical conditions and its general geochemical rarity. Thus, the “phosphate problem” bears the aspects of the “water problem” but includes an additional major caveat.

Phosphorus is a minor element in most rocks. On the Earth, 95% of the total abundance of phosphorus is concentrated in the core, giving it a phosphorus concentration of 3000 ppm. Of the remaining sources of phosphorus on Earth, the biosphere contains 6600 ppm phosphorus, while the mantle and crust are relatively depleted in phosphorus, with 90 ppm and 650 ppm, respectively (Pasek et al. 2017). While there are 16 known allotropes of elemental phosphorus (Greenwood and Hershaw 1984), neither any of the allotropes are stable nor do any occur naturally on Earth. Virtually all natural phosphorus

on Earth's surface occurs as a phosphate, with the phosphorus oxidation state of +5. Of the lithospheric (crust + mantle) phosphorus, most of it is in one of the several hundred phosphate minerals—with most of these in the apatite family—and all of the commercially important minerals are in the apatite family. The exceptions to +5 phosphorus are rare and are found either in meteorites or in areas where a high-energy event reduced phosphate minerals or where highly reducing/high-temperature environments have reduced phosphate minerals. The main phosphate group of minerals is the apatite minerals, which can also be classified as orthophosphate minerals, as they bear a phosphate group (PO_4^{3-}). The orthophosphate minerals are mostly bound in rocks and soils, and the availability of phosphorus to an ecosystem is regulated by the dissolution of phosphate minerals available in nearby rocks and soil and any available phosphorus from decaying organic matter.

The phosphorus on Earth is cycled through several primary cycles of varying lengths from weeks to millions of years. There are two rapid biological cycles: one small stable cycle on land and one in water. These fast cycles are intertwined with each other and with the much longer inorganic cycle (Benitez-Nelson 2000). In this respect, the phosphorus cycle differs significantly from the other major biogenic element cycles (C, N, H, O, and S), which all bear a significant volatile process.

5.8.5 WHAT ENVIRONMENTS WORK FOR PHOSPHORYLATION?

Taking the previously described caveats on phosphorus and its reactions, we can posit that there are two main issues associated with phosphorylation: its low reactivity and its low solutional availability. A successful prebiotic chemistry that incorporates solutions to both would be ideal. These concerns highlight that the “phosphate problem” is the “water problem,” coupled with the low solubility and cosmic abundance of phosphorus.

The cosmic rarity of phosphorus is not as obvious from its general geochemical behavior. Phosphorus sinks to the metallic cores of stony planets and asteroids, and it is also concentrated in the thin lithosphere of stony planets (where life likely arose). In contrast, it is mostly absent from the massive middle part of a planet, termed the mantle. The concentration of phosphorus on planetary surfaces is further abetted by the delivery of meteorites to a planet during bombardment (Pasek and Lauretta 2008). Thus, phosphorus is typically present on planetary surfaces and was presumably present on most rocky terrestrial planets. It is unlikely that the issue of abundance is terribly problematic for stellar systems like our own.

We highlighted two primary target molecules as goal molecules for prebiotic phosphorylation: nucleic acids and polyphosphates. Nucleic acids are formed from a combination of HCN/HCONH₂ chemistry for the nucleobases (Oró 1961; Orgel 2004) and from CH₂O chemistry for the ribose (Breslow 1959). The precursors to these compounds do not mix well (Danger et al. 2014), but routes to forming the products from other reactants have been identified (Powner

et al. 2009). Nonetheless, with respect to phosphate, both the nucleic acids and the polyphosphates must form through loss of water at some point in their reaction.

Our target reactions for formation of the organophosphates of interest is one that allowed organics to condense with phosphate. Perhaps, this reaction occurred in the presence of water, or perhaps, it occurred in a solvent where water was a constituent. We propose that the two most likely routes are those that use activated phosphorus sources or those that use non- or semi-aqueous solvents.

Activated phosphate sources must be placed in the context of general geochemical availability. The various geochemically available activated phosphates are rare, with only a few known polyphosphate minerals (see Pasek et al. 2017 for a review). There are no known TMP minerals, and the putative source of polyphosphates in fumaroles— P_4O_{10} —has never been directly observed (Yamagata et al. 1991). However, recently, a few activated phosphorus sources have been identified: the mineral schreibersite, the amidophosphates, and oxidation products of the compounds phosphite and hypophosphite. The mineral schreibersite is common to meteorites, and its oxidation and its ability to phosphorylate are a consequence of its high potential energy under aqueous conditions. The amidophosphates are robust reactants in phosphorylation (Gibard et al. 2018), but an obvious geologic source is yet to be identified. If one were to be found, these might prove to be the best route to making organophosphates. The oxidation products of phosphite and hypophosphite are polyphosphates (Pasek et al. 2008), which are known phosphorylating agents. Recently, a robust route to the formation of phosphite on the early Earth was identified: reaction of phosphate with iron(II) (Herschy et al. 2018).

Non-aqueous or semi-aqueous solvents are a second plausible route to phosphorylation. More generally, environments with low water activity have been shown to definitively produce phosphorylated biomolecules. The problem with non-aqueous solvents is their geochemical production, isolation, and concentration. In contrast, the semi-aqueous solvents may be preferable, given the ubiquity of water in the universe. The chemistry shown by Burcar et al. (2016) is also promising, as their route to phosphorylating organic molecules is coupled to the transformation of the common mineral apatite into the more soluble but rarer mineral struvite. Figure 9.5.5 displays a compilation of the environments conducive to reducing and/or condensing phosphorus species (Figure 5.8.5).

5.8.6 SUMMARY

The element phosphorus appears to have been crucial, due to several key properties that have been outlined in prior work, to the development of life on the Earth. (Westheimer 1987; Pasek et al. 2017). Some of the strongest evidences of a primordial phosphorus biochemistry are demonstrated by the fact that phosphate-based metabolism and nucleic acids are common to all known life. While phosphate-based membranes exhibit enhanced fitness, compared with the fitness of simpler fatty-acid membranes, and may have been present early on as well, they are less of a requirement for life than nucleic acids and nucleotide phosphates.

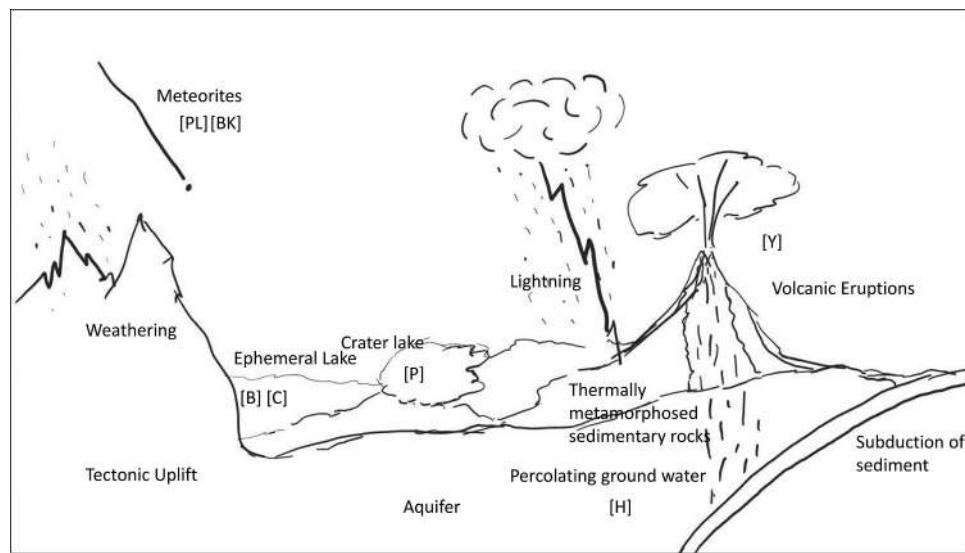

FIGURE 5.8.5 A schematic of the environments of phosphorylation. The key environments include phosphate-reacting environments, such as volcanic fumaroles, as identified by Yamagata et al. (1991), denoted with [Y], ephemeral lakes with non-aqueous solvents such as formamide (Costanzo et al. 2007, denoted with [C], and semi-aqueous solvents including urea-ammonium formate-water mixtures (Burcar et al. 2016, denoted [B]). In addition, the oxidation of reduced phosphorus compounds produces polyphosphates capable of forming organophosphates and likely occurred in lakes, especially crater lakes (denoted [P] for Pasek et al. 2008). Such a reaction requires reduced phosphorus sources such as meteorites (Pasek and Lauretta 2005 and Bryant and Kee 2006, denoted [PL] and [BK], respectively), lightning, and redox reactions occurring within sedimentary rocks (Herschy et al. 2018, denoted [H]).

To this end, the molecules likely needed by prebiotic chemistry were simple alcohol phosphates and polyphosphates akin to nucleic acids and nucleotide triphosphates present in life today. The formation of these molecules has been demonstrated in reactions that include high-chemical-energy condensing agents and polyphosphates formed by drying and the oxidation of reduced-oxidation-state phosphorus compounds, as well as in solutions that bear significant non-aqueous components or those completely water-free. Plausible geochemistry suggests that polyphosphates and semi-aqueous solvents may be the best routes to forming organophosphates. If so, the challenge of organophosphate production may be approaching a solution.

5.9.1 INTRODUCTION

Silicon (Si) is the second most abundant element in the Earth's crust (ca. 27%) after oxygen, the third most abundant element in the Earth as a whole (ca. 15%) after iron and oxygen, and the sixth most abundant element in the Milky Way Galaxy (ca. 0.065%), in which hydrogen and helium are the most abundant (Wikipedia 2018a). With an atomic number of 14, it is located just below carbon in the Periodic Table in the 14th column (formerly Group 4). Carbon and silicon have similar s- and p-electron structures, whereby the outer electrons comprise two s electrons and two p electrons. In addition, silicon has available empty d orbitals. The four outer electrons in both cases are capable of hybridization to form four equivalent sp^3 orbitals, enabling the formation of four bonds with a tetrahedral geometry, as in the structures in Figures 5.9.1 and 5.9.2. The ligands on carbon and silicon are illustrated as hydrogen, but many other elements can serve as well, such as carbon, silicon, oxygen, nitrogen, sulfur, and the halogens.

With four bonding opportunities and a plethora of potential bonding partners, both carbon and silicon can produce a wide variety of simple and complex compounds. In particular, they may bond repeatedly with like-functionalized atoms to form linear chains of molecules. Figure 5.9.3 illustrates polymethylene (more commonly, polyethylene), a linear polymer composed of methylene units, $-(CH_2)_n-$, and Figure 5.9.4 illustrates poly(dimethylsiloxane), a linear polymer composed of dimethylsiloxane units, $-(SiMe_2O)_n-$. The structures are illustrated with three units of the monomer building block, which extends further in either direction. The functionalities were chosen because they represent possibly the commonest and simplest such polymeric materials. Nonetheless, the analogous carbon polymer for siloxanes exists as polyoxy-methylenes [or polyacetals, such as $-(CH_2O)_n-$], as does the analogous silicon version of polyethylenes as polysilanes, such as $-(SiMe_2)_n-$. The structures may be augmented by replacing one or more side ligands (H in Figure 5.9.3 or Me in Figure 5.9.4) with additional chains of the same monomer to yield branched polymers. Alternatively, the ends of the polymers may be brought around and bonded to each other

to form molecular rings, as in Figure 5.9.5 for six methylene units (cyclohexane) or in Figure 5.9.6 for three dimethylsiloxane units (hexamethyltrisiloxane).

With just these three structural motifs (chains, branching, and rings), together with replacement of the ligands with other organic groups (ethyl, hexyl, phenyl, vinyl, and so on) and atoms (oxygen for ethers, nitrogen for amines, and so on), the potential exists for building millions of different organic (carbon-based) or organosilane (silicon-based) molecules.

Since carbon is the core element for the molecules of life that exist on Earth, it seems logical that silicon should be able to serve as the core element for a parallel biochemistry for what would be called silicon-based life. This idea goes back at least to the late 19th century, when the science fiction writer H. G. Wells wrote “One is startled towards fantastic imaginings by such a suggestion: visions of silicon-aluminium organisms—why not silicon-aluminium men at once?—wandering through an atmosphere of gaseous sulphur, let us say, by the shores of a sea of liquid iron some thousand degrees or so above the temperature of a blast furnace” (Wells 1894). The geneticist Haldane (1927) speculated more specifically that silicon-based life-forms would be constructed of silicates. A number of recent writers have considered the possibilities of life based on silicon and generally found the concept unlikely (Dessy 1998; Rampelotto 2010; Schulze-Makuch 2013; Darling 2014; Jacob 2016; Wikipedia 2018b). Certain characteristics of silicon chemistry are distinct from carbon chemistry, rendering silicon an unlikely or even impossible core element for life.

5.9.2 POLYSILANES AND CARBOSILANES

Polysilanes are the silicon analogues of polymethylenes (Figure 5.9.7), and polycarbosilanes contain a mixture of carbon and silicon in the main and side chains. Until about 1960, only short-chain silanes were known, but a flowering of polysilane chemistry soon thereafter resulted in the development of a robust chemistry of even long-chain polysilanes, along with branched and multiply branched (dendritic) polysilanes (West 1989; Lambert et al. 2003). Some authors have touted polysilanes as a possible basis for life, since they are

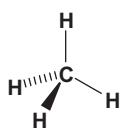

FIGURE 5.9.1

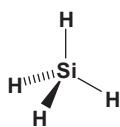

FIGURE 5.9.2

FIGURE 5.9.3

FIGURE 5.9.4

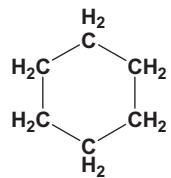

FIGURE 5.9.5

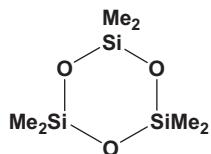

FIGURE 5.9.6

FIGURE 5.9.7

analogous to long-chain hydrocarbons (paraffins) in terms of branching and complexity and their d orbitals permit some electronic properties reminiscent of unsaturation (double bonds). Nonetheless, a number of characteristics militate against polysilanes as a basis for life.

