We already emphasized that a replicator with high k can sustain itself, even if s and r are zero. However, a replicator with high r can also sustain itself if s and k are zero. In Equation 6.2.1, it is easy to see that if s and k are zero, there is a stationary solution with non-zero replicator concentration if $r > v$. In a spatial model, the minimum replication rate necessary for survival, r_{min} , is greater than v , because the replicators grow in clusters and cannot grow into sites that are already occupied. For a square lattice in which growth occurs into the eight surrounding lattice sites, r_{min} is approximately $1.4v$. The numerical constant does not matter very much, however. For any model of this type, there is always an r_{min} , such that replicators can survive if $r > r_{min}$. This says that the rate of the templating reaction has to be fast enough that a typical strand generates at least one surviving complementary strand before it is hydrolyzed or lost from the system.

It might also seem unlikely that this scenario could occur in the real world. We are used to the idea that organisms have very large genomes that are very accurately replicated because highly evolved polymerase proteins catalyze the replication. However, on the prebiotic Earth, we don’t need to replicate whole genomes. If oligomers of just a few tens of nucleotides could be replicated by the r reaction, this would have huge importance for understanding the origin of life.

[Figure 6.2.3](#) illustrates replicating strands with r above and below r_{min} . New random sequences are generated by the s reaction at a low rate. Each of these is colored a different shade of green to emphasize that these are all different. The complementary (plus and minus) strands of each sequence are given the same color. Replication produces patches of related sequences of the same color. If $r < r_{min}$, these patches consist of just a few strands. If $r > r_{min}$, the patches fill the whole surface and the different strands compete for resources/space.

[Figure 6.2.3](#) is an example of what I will call “chemical evolution.” I will use this term in a precise way to indicate a stage on the path to the origin of life that is different from “just chemistry” and different from fully fledged biological

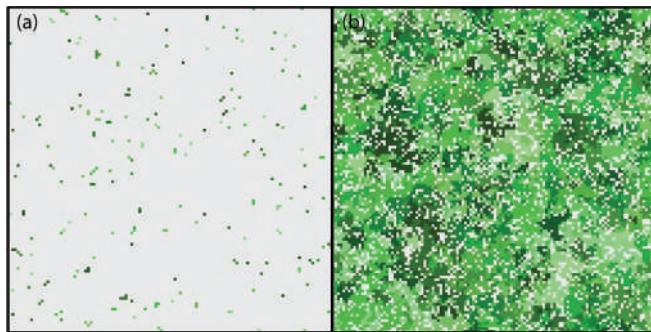

FIGURE 6.2.3 Model of chemical evolution of non-functional RNA templates. (a) $r = 0.4$. Sequences cannot spread. (b) $r = 5$. Patches of different sequences (illustrated by different shades of green) spread across the whole surface. Empty sites are gray. $s = 0.01$ and $v = 1$ in both figures.

evolution (Higgs 2017). Evolution via natural selection is often considered to be a defining feature of life. If sustainable replication occurs, whether by the r or the k reaction, then evolution is possible. A variety of sequences will arise that replicate at different rates, and replication will pass on the properties of the parent sequence. If there is no replication of either kind, then it is still possible to have selection to a limited extent, but there is no evolution. For example, suppose that spontaneous chemistry generates a range of random oligomers and that these oligomers have different mean life times because they differ in physical properties such as melting temperature of secondary structures, strength of binding to surfaces, and susceptibility to hydrolysis. These oligomers will end up with different concentrations in the mixture. In other words, selection can happen to a certain extent, but when there is no replication present, the differences in concentrations remain small and proportional to the difference in the physical properties. However, if the oligomers can replicate (by the r reaction), then differences in concentrations build up and the steady-state concentrations vary over a range that is much greater than the range of differences of the physical properties, as I have previously shown (Higgs 2017). This has also been emphasized by Chen and Nowak (2012), who use the term “pre-life” to describe the case of selection without replication, where small differences in rate constants give rise to small differences in concentrations.

The oligomer system described earlier shows evolution by natural selection when replication is present. Nevertheless, it is still much simpler than the kind of evolution that most biologists are used to thinking about. For this reason, I will distinguish between what I will call “chemical evolution” and “biological evolution.” The first distinguishing feature of chemical evolution is that it deals with molecules that are simple enough to be generated by spontaneous synthesis, as well as by replication. In biological evolution (i.e., the evolution of genes and proteins in modern organisms), we are dealing with sequences that are too long to be created from scratch; hence,

chemical synthesis is not relevant. The only way to make another copy is by replicating an existing sequence. Variant sequences arise by mutations, i.e. by errors in replicating existing sequences. On the other hand, if we consider short oligomers, as envisaged in the previous paragraph, then these are still simple enough to be made chemically from scratch, as well as by replication of existing oligomers. Thus, random chemical synthesis is a significant source of new sequence diversity, which in some cases could be larger than the diversity generated by errors in replication.