In general, bonds between two silicon atoms and between silicon and carbon (in polysilanes and polycarbosilanes, respectively) are thermodynamically and kinetically less stable than carbon-carbon bonds. The simplest silane ligand is the hydrogen atom, so that, for example in Figure 5.9.7, Si—Me ligands are replaced by Si—H. The Si—H bond is somewhat weaker than the C—H bond, for example, 95 kcal mol⁻¹ in Me₃SiH and Et₃SiH, 92 kcal mol⁻¹ in SiH₄, and 84 kcal mol⁻¹ in (Me₃Si)₃SiH (Fleming et al. 1997), compared with a typical C—H bond dissociation energy of 104 kcal mol⁻¹ in methane (CH₄) (Blanksby and Ellison 2003). Moreover, the Si—H bond is far more reactive than the C—H bond, as it is sensitive

to hydrolysis, oxidation by numerous reagents, and reduction by free radical reagents (Brook 2000a). In general, the C—Si bond (89.4 kcal mol⁻¹ in Me₄Si) is weaker than the C—C bond (90.4 kcal mol⁻¹ in CH₃CH₃), and the Si—Si bond is still weaker (80.5 kcal mol⁻¹ in Me₃SiSiMe₃ and 74 kcal mol⁻¹ in H₃SiSiH₃) (Corey 1989). The Si—C bond reacts with oxidizing reagents (C—Si → C—O), nucleophiles (C—Si → C—C), and electrophiles (C—Si → C—H, C—halogen, C—C) (Brook 2000b). Disilanes and other molecules containing the Si—Si bond are sensitive to electrophilic cleavage and to photolysis (West 1989). Thus, organosilanes of all types are less stable and more reactive than hydrocarbons and would be less practical as a platform for a biochemistry.

Possibly, even more devastating for a potential silicon life-form is a serious structural deficit. Silicon engages in only weak multiple bonds. In contrast to the robust chemistry of alkenes and aromatics in organic chemistry, analogous structures did not even exist in organosilicon chemistry until the last decades of the 20th century, and the molecules proved to be unstable and highly reactive. The first stable, crystalline molecules containing the C=Si and Si=Si bonds were not reported until 1981 (Raabe and Michl 1985). The poor stability of unsaturated organosilicon compounds results primarily from poor overlap of the p orbitals, so that the resulting π bonds are consequently weaker. In the C=C double bond and other unsaturated organic compounds, the single (σ) bond is augmented by a second bond involving overlap between two parallel p bonds to form the π bond, as in Figure 5.9.8. There are two causes for the weakness of π bonds in C=Si systems. First, the C—Si bond is significantly longer than the C—C bond because of the larger atomic radius of silicon. Second, whereas the p orbitals on carbon are from the second row (2p), those on silicon are from the third row (3p). Thus, there is a misfit between parallel 2p and 3p orbitals, as in Figure 5.9.9. Both factors allow less effective p-p overlap that constitutes π bonding. Although the fit theoretically is appropriate in Si=Si bonds, the bond length between the Si atoms is larger (C—C 1.54 Å, C—Si 1.90 Å, and Si—Si 2.34 Å) (Corey 1989). Over greater distances, p orbitals overlap less and form weaker π bonds.

The absence of available unsaturation in organosilane chemistry is highlighted by consideration of the three principal classes of molecules in our (carbon-based) biochemistry. (1) Proteins and their amino acid constituents provide a structural basis for life, catalysis of the reactions of life,

FIGURE 5.9.8

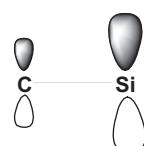

FIGURE 5.9.9

transportation of molecules within cells, various aspects of reproduction, and many other activities. Proteins comprise linear and branched chains of amino acids (Figure 5.9.10) that are connected by the peptide linkage (Figure 5.9.11), in which peptide resonance is manifested by the two illustrated resonance forms. Amino acids and both resonance forms of the peptide unit contain unsaturation, so that silicon analogues are prohibited. (2) Carbohydrates comprise monomeric sugars that can catenate to form very large molecules. The building block is the polyhydroxy (Figure 5.9.12), in which the number n varies, 4 for hexoses and 3 for pentoses. The end functionalities normally react to generate a cyclic form, which is illustrated by β -glucose (Figure 5.9.13). Carbohydrates can serve as structural components (cellulose and chitin), energy storage (glycogen and starch), energy transfer (ATP), the backbone of polynucleotide genetic material, and in many other functions. The aldehyde unit in Figure 5.9.12 is a key structural feature, which cannot exist in silicon analogues. (3) Nucleic acids are the building blocks of DNA and RNA (the critical molecules in reproduction), as well as important components of energy transfer (ATP) and other biochemical functions. Nucleic acids contain three components: a pentose sugar, a phosphate side chain, and a nitrogen heterocyclic side chain. Figure 5.9.14 illustrates a nucleic acid with thymine as the heterocycle and ribose as the sugar (thymidyllic acid). Polynucleic acids such as DNA and RNA can be constructed by reaction of the hydroxy group of the $-\text{CH}_2\text{OH}$ unit with a free hydroxy group on the phosphate unit. The nucleotide repeating unit contains not

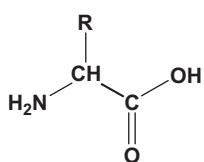

FIGURE 5.9.10

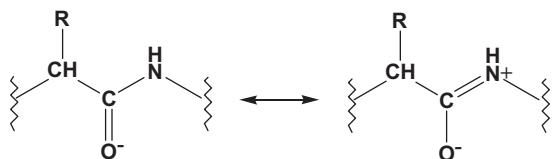

FIGURE 5.9.11

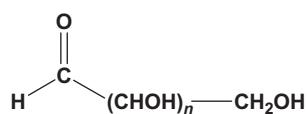

FIGURE 5.9.12

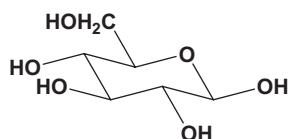

FIGURE 5.9.13

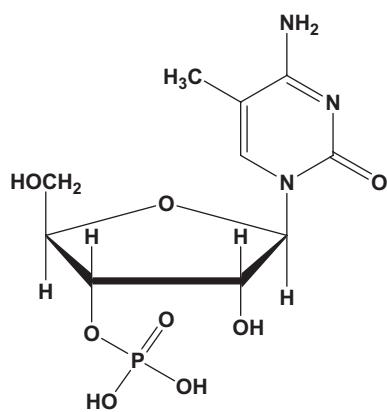

FIGURE 5.9.14

only a carbohydrate, in which the aldehyde function is necessary, but also the heterocycle, which contains unsaturation. Thus, silicon analogues are prohibited again.

These three core functionalities of biochemistry contain unsaturation and cannot admit a silicon parallel. Similarly, most vitamins are excluded from having silicon analogues. The remnant biochemistry that involves only saturated molecules would comprise paraffins (waxes), fats (but not fatty acids), and most steroids (but their earthly biosynthesis from unsaturated molecules such as squalene obviates their silicon analogues). It is extremely doubtful that the biochemistry required to attain life could be constructed from molecules lacking unsaturation.

5.9.3 POLYSILICATES

One thing silicon has going for it is strong bonds to electronegative elements such as oxygen, nitrogen, and fluorine. The Si—F bond at 135 kcal mol⁻¹ is one of the strongest known, and the Si—N bond at 100 kcal mol⁻¹ is about 20 kcal mol⁻¹ stronger than the Si—C bond. The Si—O bond at 128 kcal mol⁻¹ is nearly 40 kcal mol⁻¹ stronger than the C—O bond (Corey 1989). These properties derive primarily from the highly electropositive nature of silicon, so that bonds with highly electronegative elements have a strong, stabilizing polar component ($\delta^+\text{Si}—\delta^-\text{O}$). When silicon is fully oxygenated, SiO_4 , not only are the bonds extremely stable but they can also propagate fourfold from Si and twofold from O to form large, three-dimensional networks, known as silicates or polysilicates. When the Si—O bonds are diluted with Si—C bonds, the systems are still quite stable. The class of compounds called silsesquioxanes has the core silicon unit of SiO_3R , and silicones (polysiloxanes) have the core unit of SiO_2R_2 , as in Figure 5.9.4. The repeating unit and overall molecular formula of silicones is R_2SiO , which is analogous to the formula of ketones, $\text{R}_2\text{C}=\text{O}$, so Kipping coined the term *silicones* by analogy.

The monomeric form of the silicon analogue of carbonyl compounds has the structure $\text{R}_2\text{Si}=\text{O}$, a molecular component that has defied synthesis despite its deceptive simplicity. Thus, no silicon analogues of aldehydes, ketones, esters, or

carboxylic acids can exist, all molecules central to our biochemistry. The silicon analogue of carbon dioxide, O=Si=O, also cannot exist, so that respiration, as employed by both plants and animals, would be impossible. Silicon dioxide is unstable with respect to polymerization, which leads to three-dimensional silicate matrices. The wide abundance of silicon and oxygen on Earth and other rocky planets results in large amounts of silicate minerals as a sort of thermodynamic end product. The overall molecular formula of pure silicates is SiO₂, so that sand, for example, is often said to have that structure, in essence the polymerized analogue of CO₂. Moreover, silicate minerals are inert to reaction with water, whereas the equilibrium between CO₂ and H₂O is fundamental to respiration in most life-forms. Thus, the strong Si—O bond militates against the existence of common silicon structures in either the gas or the liquid phase. In a highly reductive atmosphere such as H₂, the silane functionality, as in SiH₄, can exist but, as the analogue of methane CH₄ in the carbon universe, offers little ability to carry out the necessary functions of life that have already been enumerated.

The question of chirality, or handedness, is central to life, because it allows the development of highly specific reactions. These terms refer to the nonsuperimposability of mirror images. When molecules have that property, the mirror-image forms, or enantiomers, are distinct molecules that can have highly specific properties. The most common structure that generates nonsuperimposability is the tetrahedral unit with four different ligands, CWXYZ or SiWXYZ (Figure 5.9.15). The chirality of both amino acids (Figure 5.9.10) and carbohydrates (Figure 5.9.13) is key to their highly specific functions. Although silicon allows the same sort of specificity in theory, in practice, chiral silanes are extremely rare, as they apparently lack the functionality that permits separation of the enantiomers.

Silicates, however, have another property that may permit chiral environments. Even if the molecules themselves are unlikely to form such materials, there is evidence that silicate crystalline lattices themselves may exhibit chirality, so that their surfaces might serve as catalysts for the formation of chiral carbon compounds (Washington 2000; Hazen and Sholl 2003). Here, silicon is not providing the chemical building blocks for life but may be fulfilling an important role in the formation of carbon-based biomolecules.

Silicon also provides an important structural role in some of Earth's organisms. Many of the organismal structural elements are carbon-based (organic). Thus, the polycarbohydrate cellulose is the main component of the cell walls of green plants and algae; the protein collagen is the main component of animal connective tissue such as bone and tendons; the protein keratin comprises hair, horns, claws, hooves, and nails;

and the protein cartilage is the main component of the exoskeleton of arthropods and insects and the scales of fish. Many structural elements also are inorganic, including calcium carbonate in sea shells, pearls, snails, and eggs and the phosphate mineral hydroxyapatite in bones and teeth. In addition to these carbon- and phosphorus-based inorganic structural elements, silicates are structurally important for a number of organisms. The shells of diatoms and radiolarians and the spicules of sponges are composed of silica. Silica occurs as a structural element of many plants in the form known as phytoliths, for example, in many grasses, conifers, horsetails, and rice husks. The wide presence of silica in organisms implies that there is a biochemistry for its uptake from inorganic silicate in the soil or water.

5.9.4 SILICATE AS A PREBIOTIC MEDIATOR

The development of life required the existence and availability of the biomolecules such as carbohydrates, proteins, and nucleic acids. Miller (1953) reported experiments based on simple reagents and mild conditions that produced essential amino acids. Miller and Urey (1959) followed up with methods to produce other types of biomolecules. Two groups described how the formose reaction can generate carbohydrates from small aldehydes (Gabel and Ponnamperuma 1967; Reid and Orgel 1967). Unfortunately, this reaction is carried out normally under highly basic conditions that decompose the carbohydrates as soon as they are formed. Lambert et al. (2010) found that sodium silicate improves the yields of carbohydrates in the formose reaction. As the sugars are formed, they react with silicate to form sugar silicates, which are stable to the basic conditions. The sugars not only are sequestered in a stable form but also are selected according to structure and stereochemistry. The high pH of the silicate-mediated formose reaction might be a drawback, because there are few environments with such characteristics. Lambert and Gurusamy-Thangavelu (2015) also have demonstrated that natural aluminosilicate clays can simulate the effects of strong base at nearly neutral pH, whereby the clays under base-free conditions produce carbohydrates that are not formed without the clay, particular at temperatures above 80°C.

5.9.5 SUMMARY

Silicon is a poor platform for the molecular basis of life, which requires structure, metabolism, growth, adaptation, response to stimuli, and reproduction. Bonds involving silicon are relatively weak compared with carbon, except in relation to highly electronegative elements. Highest structural variability is favored with higher valences, as supplied by tetravalent elements. Concatenation of silicon with other tetravalent elements, including carbon and other silicon atoms, produces weak and highly reactive Si—Si and Si—C bonds, in contrast with the stability of C—C bonds. Moreover, silicon produces exceedingly weak double bonds (Si=C, Si=Si, Si=O), unknown in nature on Earth, which form the heart of almost

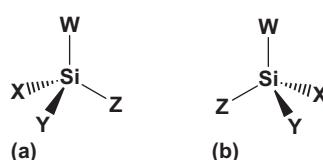

FIGURE 5.9.15

all biomolecules, including carbohydrates, proteins, nucleic acids, and fatty acids. The silicon analogue of carbon dioxide does not exist, as it is unstable with respect to polymerization to polysilicates, which in general lack functionality on which life might be based.

Although organisms that could be characterized as being silicon-based cannot exist, silicon can play important biological roles within a carbon-based biology. The stability and strength of silicate solids make them suitable to serve as biological structures, as in phytoliths and rice husks. The three-dimensionality of aluminosilicate clays can create chirality, which is useful to improve reaction specificity. Silicates and aluminosilicates can sequester carbohydrate molecules, as formed in the formose reaction, which otherwise are unstable and subject to decomposition. Thus, silicon has biological roles to play but cannot be the central element of life.

6.1.1 INTRODUCTION

In this chapter, we will discuss the role of chemical transitions from one pre-living state to another. We will focus on the popular paradigm of the RNA World as a model system to understand the stages that primordial chemical systems went through to become simple, and then more complex, life. In particular, we will survey the evolutionary pressures that populations of RNA went through to become more life-like.

6.1.2 RNA AND RIBOZYMES

RNA, or ribonucleic acid, which refers most often to the 3'-5'-linked single polyanionic chains of β -D-ribonucleotides, is a water-soluble macromolecule that plays a central role in contemporary metabolism. It is typically, but not always, synthesized in a transcription reaction by the protein enzyme RNA polymerase from a complementary DNA template. This

molecule turns out to hold many clues for the origins of life (OoL) on the Earth and elsewhere in the universe.

6.1.2.1 THE RNA WORLD HYPOTHESIS

The RNA World hypothesis was introduced in [Section 1](#) of this handbook, and recent advances in prebiotic chemical pathways to RNA and the features of RNA that enable its reproduction and enzymatic activity are covered in [Sections 5](#) and [6](#) of this handbook. This hypothesis postulates that RNA, or something very chemical similar, was the first informational polymer to acquire the characteristics most commonly attributed to life, namely evolution and concerted metabolism. While the RNA World takes many forms, and the simplest view—that an RNA molecule emerged spontaneously from a pre-biotic milieu, with the ability to self-replicate—has been challenged on many fronts (*e.g.*, Shapiro 1987; Lehman 2008; Branscomb and Russell 2013; Hud et al. 2013), the hypothesis undeniably

serves as a scaffold to begin to make and test hypotheses about how life could originate from a molecular perspective. The RNA World's popularity in this regard derives from four very powerful observations: (1) that ATP is not only the energy currency of the cell but also a fragment of RNA; (2) that protein enzymes often depend on ribonucleotide-like cofactors for activity (White 1976); (3) that the core of the ribosome where polypeptide synthesis occurs is composed entirely of RNA (Nissan et al. 2000); and (4) that RNA can be a catalytic molecule and hence can simultaneously possess both a genotype and a phenotype (Kruger et al. 1982; Guerrier-Takada et al. 1983; Gilbert 1986). It is the last of these four points on which we will elaborate in this chapter, with an eye toward understanding how evolutionary transitions from one state to another are key phenomena to describe and understand.

6.1.2.2 CATALYTIC RNA

One of the greatest surprises in biology in the latter quarter of the twentieth century was that RNA could be a catalyst. Prior to the discoveries of Cech and Altman that RNA could speed up the rates of a chemical reaction, RNA was thought by many to serve an intermediary role between DNA and proteins. Starting with the discoveries of self-splicing introns (Kruger et al. 1982) and with the catalytic ability of the RNA portion of RNase P (Guerrier-Takada et al. 1983), we have now discovered 13 distinct classes of catalytic RNAs throughout biology. The search is underway continually for additional catalytic RNAs, termed ribozymes, and by the time this handbook is published, there may, in fact, be more than 13 known classes. The majority of these classes of ribozymes catalyze a single type of bond conversion, phosphor-transfer reactions (including bond cleavage). However, the ribosome speeds up the rate of peptide bond formation by many orders of magnitude over the uncatalyzed rate by exploiting an anhydrous environment in its RNA core. Thus, even in a biological setting, RNA has evolved to catalytically make and break substrate chemical bonds. In the laboratory, the repertoire of RNA catalysis has been extended to myriad chemical chemistries, including the Diels-Alder reaction, aminoacylation, and porphyrin metalation, just to name a few (Chen et al. 2007). Moreover, hundreds of ligand-specific RNAs have been selected as binding molecules; these are termed aptamers. These observations suggest that RNA has a latent ability to serve as a broad-spectrum catalyst, even if the majority of biological catalysis was eventually subsumed by protein enzymes. A major question remains: How this and other prebiotic transitions were accomplished by geochemical and evolutionary mechanisms?

6.1.3 TRANSITION FROM A CHEMICAL WORLD TO A BIOLOGICAL WORLD

Life on the Earth formed some 4.0–4.4 billion years ago (see Chapter 4.6) and was initially, by definition, a purely chemical process. In the sections that follow, we will discuss some

of the key transitions from chemistry to biology—however defined—that must have taken place.

6.1.3.1 PREBIOTIC SCAFFOLDS AND THE EMERGENCE OF COMPLEXITY BY A PREBIOTIC PROCESS

The formation of relevant chemicals in the universe and their delivery to the early Earth were necessary events during the formation of the Earth and during the Hadean Eon (4.6–4.0 Gya). The tiny subset of chemical systems that could have led to life must have been both non-equilibrium systems and those capable of possessing some form of evolutionary character. The former requirement has been discussed at length (Pross 2012; Branscomb and Russell 2013). The latter, though, is often equated to Darwinian processes that are apparent in cellular life but not so clearly defined in chemical collections. Wu and Higgs (2009) have made inroads in reconciling this dichotomy by delineated “dead” and “living” states for nascent life. Similarly, Nowak and Ohtsuki (2008) describe “pre-life” by a system of monomers that can polymerize to produce an informational and evolvable polymer. In this chapter, we amalgamate both of these ideas and others into two simple diagrams that indicate a sharp transition from the many unsuccessful attempts to make this transition to the single successful example that we know of with extant terran life. First, we trace the rate of energy consumption (power density) of the living or pre-living system as a function of time it takes for the system to reproduce itself (Figure 6.1.1). A sharp transition at the OoL would occur when the system is able to capture local energy and successfully direct that into reproduction, rather than random dissipation as heat. One of the more remarkable facts about biology is that the power density of a bacteria is approximately equal to that of a jet turbine engine. Stated simply, the free-energy flux across a bacterial surface in exponential growth corresponds to a power density within the cell of about 0.2 MW/m³ (Lane and Martin 2010). When information can capture energy, life can begin.

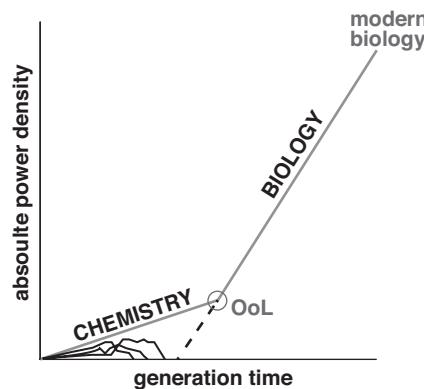

FIGURE 6.1.1 The chemistry-to-biology transition. The green lines represent the ultimately successful lineage leading to extant life. The black lines represent failed lineages that did not make the transition: chemical systems that did not acquire evolvable informational capacity. The dotted line represents an extrapolation of a “biological system” down to zero cells.

6.1.3.2 POPULATING SEQUENCE SPACE WITH FUNCTIONAL RNAs

A second way to visualize the chemistry-to-biology transition is to focus on complexity. Using the RNA World as a model, the embodiment of evolvable information in polymeric form was a key component of the transition discussed earlier. We have already posited that this transition was coincident with a parallel changeover from an analog characterization of the chemical state to a digital one (Baum and Lehman 2017). In the analog stage, the chemical nature of the backbone was the dominant feature; selection would have taken place between polyanions and polycations (Benner 2016); between ribose and its alternatives such as threose, arabinose, and even pentides; and between linear chains and branched chains (Eschenmoser 1999). At this stage, information storage would have been poor, as the information content (*i.e.*, the reduction in ambiguity compared to random conformations) would have been minimal. With the inclusion of side chains with specific hydrogen bonding patterns, a later, digital stage of pre-living systems could arise (Benner 2016; Baum and Lehman 2017). As side-chain complementarity (*e.g.*, A with U and G with C) became more defined with a selection process occurring among possible side chains (Krishnamurthy 2015), then the informational capacity of the polymer could sharply improve, leading to a more rapid cycle of selection. A relationship between polymer length and complexity would have iteratively fed back on one another (Figure 6.1.2). Eventually, some type of template-directed RNA replication catalyst came into being. This chemical innovation would have been the canonical point at which biology, with exponential replication and Darwinian-type selection, could fully explode. However, there was likely a previous period during which the broad-scale shuffling of blocks of information, via recombination, was a dominant means of creating diversity prior to the emergence of genomes capable of exponential growth with mutation and selection *per se* (Lehman and Unrau 2005; Lehman 2008; Pesce et al. 2016).

Once some mechanism for template-directed polymerization came into existence, then Darwinian evolution could firmly take hold. For such evolution, a system of inheritable point mutations, with intervening selection and amplification, is necessary (cf. Joyce 1989). For polymerization, either an RNA replicase (Johnston et al. 2001; Cheng and Unrau 2010) or a protein RNA polymerase would be necessary. Note that the most effective RNA replicase ribozymes today are laboratory-derived evolutionary derivatives of a particular class of ligase ribozyme (Zaher and Unrau 2007; Mutchler et al. 2015; Samanta and Joyce 2017) (Figure 6.1.3). With any such polymerase, errors would accrue during the copying of any RNA, and those errors would generate genetic diversity on which natural selection could act. This stage of life, however, could be either encapsulated as cells (or protocells) or still be free in a solution. Theory predicts, from many points of view, that replication would be far more efficient—and be able to circumvent

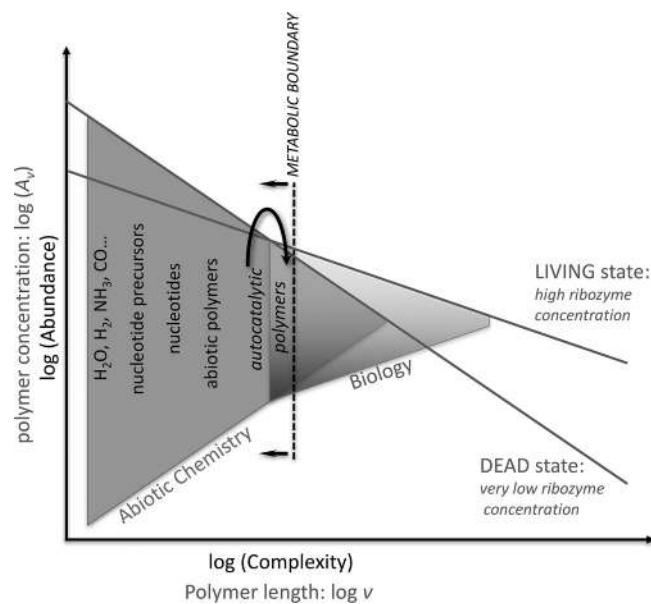

FIGURE 6.1.2 Metabolic need drives the crystallization of complex information-rich polymers at the transition from prebiotic chemistry to biology. The black vertical line/text defines a metabolic boundary where ribozymes of high complexity (light grey triangle) consume abiotically available compounds (dark grey triangle), driving the emergence of a complex biological metabolism that consumes ever-simpler compounds. Over evolutionary time, the metabolic boundary moves to the simplest compounds, as reflected by modern metabolism. In green, two views of the line between non-life and life are overlain, in which the living and the dead states display distinct relationships between polymer abundance and length. (From Wu, M. and Higgs, P.G., *Astrobiology*, 11, 895–906, 2011.)

Eigen's error threshold and escape parasitic extinction if encapsulated, and thus, it is likely that life would have been cellular at this point. This was recently demonstrated experimentally by Matsumura et al. (2016). In any event, a key realization is that multi-level selection would now be operating.

Both individual RNA sequences and the populational context in which they exist and “segregate” as alternative alleles would exert influence over which sequences would possess a fitness advantage and hence be reproduced disproportionately greater than others. RNAs at this stage of evolution would squarely fall within the quasispecies concept (Eigen and Schuster 1978). Here, individual genotypes would flounder or flourish depending on the distribution and frequencies of closely related sequences. An entire cloud of similar sequences would be moving through the space of all possible sequences (see Sections 6.1.4 and 6.1.5), with interrelated fates. This has been shown empirically for RNA viruses (Domingo et al. 2006), for ligase ribozymes evolving *in vitro* (Díaz Arenas and Lehman 2010), and for aptamers (Jiménez et al. 2013). These clouds of similar sequences set the stage for the mechanisms by which networks of RNAs interact, to be considered in the following sections.