The second distinguishing feature of chemical evolution is that selection acts mostly on physical properties of the molecule rather than encoded properties. We are used to thinking of biological evolution, where selection acts on the encoded properties of gene sequences. For example, a particular gene sequence makes a particular protein enzyme that makes a color pigment that makes a flower more attractive to the bee. However, at the chemical evolution level, selection acts directly on the properties of the molecule. In the oligomer example, properties such as surface binding and susceptibility to hydrolysis are relevant. These are properties possessed by all short oligomers. In contrast, having an encoded function is a rare property of long information-carrying molecules. Most DNA sequences do not encode a protein with a useful function.

In the RNA World, the separation of genotype and phenotype is not as clear as it is in modern organisms, because replicating RNAs have to act as both a template and a catalyst. However, if we have reached the stage of functional polymerase ribozymes (as in [Section 6.2.2](#)), then we have reached what I consider to be biological evolution. The ribozyme would be quite long (maybe a hundred or more nucleotides), and it could not be synthesized again by random polymerization. It would be relatively sensitive to mutations, with many deleterious mutations that would destroy its function and a small number of beneficial mutations that might improve its catalytic ability. If we added the possibility of beneficial mutations to the polymerase system in [Figure 6.2.2](#), then better ribozymes would evolve.

The common evolutionary definition of life states that “life is a self-sustained chemical system capable of undergoing Darwinian evolution” (Joyce 1994). This means that an RNA World sustained by a polymerase ribozyme would count as living. On the other hand, if there is no polymerase, as in [Figure 6.2.3](#), then we are envisaging a situation where the r reaction is sufficient to allow replication of short oligomers but insufficient to replicate long sequences with encoded function (like ribozymes). Such a system still satisfies the evolutionary definition of life because it has Darwinian evolution with heredity and natural selection. However, I would prefer not to call it living. I have advocated (Higgs 2017) a stricter evolutionary definition of life, where the requirement is for biological evolution and not just chemical evolution. Biological evolution is defined (in a non-circular way) by the requirement that it involves sequences that are too long for spontaneous chemical synthesis to be relevant and are long enough to have encoded function. Additionally,

biological evolution is complex enough to be open ended and not repeatable, whereas chemical evolution occurs in a relatively small sequence space and is likely to result in the same outcome if we start again from the same initial conditions.

Whether a system of oligomers replicating by the r reaction counts as alive is, of course, simply a matter of definition. Here, I want to turn away from the definition question and consider the significance of chemical evolution for the origin of life. The essential point so far is that, if short sequences can replicate without the necessity of a biological catalyst, this makes a lot of difference to scenarios for the RNA World and the origin of life, as we shall now consider.

6.2.4 SCENARIOS FOR THE ORIGIN OF LIFE AT LOW r AND HIGH r

The way we envisage the origin of life depends a lot on how effective was the r reaction. Table 6.2.1 summarizes important differences between cases where r is above and below r_{min} . First, if $r < r_{min}$, a single short sequence formed spontaneously will tend to be destroyed faster than it replicates. Therefore, there is no heredity and evolution. There may be a diverse mixture of sequences, but the common components of this mixture will stay the same over time, because short oligomers will be continually reformed. However, we are presuming that functional ribozymes must be quite long and that they are rare in sequence space. In the low- r scenario, it is necessary for relatively long sequences to be formed chemically. As a round number, let us suppose that there is a polymerase ribozyme of length 100 nucleotides. If we (optimistically) presume that chemistry generates an appreciable total concentration of 100-mers, there are still 4^{100} possible 100-mers, so there will never be more than a handful of copies of any one sequence. Of course, there are many sequences that fold to a given secondary structure, as we know from computational studies of RNA folding (Szilagyi et al. 2014) and also from the diversity of biological molecules such as tRNAs (Jühling et al. 2009), whose sequences differ widely, despite having the same structure and function in different organisms. Thus, we are searching for *any* sequence that has a ribozyme function,

not for one specific RNA out of 4^{100} . Even accounting for this, however, it is likely that functional sequences will be rare in the mixture generated by chemistry. This means that the origin of life is stochastic: we may have to wait for some unpredictably long time before any functional sequence is generated at all.