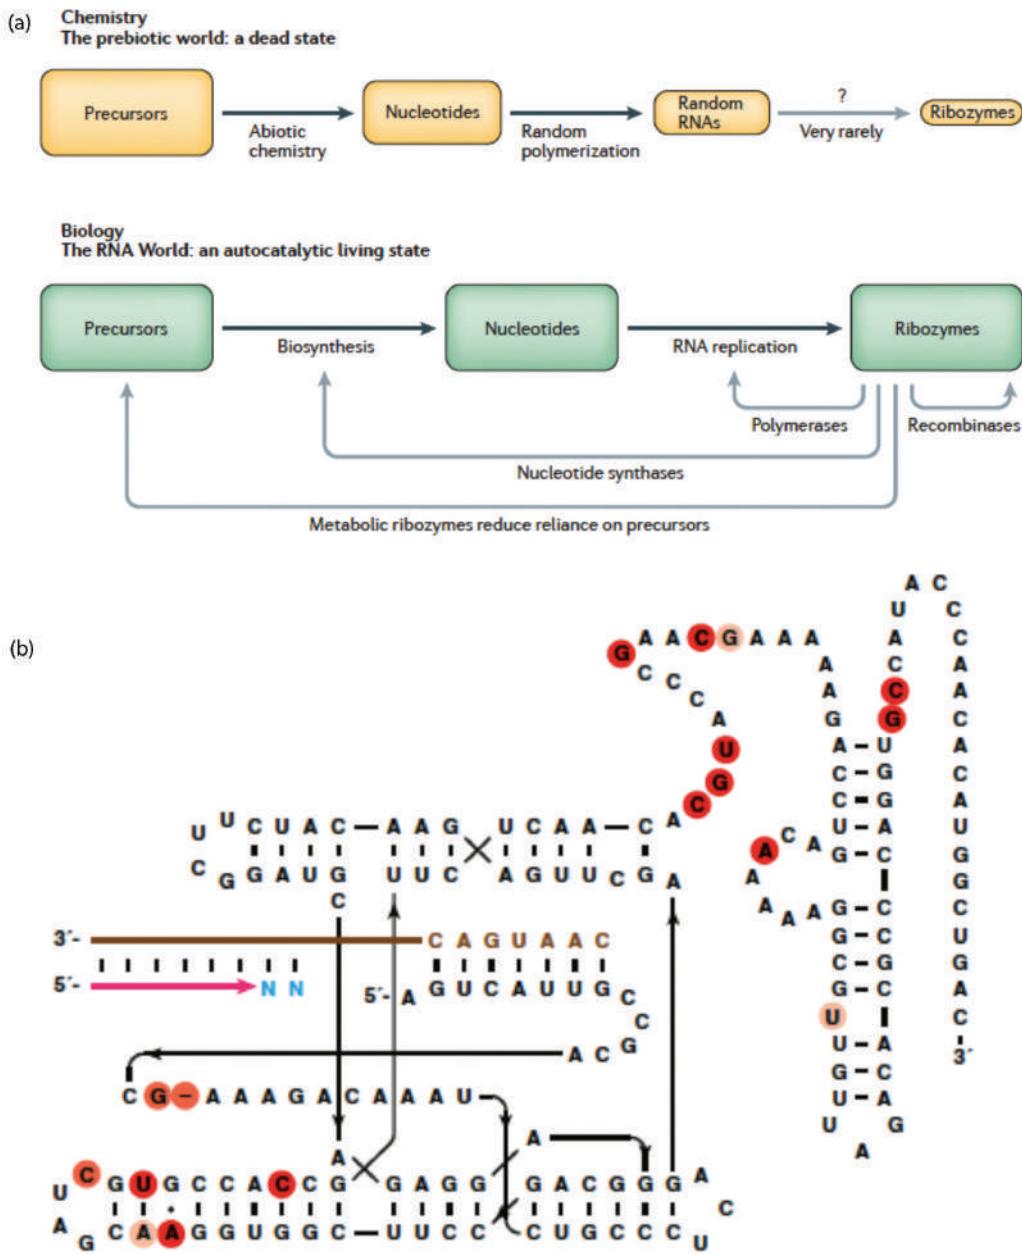

FIGURE 6.1.3 (a) The transition to biological catalysis and metabolism. The abiotic synthesis of high-diversity random polymers rarely leads to high-functioning ribozyme polymers. Once ribozymes are capable of sustaining evolution (shown here as recombinases and polymerases), metabolic processes capable of using prebiotic precursors become essential. (From Higgs, P.G., and Lehman, N., *Nat. Rev. Genet.*, 16, 7–17, 2015.) (b) The most efficient known (laboratory-derived) RNA polymerase ribozyme is derived from the class I ligase ribozyme. This ribozyme can catalyze the polymerization of dozens of nucleotides onto the 3' end of a primer (shown in pink). Nucleotides in circles are those that were mutated relative to a less efficient version of the ribozyme. (From Horning, D.P. and Joyce, G.F., *Proc. Natl. Acad. Sci. U.S.A.*, 113, 9786–9791, 2016.)

6.1.4 RNA WORLDS: THE POSSIBLE AND THE PROBABLE

6.1.4.1 IN VITRO SELECTIONS—THE POSSIBLE RNA WORLD

Ribozymes filled in a missing link to life's origins, because they provided both the heritable properties of DNA and the catalytic properties of proteins. RNA, it was proposed, could greatly

simplify origins, because only a single type of macromolecule needed to rise from the prebiotic soup (Crick 1968; Orgel 1968). While the discovery of ribozymes was quite serendipitous, it quickly became intentional. Researchers began devising creative strategies to pull RNA sequences with specific catalytic properties out of large random pools of RNA oligonucleotides. The initial goal, it seemed, was simply to see the extent of chemical reactions that could be catalyzed by RNA molecules.

Some of these research goals had biotechnology motivations, but many *in vitro* selections were aimed at reactions that seemed critical for RNA-based life, such as the chemistry required for RNA replication and metabolic reactions (e.g., Figure 6.1.3b). This body of work has demonstrated that RNA can catalyze a plethora of chemical reactions, that even short RNA sequences can provide considerable catalysis, and that RNA sequences with catalytic capacity are not exceedingly rare within random pools of RNA sequences (Chen et al. 2007; Joyce 2007). These *in vitro* selected ribozymes have resoundingly demonstrated that complex chemistry is possible with RNA alone.

6.1.4.2 THE PROBABLE RNA WORLD: DISTRIBUTION AND CONNECTION OF FUNCTIONS

To truly evaluate the RNA World scenario, we need to ask not only *What is possible?* but also *What is probable?* The probability of finding a given RNA function in a random pool of sequences remains difficult to determine and depends on several factors such as the complexity of the structure, the stringency of the selection, and the length and complexity of the random pool (Sabeti et al. 1997; Legiewicz et al. 2005). Nevertheless, the data that does exist suggest that all given ribozymes exist in a very low frequency in a random pool, with sufficient length diversity. Obviously, a ribozyme of a particular length cannot exist in a pool that only contains RNA shorter than this length, although some combinations of small functional motifs can be present in only a zeptomole of material (Knight and Yarus 2003). Nevertheless, the emergence and coalescence of many different ribozymes simultaneously from a prebiotic soup could be just as unlikely as the simultaneous emergence of primitive ribosomes and DNA polymerases, thus negating the perceived advantage of RNA as a simpler route to life. An alternative scenario is that crude RNA reproduction emerged first, in some form, and then evolution took over. Evolutionary innovations, defined as new forms and functions that help survival or replication, can then occur through the forces of evolution, namely replication with mutation, drift, gene flow between populations, and selection. Under this scenario, it becomes critical to understand how new RNA functions emerge through the process of evolution. This rest of this section will review the research that has contributed to our understanding of this topic and will describe future research directions that are still needed to evaluate the role of evolutionary innovations of RNA in life's origins.

6.1.4.3 SEQUENCE SPACE AND FITNESS LANDSCAPES

The concept of sequence space (SS) is useful for discussing evolutionary innovations. For our discussion here, we will define sequence space (SS) as the space of all possible RNA nucleotide sequences. Each unique sequence of nucleotides occupies a discrete point in this space. While the space is of high dimension and is discrete because there can be no partial mutations, every point in SS has a set of nearest neighbors that allows a sequence to move through sequence space in a pseudo-continuous fashion. For RNA of length $n = 10$, every point in SS has $3n = 30$

neighbors, because each position can be changed to three different nucleotides via point mutation. When insertions and deletions are considered, a total of $5n + 4 = 54$ nearest neighbors exist for this particular example. The size and dimensionality of SS increases exponentially as longer RNA molecules are considered. For even modest-sized RNA molecules, such as length $n = 100$ nucleotides, there exist so many unique sequences ($4^{100} = 1.6 \times 10^{60}$) that they could not be synthesized, even with all the carbon on the Earth as the mass of such diversity if realized would be 9×10^{37} kg, exceeding the mass of the Earth by some 13 orders of magnitude. This is important because it means that life has not sampled all possible genotypes, and no experiment in a lab or in a computer could hope to. Instead, we should aim to understand the properties of sequence spaces that support life and promote innovations and how these properties change through different evolutionary scenarios.

6.1.4.4 COMPUTATIONAL WORK: THEORY OF GENOTYPE NETWORKS

To objectively evaluate the challenge of evolutionary innovations under RNA World scenarios, we must attempt to understand how functions are distributed and connected within RNA genotype space. Considerable computational experiments have contributed greatly to our understanding on this topic. For computational experiments, genotype is defined by the nucleotide sequence, and phenotype is typically defined as an optimal secondary structure, which is predicted from the most energetically favorable combinations of base-pair interactions (termed the minimum-free-energy [MFE] structure). Collectively, these experiments have shown that there are vastly more genotypes than there are phenotypes, because many sequences fold into the same MFE structure. Put another way, each individual RNA structure can tolerate many consecutive changes in nucleotide sequence, without changing the most probable structure (Schuster et al. 1994). RNA molecules possess *mutational robustness*. There exist webs of RNA genotypes that are well connected by individual mutational changes and all form the same genotype. These webs have been termed *genotype networks* (Figure 6.1.4).

The robustness of RNA structures to mutations, facilitated by large genotype networks, suggests that the specific sequence required for a function is flexible. Evolving populations can move throughout sequence space along their genotype network, even while under selection to maintain a structure or function (Sumedha et al. 2007). However, as evolving populations move within their own genotype network, they may encounter different phenotypes, enabling evolutionary innovations (Figure 6.1.4). This has led to the idea that seemingly “neutral” evolution that maintains a molecular phenotype can nevertheless pave the way for new adaptations (Wagner 2008).

A few experimental examples have tested the prediction that genotype networks can promote innovations. For example, the genotype networks of the self-cleaving Hepatitis Delta Virus (HDV) ribozyme and the class III ligase ribozyme were shown to come in close proximity in at least one point in sequence

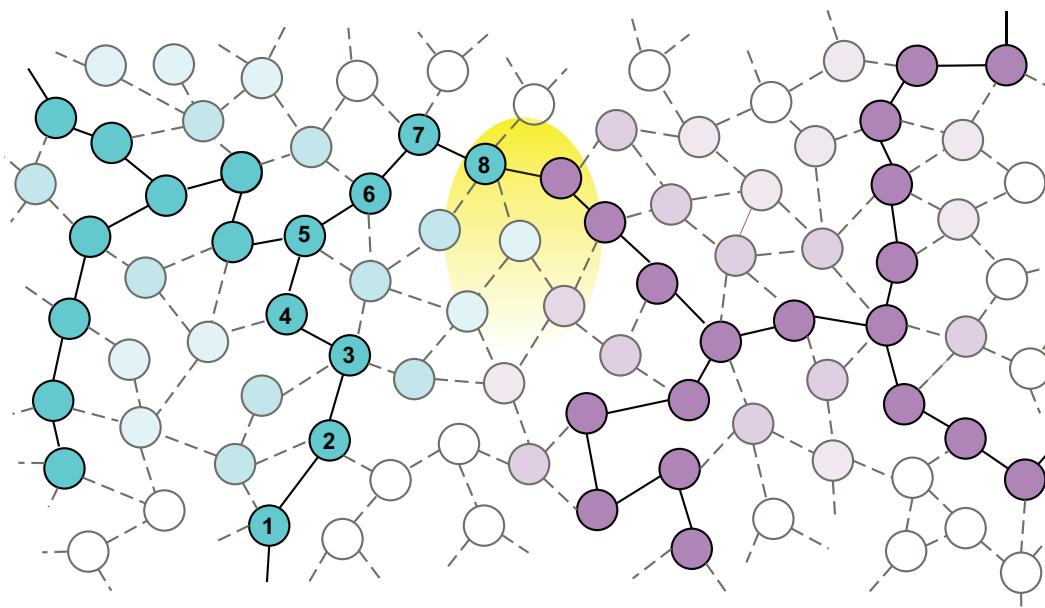

FIGURE 6.1.4 An evolutionary innovation in sequence space (SS). Circles represent different genotypes, and lines connect genotypes that differ by a single mutation. Circles with the same color have the same phenotype and belong to the same genotype network. Fitness is represented by the intensity of the color. Solid black lines indicate nearly neutral mutational steps, while dashed gray lines indicate deleterious mutational steps. Numbered circles follow a path of eight nearly neutral mutations that maintain the blue phenotype but allow the discovery of the purple phenotype. The yellow region highlights where the two genotype networks are proximal and a mutation can enable an evolutionary innovation, defined as the emergence of a new phenotype.

space (Schultes and Bartel 2000) and are described in more detail in [Section 6.1.5](#). Related work studied the sequence space between two RNA aptamers that bind either ATP or GTP. Only a few mutations were required to switch specificity (Huang and Szostak 2003). Finally, a study of the genotype network of the *Azoarcus* group I ribozyme ([Figure 6.1.5](#)) demonstrated that a population that had spread out into its genotype network adapted faster to the challenge presented by a modified substrate than did a population that started from a smaller region of genotype space (Hayden et al. 2011). Taken together, all these experiments support the ability of genotype networks to promote RNA innovation within SS.

6.1.4.5 EXPERIMENTAL FITNESS LANDSCAPES

One important parameter that is missing from our discussion of genotype networks so far is ribozyme fitness. Quantitatively, once a selective pressure (P) is defined experimentally (or biologically), then in principle, the fitness (W_P) can be defined as the probability of a ribozyme surviving this condition. As it is rare that a ribozyme needs to survive only one selective pressure, one can consider either the elemental fitness of a particular selective pressure or the total fitness, which would include the probability that, in a particular environment, the ribozyme is replicated ($W_{Replication}$). To the extent that selective pressures are independent, these individual fitness values are multiplicative in nature ($W_{total} = W_{P1} \dots W_{Pn} W_{Replication}$). For any given ribozyme, the effect of a mutation for a specified selective

pressure P_1 can therefore fall on a continuous spectrum, from beneficial to approximately neutral to deleterious. As the effect of this mutation under a second selective pressure P_2 need not correlate with the phenotype induced by P_1 , it is entirely possible that a mutation might be beneficial or neutral in one instance and detrimental in another (Gibson and Dworkin 2004). Despite this complexity, for a given overall selective pressure, a fitness landscape can be defined when each genotype is assigned a fitness value.

Due to the underlying complexity of sequence space, fitness landscapes are very high-dimensional. However, a common metaphor is to imagine them as three-dimensional landscapes where the height on a two-dimensional landscape is determined by fitness. While this image fails to capture the very high dimensionality of actual SS landscapes, it provides a simple way to visualize movement in SS. More realistically, in this picture, a set of flat topped “mesas” exists, where a set of genotypes all have approximately the same fitness and are bounded by genotypes with lesser fitness. This is the expectation of the quasispecies phenomenon. Increasing selective pressure on such a metaphorical landscape results in populations climbing “up-hill,” where the flat population of equivalent genotypes found in a weaker selective pressure are steadily differentiated from each other into a complicated set of “optimal” peaks.

Assigning fitness to a genotype requires an appropriate experimental assay. The utilization of next-generation sequencing to analyze RNA function has greatly expanded the number of genotypes that can be assigned a fitness, increasing the size of fitness landscapes (Pitt and Ferre-D’Amare 2010;

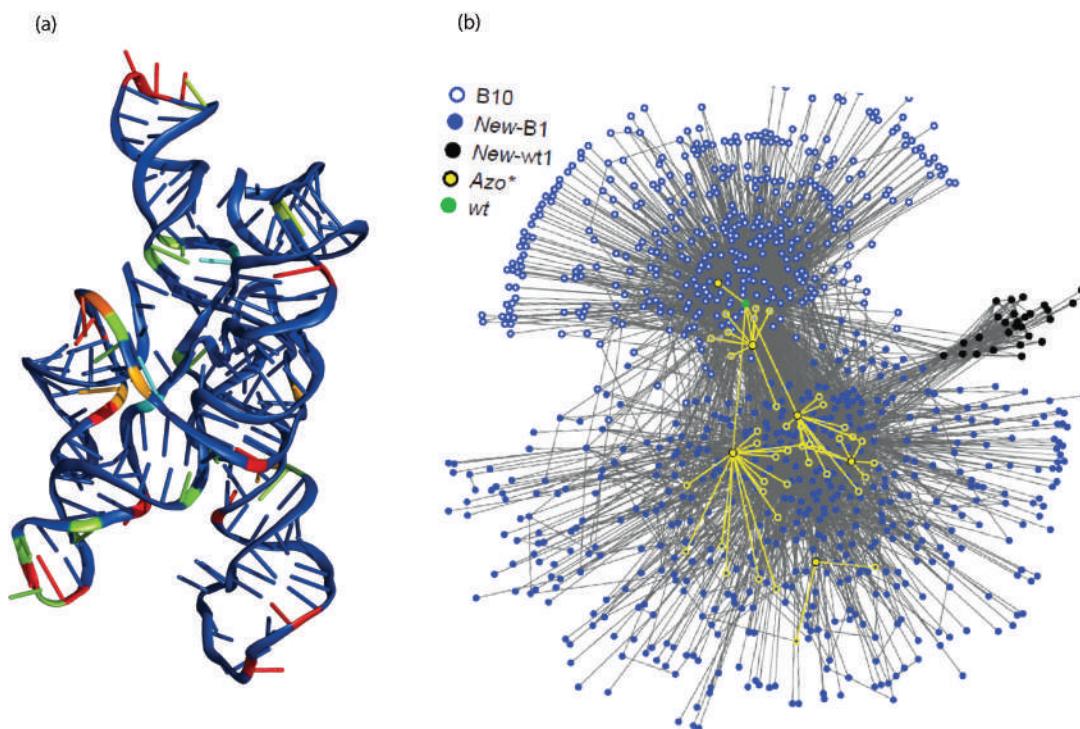

FIGURE 6.1.5 The *Azoarcus* ribozyme and its mutational landscape. (a) Nucleotide positions with non-zero mutation accumulation were mapped onto the crystal structure of the *Azoarcus* ribozyme, by replacing the b-factor column with P value from regression analysis, with red being lowest P values and blue being higher than $P = 0.05$. (b) Networks produced from selected sequences. Each node represents genotypes determined by clustering several sequences at a desired similarity cutoff (*i.e.*, 97%). Edges connect nodes if within two nodes there are sequences that differ by less than a specific edit distance. The green node represents the starting wild-type sequence. (From Hayden, E.J. et al., *Nature*, 474, 92–95, 2011.)

Kobori and Yokobayashi 2016; Xulvi-Brunet et al. 2016). In fact, in one case, all sequences of length 25 nucleotides were assayed for their ability to bind a small molecule, GTP (Jiménez et al. 2013). The results not only largely confirm the presence of vast genotype networks, but also show that the space is divided into clusters of sequences with very high fitness that are connected by networks of lower fitness. The effect of such landscape properties on evolutionary innovations and whether such properties extend to other functions remain unknown.

Mutational robustness should predict the size and connection of genotype networks, even when they cannot be exhaustively measured. Computational work on a few structures, and experiments on the *Azoarcus* ribozyme have measured robustness and epistasis. The former work has shown that natural RNA structures are more robust to mutations than 99% of random structures (Jörg et al. 2008), and had also showed that *in vitro* selected ribozymes structures are less robust to mutations than natural structures (Meyers et al. 2004; Hayden et al. 2012, 2015). In concert, laboratory experiments on ribozymes have shown that mutational robustness can be measured and can be altered by *in vitro* selection. For example, selection for more active variants of the *Azoarcus* ribozyme resulted in the unintentional reduction in mutational robustness (Hayden et al. 2012).

6.1.5 NEUTRAL NETWORKS

The digital information encoded and decoded *via* Watson-Crick (WC) pairing helps to ensure that RNA folds in a highly hierarchical fashion. The primary sequence of an RNA immediately after transcription or denaturation has the potential to rapidly find and stitch together self-complementary regions of sequence into stable helical secondary structure elements that then slowly relax into a final tertiary shape. It is this final fold that is typically associated with a functional RNA. Such a folding hierarchy exists, from the smallest stem-loop structures (Crick 1958) to the ribosome (Davis and Williamson 2017), the largest functional RNA known. Even random-sequence RNAs are highly likely to be structured as a result of the intrinsic self-recognition properties of RNA (Schultes et al. 2005).

The existence of RNA secondary structures along the folding pathway from primary sequence to final functional RNA implies that functional RNAs are highly degenerate in their primary sequences. Equivalent secondary structures for any specific RNA are easily found as in the absence of any other constraint, because in principle, any particular WC pair has three equivalent digital matches (*i.e.*, a C-G pair can be G-C, A-U, or U-A at the digital level of base recognition). This simple fact implies that RNA secondary structure motifs are highly degenerate. This degeneracy

rises still further for RNA folds that involve multiple helical elements as typically such helices can be arbitrarily spaced from each other while still having the potential to form a desired secondary structure (Sabeti et al. 1997). The requirement that these otherwise-equivalent secondary structures correctly form a tertiary fold places a constraint on primary sequence regions that must stay invariant in order to adopt a functional fold. The self-cleaving hammerhead ribozyme, for example, consists of three arbitrary RNA helices that converge on a common central core defined by 12 critical residues required for RNA cleavage. Conservatively, assuming a minimal primary sequence of 43 nt for this ribozyme, there are nevertheless some 10^{12} nearly equivalent secondary structures (Figure 6.1.6) that are all predicted to fold and potentially be functional self-cleaving hammerhead ribozymes (Sabeti et al. 1997). Consistent with this high degeneracy, selections for self-cleaving ribozymes have overwhelmingly returned hammerhead ribozymes (Salehi-Ashtiani and Szostak 2001). Likewise, many important biological RNAs are also highly degenerate. The 6S regulatory RNA, for example, which resembles an open DNA promoter complex, has 30 absolutely conserved nucleotide residues in sequences that span the gamma proteobacteria (Barrick et al. 2005; Shephard et al. 2010), with these residues being correctly positioned by at least 28 bp of arbitrary stem-loop structure. This yields a helical degeneracy for this RNA of at least 10^{17} sequences. Such high degeneracies are typical for RNA folds but can be hard to visualize. To set the scale for

such large degeneracies, picture a hockey arena filled to the brim with sand; this would correspond to $\sim 10^{15}$ sand grains.

Not only are RNA secondary structures highly degenerate, but these degenerate sequences are also typically connected to each other through sequence space, as previously discussed. Defining the distance between two sequences as the number of mutations required to move in SS from one to the other allows the introduction of the concept of a *neutral network*. RNA secondary structural degeneracy largely results from the fact that the secondary structure—and to a large extent the tertiary structure—of a RNA helical element is independent of its sequence. As a consequence, no member of a population of molecules sharing a common secondary structure can be further than two mutations away from another degenerate member. Thus, a helix containing a C-G pair is substantially equivalent to one containing a A-U pair at the same position. This mutational distance can be less when wobble pairs are considered, as a C-G pair is two mutations away from an A-U pair at that position but only one mutation away from a U-G wobble pair. Likewise, when helical structures can tolerate helical bulges caused by the insertion or deletion of a single nucleotide within a helix, mutational distances can be pseudo-continuous. Thus, the huge reservoir of degeneracy that exists for any functional RNA is not scattered randomly throughout sequence space but can be thought of as a neutral network of nearest neighbors that are capable of stretching a surprisingly large distance through sequence space, like a cosmic filament.

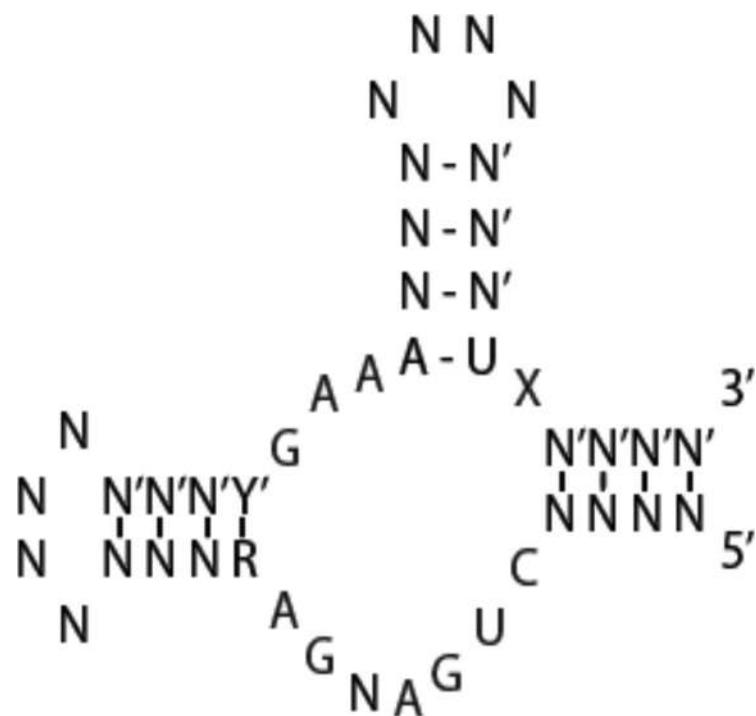

FIGURE 6.1.6 The hammerhead ribozyme has a small catalytic core connected to three arbitrary helices, giving the motif huge sequence degeneracy, shown here with two helices closed by 4-nt loop structures. R: any purine, Y: any pyrimidine, X: A, C, or U. N: arbitrary base. Prime indicates a pairing requirement.

When fitness is once again added into this picture, the concept of a neutral network makes more precise the previously discussed and more limiting three-dimensional picture of a “mesa.” This implies that, in addition to a high degeneracy of sequences, there is also a high degeneracy of mutational paths that link together these degenerate sequences into a set of trajectories that natural evolution can move along by the conservative strategy of mutating, as little as one or at times two nucleotides at a time. Remarkably, experimental realizations of such a beautiful idea have been obtained.

6.1.5.1 BOUNDARIES BETWEEN DISTINCT NEUTRAL NETWORKS

How might two distinct folds of the same sequence length occupy sequence space? A more accurate mental picture resembles the mixing of spaghetti and fettuccine into a bowl, no strand of spaghetti is that far from a fettuccine strand. While this does not capture the high dimensionality of the problem, neutral networks with one function are commonly neighbors with a network of another. This was demonstrated clearly by Schultes and Bartel (2000), when they moved 80 nt through sequence space, one point mutation at time, keeping the function of the HDV self-cleaving ribozyme (Figure 6.1.7a) for some 40 distinct point mutations, before moving abruptly to the fold of a new ribozyme. This class II ligase ribozyme (Figure 6.1.7a) was then moved a further 40 nt, all the time keeping within this fold’s neutral network (Schultes and Bartel 2000). Interestingly, one single intersection sequence had the properties, albeit weakly, of both the HDV and the ligase, suggesting that this sequence was balanced energetically between either fold and was therefore optimal for neither

(Figure 6.1.5b). In the following three sections, we will discuss other types of intersections between distinct neutral networks that have occurred with surprising frequency in the experimental literature.

6.1.5.2 POINT-MUTATION-INDUCED DIVERGENCE IN NETWORK FUNCTION: CONSERVED STRUCTURAL MOTIFS

The notion that mutational networks connect motifs of similar function is a powerful one that appears to be actively used, at least as evidenced by modern biology. A surprising finding in the riboswitch RNA gene-regulation fields was the discovery of adenine- and guanine-sensing riboswitches that share an entirely common secondary and tertiary structure fold. These two riboswitches are distinguished by a single U (found in the adenine riboswitch core) to C (found in the guanine riboswitch) mutation (Mandal and Breaker 2004). Thus, in sequence space, the neutral networks for these two networks are always one nucleotide distant from each other, with discovery of either by evolution, guaranteeing with near certainty the immediate evolutionary discovery of the other via a single point mutation. While painting a picture of parallel sheets of adenine and guanine riboswitch networks stretching through sequence space, this example is not alone. The *glmS* riboswitch, which requires glucosamine-6-phosphate as a small coenzyme to promote self-cleavage can, *via* the clever *in vitro* selection of only three point mutations, adopt an identical fold that now achieves self-cleavage in the complete absence of coenzyme (Lau and Ferré-D’Amaré 2013). Together, these two examples suggest that structurally related but functionally distinct ribozymes must, as a consequence of

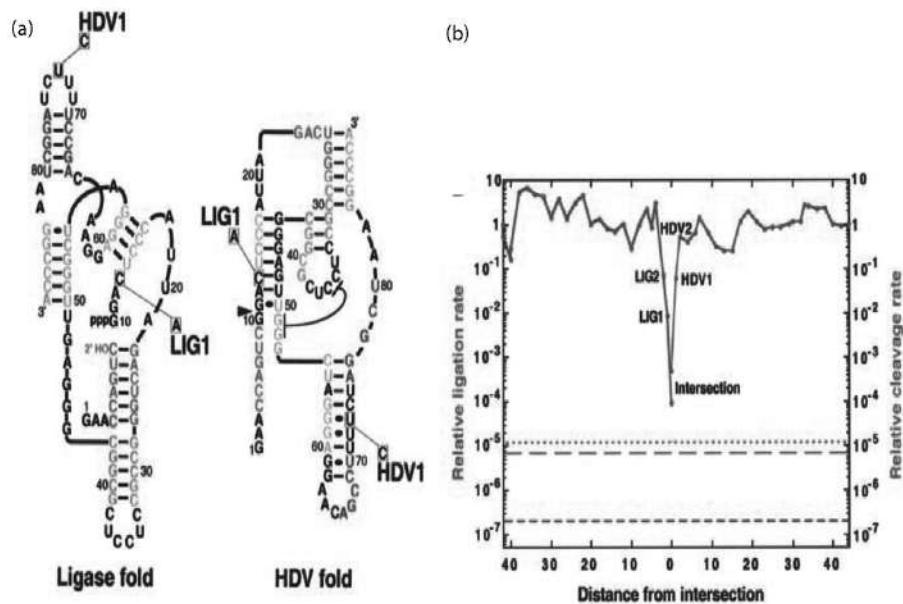

FIGURE 6.1.7 A neutral network between two ribozymes. (a) A ligase ribozyme and the HDV ribozyme were endpoints of a study to find a path through sequence space from one RNA to the other. (b) The neutral network that resulted; there is even an intersection sequence that retains (weakly) the catalytic activities of both ribozymes. (From Schultes, E.A. and Bartel, D.P., *Science*, 289, 448–452, 2000.)

their shared sequence motifs, have neutral networks that are extensively proximal to each other and may in fact be quite common in evolution.

Before embracing this picture fully, it is worth noting that experimental attempts to test this idea with more complex ribozyme functions have not always been productive. Using a highly degenerate library of sequences having the proposed secondary structure of a pyrimidine nucleotide synthase ribozyme, *in vitro* selection did not result in purine nucleotide synthase ribozymes having the same secondary structure as the starting ribozyme fold (Lau et al. 2004). Here, it may be important that the chemistry of pyrimidine nucleotide synthesis is thought to be considerably more challenging than that of purine nucleotide synthesis, implying that the discovery of considerably simpler motifs was favored in this case over the discovery of motifs having an identical secondary structure scaffold.

6.1.5.3 CATALYTIC PROMISCUITY: ONE SEQUENCE, ONE FOLD, TWO FUNCTIONS

While we have discussed intersection sequences that can fold into two structures, each with a distinct function (Section 6.1.5.1), and sequences that can rapidly adopt a new function while maintaining the same fold (Section 6.1.5.2), a surprisingly large number of ribozymes appear to have a single fold, with many distinct promiscuous functions. Uncontrolled promiscuity is clearly dangerous for complex metabolic processes where chemical reactions need to be precisely controlled, but early in evolution, such sequences might have played a useful role in helping to discover new catalytic function from old. Evolution would then have had the responsibility of moving such sequences away from sites of promiscuity toward that of unique function.

Perhaps, the best characterized of these bifunctional RNAs consists of the phosphodiester-forming and -cleaving ribozymes. A large number, but not all (*e.g.*, RNase P mediates cleavage by the attack of water), self-cleaving ribozymes generate a cyclic phosphate upon cleavage. The thermodynamic difference in energy between a phosphodiester linkage and a cyclic phosphate is close to zero, allowing RNA cleaving motives to either strongly favor the forward reaction (*e.g.*, the HDV ribozyme) or tolerate cleavage and re-ligation (*e.g.*, the hammerhead ribozyme). This balance of cleavage and religation properties is very important for the rolling-circle replication of the viral RNAs from where these ribozymes originate. These viruses generate linear transcripts from a circular genome that must be cleaved, but, at least, a small fraction of these cleaved products must re-ligate to allow replication of the opposite viral strand (Soll et al. 2001). This form of promiscuity, which exploits the near-equivalent energetics of products and reactants, is not perhaps unexpected and, in fact, is the basis for spontaneous RNA-RNA recombination that could have generated diversity prior to the advent of more complex chemistry (Lutay et al. 2007; Lehman 2008).

More complicated forms of ribozyme promiscuity have interesting potential to diversify the chemistry of an early RNA World ecosystem. The ribosome, which has evolved for over 3.5 billion years to promote peptide-bond formation, is known

under laboratory conditions to promote a range of chemistries that relies on spatial proximity of the reactants (Petrov et al. 2015). Purine nucleotide synthesis ribozymes selected for the ability to promote phosphoribosyl pyrophosphate (PRPP)-dependent nucleotide synthesis were found to also promote a distinct Schiff-base type of chemistry (Lau and Unrau 2009). RNA polymerase ribozymes that have been evolved in the laboratory to copy RNA templates using NTPs (Horning and Joyce 2016) were recently demonstrated to have the surprising ability to use dNTPs in addition (Samanta and Joyce 2017). This type of unexpected promiscuity could have surprising implications for the evolution of DNA genomes, even early in the evolution of an RNA World. In short, RNA sequence space can be traversed by evolving populations that take advantage of a wide variety of adaptive mechanisms, including neutral evolution, epistasis, exaptations, and parallel evolution.

6.1.5.4 COEVOLUTION OF NEUTRAL NETWORK SYSTEMS

Neutral networks in this chapter have been defined by selective pressures that are defined by external boundary conditions. Evolving multicomponent RNA systems are much more complex than this and respond to selective pressure from both the external environments and their coevolving partners. In this picture, a network of functionally distinct RNAs is a set of RNA sequences coevolving within SS simultaneously in response to externally defined and constantly changing selective pressures. For any one functional RNA sequence, then a complex local environment is defined by both external selection and local selective pressures that at least partially must be defined by the shape and function of the specific RNA fold and by its coevolving sequences (Figure 6.1.8). Biologically, this is best exemplified by the ribosomes, where the small and large subunits have coevolved in lock step over billions of years while maintaining the common function of protein synthesis, so as to systematically change their external environment from an RNA World to a protein-dominated one. In this framework, sequence space, RNA shape space, and RNA function are interconnected via evolution. Some typical biological examples of this connection are given in Figure 6.1.9.

Experimental evidence suggests that RNA can respond both positively and negatively to changes in external selective pressure. The pathways to higher-fitness genotypes of the group I *Azoarcus* self-splicing intron were studied under three distinct selective pressures (Hayden and Wagner 2012). These selective pressures changed the fitness of individual genotypes such that some mutational pathways were only beneficial in some environments. Interestingly, RNase P, which cleaves pre-tRNA transcripts, is an RNA-protein complex in *Escherichia coli*. In the absence of the C5 protein, this ribozyme is still functional but no longer recognizes distinct pre-tRNAs homogeneously, highlighting how the presence of a peptide sequence in the environment can alter the function of a ribozyme (Sun et al. 2016). Perhaps, an RNA able to interact with the RNaseP RNA could be selected artificially in the future to recover this homogeneity in the complete absence of

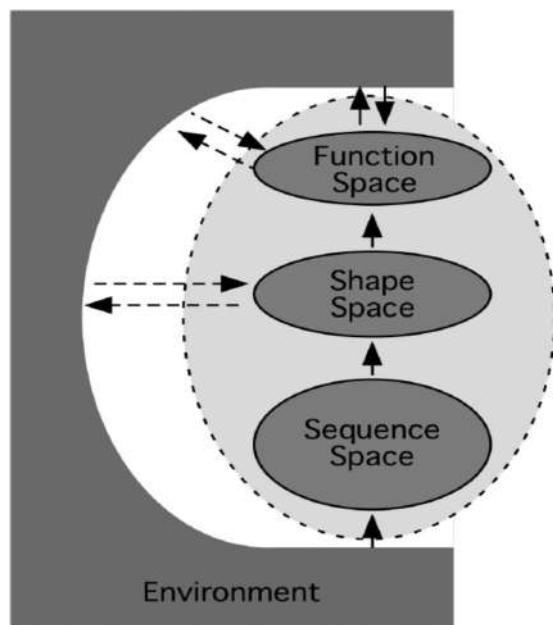

FIGURE 6.1.8 A system-based approach for the analysis of functional RNA evolution. An RNA system (dotted oval) contains RNA sequences (as points in sequence space) that have definable shapes and functions (phenotypes) once the RNA system is placed into a specific environment (solid horseshoe). Interactions with this environment (paired arrows) define the selective pressure that drives the evolution of the RNA system. In this example, the environment is responsible for RNA replication (by, e.g., a protein polymerase) and thus controls the sequence diversity available to be sampled (bottom vertical arrow). Complex environments can be difficult to characterize and may generate a multicomponent selective pressure (dotted paired arrows). In contrast, *in vitro* selection can often be used to apply a particular pressure (solid paired arrows), making the relationship between selection pressure and RNA functionality simpler to understand. (From Wang, Q. and Unrau, P.J., Evolving an understanding of RNA function by *in vitro* approaches, in *The Chemical Biology of Nucleic Acids*, G. Mayer (Ed.), pp. 355–376, John Wiley & Sons, Chichester, UK, 2010.)

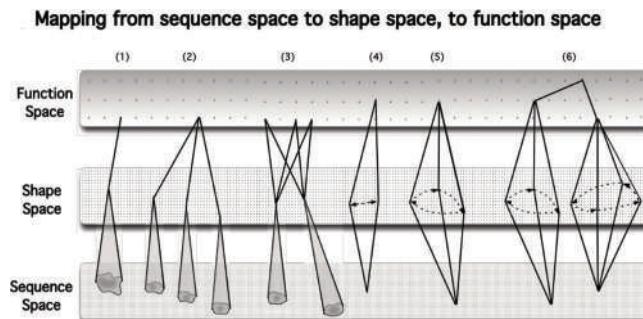

FIGURE 6.1.9 Mapping between sequence, shape space, and function space. Some of the common mapping relationships from sequence to shape to function space are shown: (1) One-to-one-to-one relationship: a set of sequences can fold into a common structure (one point in shape space) that performs a unique function (one point in function space), the hammerhead ribozyme being a good example. (2) Many-to-many-to-one relationship: many different sequence motifs (not directly connected in sequence space) can fold into distinct structures that each perform the same function. The functions of RNA ligation and cleavage are typically satisfied in this way. (3) Many-to-one-to-many relationship: a group of similar sequences can fold into a structure that performs many different functions that are in common with a distinct second fold. For example, two capping ribozymes have distinct secondary structures and yet perform the same set of chemical reactions. When the thermodynamic equilibrium of shapes is also considered as in (4), (5), (6), a point in sequence space often samples more than one point in shape space, each representing one of the substrates of the RNA system. The equilibrium between those states depending on environmental conditions. (4) Two states representing a conformational change before and after a binding event, such as occurs commonly with aptamers and some allosteric ribozymes. (5) Three structures representing three states of a ribozyme, before, during, and after the transition state for a particular reaction. (6) Multi-component RNA systems, such as the ribosome, have subunits that each move through a set of states in order to complete a catalytic cycle. Here, the large and small subunits of the ribosome provide discrete contributions (peptide bond formation and mRNA triplet decoding, respectively) to the overall function of peptide bond formation. (From Wang, Q. and Unrau, P.J., Evolving an understanding of RNA function by *in vitro* approaches, in *The Chemical Biology of Nucleic Acids*, G. Mayer (Ed.), pp. 355–376, John Wiley & Sons, Chichester, UK, 2010.)

protein factors and to enable a model system for RNA-RNA coevolution.

All the observations presented above reinforce the notion that a specific functional RNA can respond to external selection by moving through sequence space (Figure 6.1.8) while preserving its original function (Figure 6.1.9; type 5). But how might highly cooperative systems such as the ribosome initially evolve? Artificially created networks of three RNAs have displayed a level of cooperation so as to ensure their own replication, even in the presence of molecular parasites that might have been expected to overwhelm such altruistic behavior (Vaidya et al. 2012). This unexpected behavior has a number of ramifications for the spontaneous emergences of metabolic type networks of RNA interactions early in the evolution of life. Moreover, this work strongly suggests that even in the absence of compartmentalization, RNA networks could have existed and presumably gained the evolutionary

traction required to form fully functional metabolic networks once encapsulated. While such multicomponent RNA systems have not been subjected to evolution, the presence of extensive hydrogen bonding between each of the three RNAs is shown in Figure 6.1.10, indicating that coevolution of such systems would sample an interesting three-way neutral network, where mutations in one network would require coevolution in a second and possibly a third.

Despite the evidence that RNAs are capable of cooperation, such systems are vulnerable to external changes in environment. Most specifically, maintaining a high effective concentration of polymers and the smaller substrates required to make such polymers could easily be imagined to be disrupted by, for example, simple dilution. Compartmentalization has long been recognized as an effective solution to this important problem (cf. Szathmáry and Demeter 1987; Bartel and Unrau 1999) and is particularly effective against parasitic

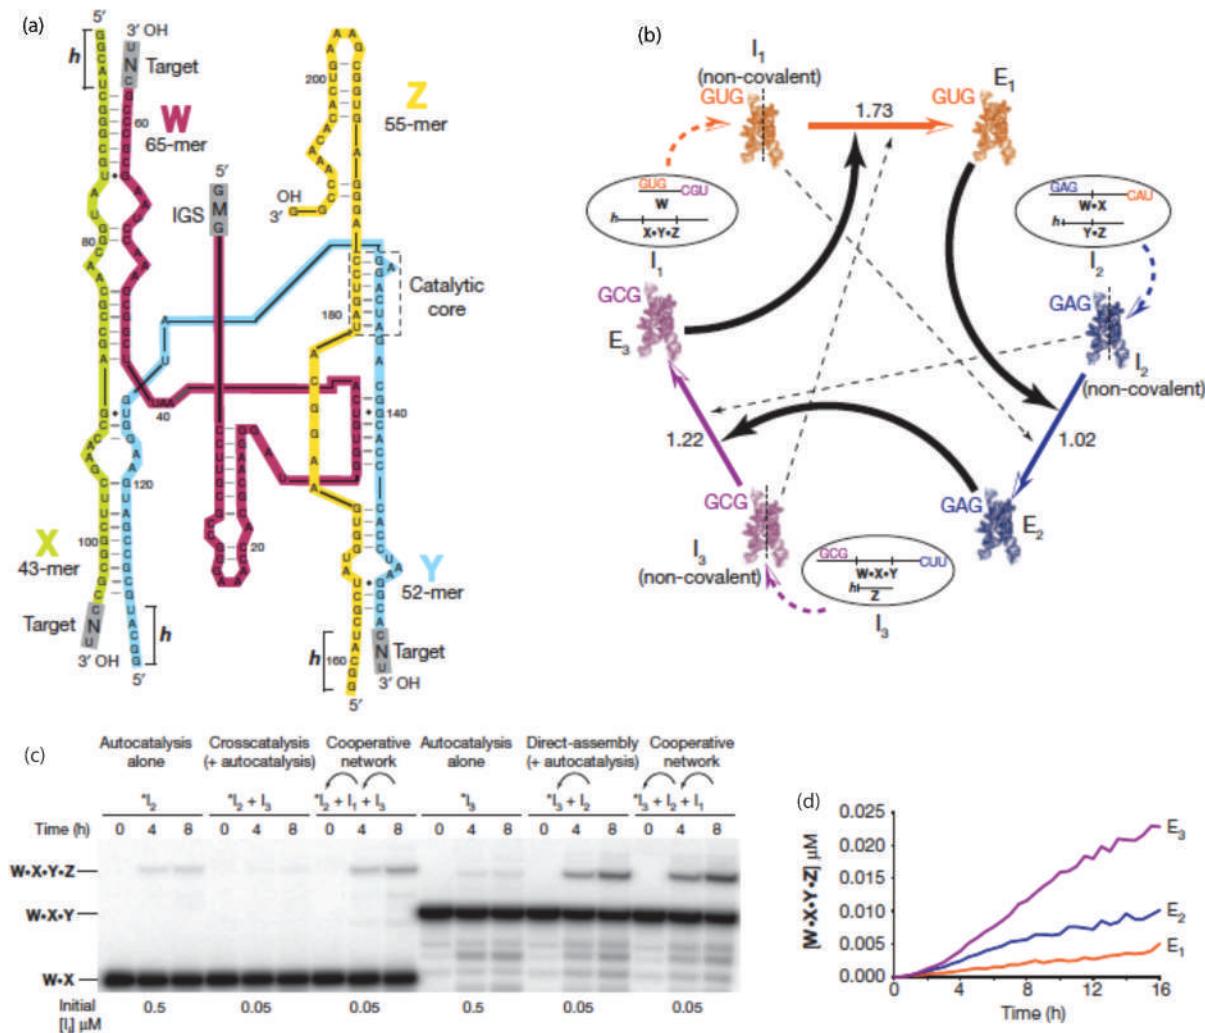

FIGURE 6.1.10 Cooperative covalent assembly of recombinase ribozymes. (a) The *Azoarcus* RNA, broken into four fragments that can spontaneously and covalently reassemble when mixed together. (b) The cooperative action of three separate subsystems. In each, the ribozyme has been broken into two pieces but cannot self-assemble due to mutational mismatches. However, when all three subsystems are combined, the collective set can assemble and reproduce. (c) Gel electrophoretogram showing this obligatory cooperation. (d) Each subsystem, when together, assembles at characteristic rates. (From Vaidya, N. et al., *Nature*, 491, 72–77, 2012.)

sequences, as demonstrated by Matsumura et al. (2016). In this framework, compartmentalization serves as a fundamental environmental selective pressure, without which modern life could not be contemplated. Imagine a protocell containing an RNA replicase and a non-functional extra RNA molecule that is neutral; its presence neither hurts nor helps the replication of the protocell. The extra molecule is free to mutate, and because it has no sequence requirements, it does not contribute to the information capacity of the system. Now, imagine that a selection pressure for GTP sequestration or membrane creation arises from a drop in the concentration of GTP in the environment that becomes rate limiting for replication. This drop could come from a lack of production (chemical environment) and/or because other protocells are depleting the local GTP (genetic environment). One of the several randomly evolving extra molecules happens to be an aptamer for GTP and can sequester GTP, increasing its local concentration inside the protocell. This provides the protocell with a growth advantage, and now, the sequence is under selection. In this scenario, a novel function (GTP binding) now provides the system with not only greater functionality but also greater information capacity. This simple example illustrates several points: (1) molecules spatially confined can become cooperative for survival; (2) environmental change is needed to promote innovations; and (3) innovations expand the information capacity of a system. It remains to be seen if such systems can be manifested in the laboratory (Figure 6.1.11).

6.1.5.5 FUTURE RESEARCH—SEASCAPES—GENOME BY ENVIRONMENT INTERACTIONS/EVOLUTIONARY EQUILIBRIUM

Experimentally, much remains to be learned about the coevolution of RNAs within sequence space. While several data sets contribute to our understanding, intentional and systematic laboratory studies are lacking. Here, we speculate briefly into potentially interesting directions that are yet to be explored experimentally.

A coevolving system of RNAs appears highly likely to place evolutionary pressure on specific parts of the coevolving neutral networks in response to changes in external selective pressures: How, then, does such a system pick it up a notch when a specific neutral network is under strong selective pressure for enhanced function? For example, it is well known that the hammerhead ribozyme, even when selected for optimal self-cleavage, is not a tremendously fast ribozyme. How would an evolving network of RNAs in all likelihood replace the hammerhead with a faster ribozyme (such as the HDV) when required? Future experiments could explore connections between the neutral networks of two or more self-cleaving ribozymes that catalyze the same reaction but do so with different supporting secondary and tertiary folds.

As previously discussed, sequence space is rugged when selective pressure is high enough to distinguish even between nearest neighbors. If selective pressure is low, then a substantial

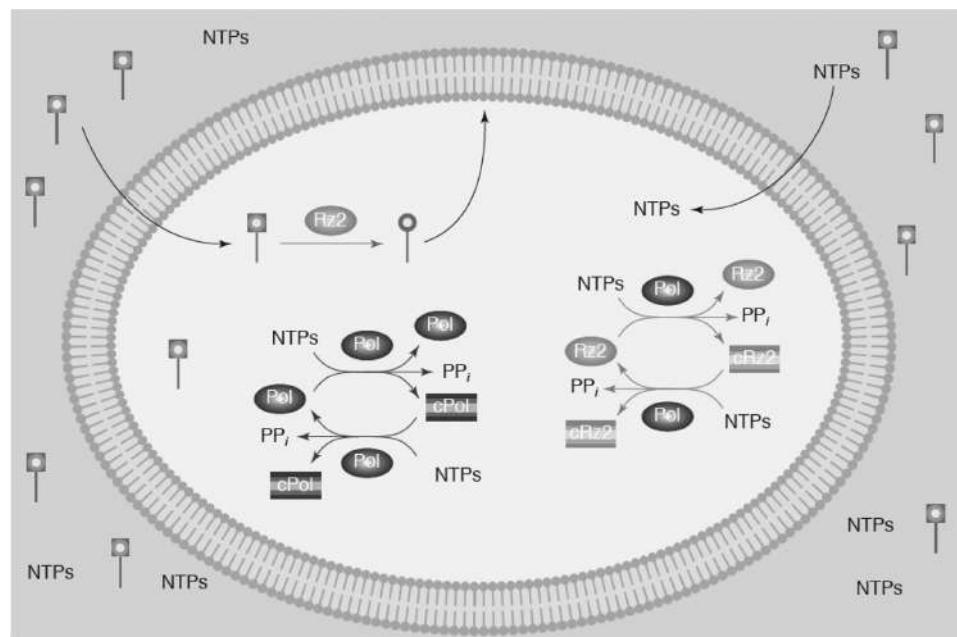

FIGURE 6.1.11 A minimal ribo-organism could eventually be constructed in the laboratory, provided that suitable ribozymes and membrane components can be identified. Although not an autotroph, and likely to be different from the first life in the RNA World, such an organism would be capable of sustained evolution. A polymerase ribozyme (Pol) uses externally supplied nucleotide triphosphates (NTPs) to replicate itself and its reverse complement (cPol) in an autocatalytic cycle (purple arrows). The polymerase ribozyme also makes copies of a second ribozyme and its complement (Rz2 and cRz2, respectively; green arrows). This ribozyme promotes a reaction that facilitates growth and eventual division of the membrane-like compartment. In this example, the second ribozyme matures a membrane precursor (square heads) into an active membrane component (round heads). Insertion of such a compound into the membrane is imagined to lead to its growth and eventual bifurcation, leading to a form of cellular replication. (From Bartel, D.P. and Unrau, P.J., *Trends Biochem. Sci.*, 15, M9–M13, 1999.)

fraction of the neutral network for the motif can be occupied, provided that the evolutionary system can populate the network. Such a sustained population can be imagined to be in a near-equilibrium state, with mutations moving sequences around the neutral network. At the edges of the network, two things can occur: (1) the RNAs are of no functional relevance and become rapidly extinct or more interesting; (2) they can interact with functionally relevant RNA motifs. In the instance that this motif is a faster RNA ribozyme fold than the neutral network previously occupied, this network will also be in a near-equilibrium state with the slower neutral network. While the second neutral network is intrinsically capable of faster catalysis at this stage, such activity is never realized due to the absence of selective pressure. As faster activities require a more complex RNA fold, the more functional RNAs will tend to be longer in sequence. Since longer RNAs are at a slight replicative disadvantage in low selection pressure conditions, they will only tend to be found at the extreme boundary of its intersection with the slower neutral network.

When selective pressure is raised (in this chapter most easily imagined as being driven by the demand for higher metabolic capacity envisioned in Figure 6.1.2), the near-equilibrium state between the two neighboring neutral networks will be violated. At this point, the slower network cannot sustain metabolism and is replaced by the faster ribozyme activity. At this transitional point, the faster neutral network will become heavily populated, driving the apparently sudden emergence of a new RNA fold in the RNA population. Relaxing selection pressure would allow the slower, less-information-rich ribozyme to be resampled, which if tracked again to evolutionary equilibrium would result in the system depopulating the faster neutral network. While such ideas are thought experiments for now, there is no reason in principle why such experiments could not be performed with the *in vitro* technologies currently in hand.

Another important set of future experiments will be needed to understand the role of environmental changes to genotype networks and evolutionary innovations. While several experiments are now expanding the size of genotype space that is being analyzed, typically the fitness landscape is only studied under a single biochemical condition (pH, temperature, ionic strength, etc.). Future experiments will require studying the same fitness landscapes under several different environmental conditions to understand the extent to which these environmental changes restrict or promote evolutionary exploration of genotype networks and the emergence of evolutionary innovations.

6.1.6 SUMMARY

This chapter provides a review of the role of RNA in the OoL, with special attention to how function can evolve once a diversity of sequences comes into existence. RNA can be a catalytic molecule, and the RNA World hypothesis suggests that, at some point, populations of RNA guided their own reproduction by using this catalytic prowess. We do not yet understand fully which catalytic functions came into being in

what order during the history of the development of life on the Earth. However, we are beginning to define the powerful evolutionary mechanisms that could have guided RNA populations through a network of interactions, as they searched sequence space for ever more potent means of survival and reproduction.

DEDICATION

We dedicate this chapter to our immediate ancestors in the scientific tree of investigators, namely Thomas Jukes, Gerald Joyce, Andreas Wagner, and David Bartel. Without their inspiration and guidance, we would not have made the advances that we did, which we hope to pass on to the next cohort of origins researchers.

GLOSSARY

Mutational Robustness – *the capacity of a phenotype to remain unchanged upon mutation*

Genotype Network – *the collection of all genotypes with the same phenotype*

Neutral Network – *the collection of all genotypes with the same secondary structure that have the same phenotype*

6.2.1 INTRODUCTION AND OBJECTIVES

It is widely believed that life on Earth passed through an RNA World stage in which RNA sequences acted as both genes and catalysts (Gilbert 1986; Joyce 2002; Higgs and Lehman 2015). The universality of ribosomal protein synthesis in current cellular life and the essential roles of rRNA, tRNA, and mRNA in this process make it clear that some form of RNA replication existed very early in evolutionary history, prior to the origin of genetically encoded proteins and the translation mechanism. The simplest version of the RNA World hypothesis for the origin of life therefore proposes that life emerged due to the formation of catalytic RNAs (ribozymes) that were able to self-replicate (Cheng and Unrau 2010). This is supported by the large number of ribozymes with diverse functions that have been synthesized in the lab and studied experimentally. In particular, autocatalytic RNA systems of ligases (Lincoln and Joyce 2009) and recombinases (Hayden et al. 2008) have been demonstrated, in which specific sequences catalyze formation of the same sequences. However, it is usually envisaged that the RNA World would have required an RNA polymerase ribozyme that used another strand as a template to synthesize a complementary strand. If the polymerase could operate with any general template sequence, then it would be able to synthesize further copies of itself, as well as replicate any other ribozymes with different functions. Hence, it would form the basis of a genetic system that could evolve and diversify. There has been considerable progress in developing polymerase ribozymes in the laboratory (Johnston et al. 2001; Lawrence and Bartel 2005; Zaher and Unrau 2007; Wochner et al. 2011;

Attwater et al. 2013). The best current polymerases are able to replicate sequences of their own length but require specific template sequences and therefore cannot yet self-replicate.

Supporters of the RNA World see this as evidence that a self-replicating RNA polymerase could have arisen on the early Earth, given the large amount of time available. Nevertheless, many alternative scenarios are also possible. In this chapter, I discuss possible scenarios for the origin of life from the point of view of mathematical modeling and evolutionary theory. Of course, models are always much simpler than reality and always leave out many details, but defining a simple model forces us to focus on the key aspects of a problem and to properly define the questions we are asking. Results from a simulation or analytical solution of a model tell us clearly what happens if we make the assumptions on which the model is based. This helps to avoid confusion from speculative verbal arguments.

The theoretical models discussed here describe replication of strands of a biopolymer that is built up from a small alphabet of monomers that have complementary pairing. It is assumed that a strand can act as a template for synthesis of its complementary strand, and that sequence information is passed on in this process. It is assumed that all or most sequences have the ability to be a template. Additionally, at least some of the sequences have the ability to fold to a specific structure that is a functional catalyst. It may be that functional sequences are very rare in the space of possible sequences, so that it might take a very long time for non-living chemistry to find a functional sequence. This also means that maintaining accurate sequence replication is important, because errors in

replication will often generate non-functional sequences. I will call the polymer RNA, but similar polymers with different backbone chemistry and/or different base pairs might also function in a similar way, so these models do not rule out alternative nucleic acids existing prior to or alongside RNA. However, we *are* excluding the possibility that the principal polymers were proteins, because complementary pairing of proteins is not known to occur and because the evidence from current biology is that proteins are synthesized by ribosomes, whose catalytic part is made of RNA.

Since I am operating under the premise that life *did* originate on Earth and that it wasn't a miracle, then the first functional sequences must have been synthesized by non-living chemistry. This means that there must have been an environment in which biopolymer sequences could be synthesized chemically that were sufficiently long to have catalytic function. The most obvious function that would be required in the RNA World would be a polymerase ribozyme that catalyzed RNA replication. However, there are also scenarios in which other kinds of catalysts could have come first. One of the main aims of this chapter is to consider *which* kinds of catalysts came first.

6.2.2 THE ORIGIN OF LIFE AS A SPATIALLY LOCALIZED STOCHASTIC EVENT

There are three qualitatively different ways to make an RNA strand, as in Figure 6.2.1. The spontaneous or *s* reaction is spontaneous chemical synthesis from monomers by polymerization, without a template strand. The replication or *r* reaction is template-directed synthesis, (i.e. synthesis of a strand that is complementary to a template strand, without the presence of a ribozyme or other biological catalyst). The catalysis or *k* reaction is template-directed synthesis that is catalyzed by a polymerase ribozyme. All three of these cases may proceed one monomer at a time or by formation of short oligomers that then join to form longer ones. Experimental support for these three reactions will be discussed in Section 6.2.7. The models discussed in this chapter assume that all these three reactions can occur to some extent.

The simplest possible model for RNA replication incorporating the *s*, *r*, and *k* reactions (Wu and Higgs 2012) can be defined by a single equation for the rate of change of the concentration, ϕ , of a single type of replicating strand.

$$\frac{d\phi}{dt} = (s + r\phi + k\phi^2)(1 - \phi) - v\phi \quad (6.2.1)$$

The distinction of these three reactions is that the *s* reaction occurs at a rate independent of the current strand concentration, the *r* reaction occurs at a rate proportional to ϕ (the template concentration), and the *k* reaction occurs at a rate proportional to ϕ^2 (the product of the template and catalyst concentrations). Replication is limited by resources (*i.e.*, finite numbers of monomers), which is included via the $(1 - \phi)$ term. The concentration scale is defined such that

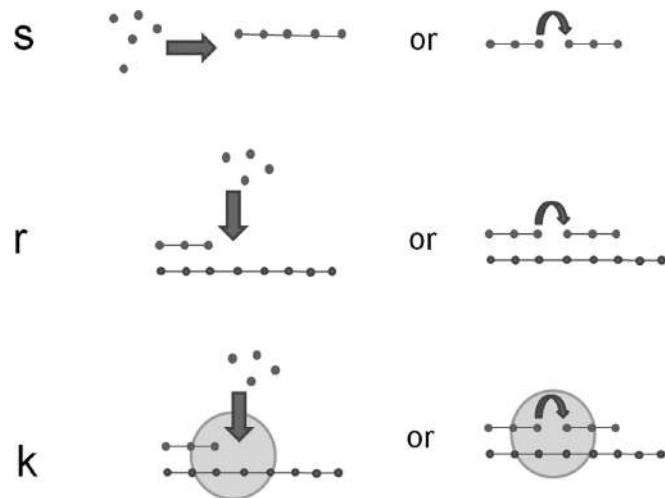

FIGURE 6.2.1 Three categories of reaction that form RNA strands. The *s* reaction (meaning “spontaneous”) is the formation of a strand by spontaneous polymerization of monomers or by linking oligomers. The *r* reaction (meaning “replication”) is the non-enzymatic template-directed synthesis of a complementary strand, either by addition of monomers or by ligation of two oligomers that are bound to the same template. The *k* reaction (meaning “catalysis”) is the ribozyme-catalyzed template-directed synthesis of a complementary strand. The ribozyme is a separate strand from the template and the substrate oligomers and monomers.

the maximum possible concentration when all resources are used is $\phi = 1$. The final $-v\phi$ term represents breakdown of the strands or loss of the strands from the system.

For appropriate values of the reaction rate parameters, there are two possible stable states for ϕ , which we have termed living and dead. In the dead state, ϕ is very small. The spontaneous synthesis term is balanced by the breakdown rate; hence, $\phi \approx s/v$. In \approx the living state, the catalytic replication term, $k\phi^2$, is large, and replication becomes resource limited; hence, ϕ is close to 1. We have assumed that the strand is a self-replicating ribozyme with a high *k*. This means that it can sustain itself by the *k* reaction if it manages to achieve a high-enough concentration to get started. If *k* is large enough, there is a living state solution of Equation 6.2.1, even if *s* and *r* are zero. This means that the ribozyme sustains itself by its own replication, which is why we call it “*living*.” On the other hand, in the dead state, the existence of the strand depends on the very small rate of chemical synthesis, *s*, and the strand is not self-sustaining.

We also found living and non-living states in more detailed models for RNA polymerization and replication that we studied previously (Wu and Higgs 2009, 2011). The model described by Equation 6.2.1 was introduced because it captures this idea in a very simple way. In this picture, the origin of life is a transition from the non-living to the living stable state. It requires a rare stochastic event for this to happen. In a well-mixed solution with very large numbers of molecules, this is extremely unlikely, but in a spatially distributed model, where molecules interact with local neighbors on a surface, this becomes much more likely. A small patch of replicators can arise in one location, which can

then spread across the surface. We have compared the waiting times for replication to become established in the spatial and well-mixed version of this model (Wu and Higgs 2012).

For the discussion in this chapter, we will use a slightly more detailed model for RNA replicators (Shay et al. 2015; Kim and Higgs 2016; Tupper and Higgs 2017), in which there are three types of strand: a polymerase P, the complementary strand to the polymerase C, and a non-functional strand X. The figures in this chapter use a version of this model with a two-dimensional lattice, in which each site may be either empty or occupied by only one type of strand (Kim and Higgs 2016). The model proceeds in short time steps in which stochastic events occur on each site with the following rates. Non-functional strands appear at a small rate s . All strands replicate at a rate r . Strands that are next to a polymerase are copied by the polymerase at rate k . All strands die at rate v . When replication occurs, new strands are placed on vacant lattice sites next to the template. If replication is accurate, a P template produces a C, and a C template produces a P. If an error occurs in replication, an X is produced instead of a P or C. The probability that an error occurs somewhere in the whole template is M . Replicating an X always produces another X (i.e. beneficial mutations that create functional strands are not included).

In this model, chemistry creates a mixture of random strands. If s is low, the density of the random strands is low. If r is also low, a strand will usually be destroyed faster than it produces new strands by the r reaction. Within this mixture, after some very long time, we suppose that an unusual sequence is created by chemistry that functions as a polymerase. Such a polymerase can spread if its catalytic rate k is large enough and if its error rate M is small enough. [Figure 6.2.2](#) illustrates the spread of a patch of polymerases and complements that has arisen from the introduction of a single polymerase. This patch will continue to grow and fill the whole surface, even if we set s and r to zero from this point on.

How likely this scenario is to occur in the real world depends on the distribution of lengths of strands that can be synthesized chemically; on how long a sequence has to be,

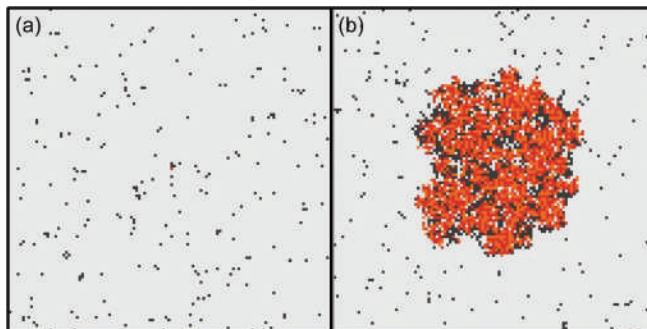

FIGURE 6.2.2 Model of the origin and spread of RNA polymerases (Kim and Higgs 2016). Red sites are polymerases, and orange sites are complementary strands. Non-functional strands are black. (a) The non-living state has a low density of non-functional strands. A single polymerase has been added in the center of this figure. (b) A living patch of polymerases and complements has spread from a single polymerase. Parameters $s = 0.01$, $r = 0.4$, $k = 25$, and $v = 1$.

in order to have significant catalytic ability; and on how rare catalytic sequences are, among random sequences. We do not know these things with any certainty. Some people have a gut reaction that polymerase ribozymes are just “too complicated” to have arisen from random chemistry. However, it should be remembered that rare events are not equivalent to miracles. If an event occurs only once on a whole planet in a billion years, then it is quite likely to have occurred once on a planet of the Earth’s age (4.5 billion years). There are now known to be many potentially habitable planets in our own neighborhood of the galaxy (Petigura et al. 2013); hence, with numbers such as those above, life would be frequent in our galaxy. We will return to some of these questions later, after considering another possibility that can arise in a chemical system with s , r , and k reactions.

6.2.3 CHEMICAL EVOLUTION IS ENABLED BY THE r REACTION