For replication to begin with a polymerase ribozyme, there needs to be a minimum of one polymerase and one complement (or two polymerases). Therefore, it is necessary for r to be non-zero, even in the low- r scenario. This is what the simulation shows in Figure 6.2.2. If a single P or C arises by the s reaction, there is an appreciable probability that the complement (C or P) is created by the r reaction and that the P begins to copy the C before either of them is destroyed. Once we get beyond a handful of sequences of both strands, the spread of the polymerase is deterministic because not all copies of the polymerase will be destroyed at the same time. Although not every single polymerase that arises will generate a stable spreading cluster, we have shown (Shay et al. 2015) that there is a relatively high probability of the cluster spreading, assuming that the k rate of the polymerase is high. Hence, the major stochastic element of this scenario is waiting for the polymerase with high k , rather than the difficulty of the polymerase spreading once it arises.

It should also be clear that, in the low- r scenario, the first ribozyme must be a polymerase—that is, it must have a k rate. Many other beneficial functions of ribozymes can be envisaged, for example, nucleotide synthetases; or ribozymes that make sugars, nucleobases, and lipids; or any other ribozyme with a function that contributes to the formation or survival of RNAs in its vicinity. However, if the ribozyme has some beneficial property that does not directly create another copy of itself, and if it cannot replicate by the r reaction, then the beneficial property will disappear after the finite life time of the original molecule.

A variation on this argument is possible if r is only slightly below r_{min} . Suppose a ribozyme arises with a beneficial function, such as a nucleotide synthetase. It causes an increase in concentration of nucleotides in its vicinity, which increases the rate of the r reaction. If the original r is not too low, then the increase might cause it to rise above r_{min} , in which case a cluster of sequences containing the nucleotide synthetase

TABLE 6.2.1
Comparison of Scenarios for the Origin of Life, with Low and High Rates of Template-Directed Replication r

Low- r Scenario ($r < r_{min}$)

No significant chemical evolution before the origin of ribozymes. Biological evolution is enabled by the polymerase.
The origin of life is stochastic. Wait for a rare sequence and then wait for the establishment of a growing patch.
The first ribozyme must be a polymerase.
Once the k reaction is established, s and r are no longer required. Life can move outside the initial environment.

High- r Scenario ($r > r_{min}$)

Significant chemical evolution before the origin of ribozymes.
Chemical evolution of short strands is deterministic. Still need to wait for a rare sequence to initiate catalysis.
The first ribozyme could be a polymerase or nucleotide synthetase or any beneficial function. Maybe there was no polymerase at all.
Constrained to an environment where $r > r_{min}$ unless a polymerase subsequently evolves.

can spread. In this variant scenario, the nucleotide synthetase is affecting its local environment. It is important that the nucleotides it generates remain close by, so that it directly benefits itself and copies of itself on neighboring sites. In this case, it can spread in a cluster in the same way as a polymerase that performs the k reaction. The variant case is also similar to the original low- r case, because it requires waiting in the non-living state for a long time until the beneficial function arises in the mixture of random sequences.

Let us now contrast the high- r case with the low- r case. If $r > r_{min}$, sequences do not need to have a function in order to spread. Any sequence that is a template can replicate via the r reaction. Chemical evolution is possible, as described in [Section 6.2.3](#). Since sequences are likely to differ in their ability to be templates, then we expect short strands to evolve with sequences that are efficient templates. This differs from the low- r scenario in that the concentration of strands will be high even before ribozyme function has evolved, and there will be chemical evolution of non-random properties of the sequences. So far, this scenario is not a stochastic one. We would expect the same simple physical properties (templating ability, stability against hydrolysis, etc.) to evolve in a repeatable way.

Thus, if $r > r_{min}$, we reach a state with simple replicating strands with no function other than to be templates. This system would not count as living, but if a functional ribozyme arises and spreads within this state, then we switch from chemical evolution to biological evolution, and the system becomes living, by my definition ([Higgs 2017](#)). In the chemically evolving system, there will be clusters with multiple copies of each sequence. If a ribozyme does arise by random chemistry, there will usually be many copies of the functional strand and its complement. Hence, the spread of a beneficial ribozyme, when it arises, should also be fairly deterministic. Nevertheless, this does not get around the fact that long sequences may be rare in the mixture and that the fraction of functional sequences of a given length may be very small, which is the same issue, whether r is high or low. Hence, there may still be an unpredictably long waiting time until the first catalyst arises.

Another important point is that it is easier for ribozymes to evolve with functions other than polymerases if r is high than it is if r is low. A template strand can spread and reach multiple copies, even if it has no function. If it does have a beneficial function of any type, it is relatively easy for this to feed back to the replication rate of this strand. If a nucleotide synthetase arises, then any slight increase in the r rate that this causes will be beneficial. It does not have to tip the balance from below to above r_{min} , since the chemical environment is already giving us an r greater than r_{min} . The beneficial effects of the ribozyme need not be so local, as in the previous case, because there will be relatively large clusters of each sequence, even before the function arises. A computational model that simulates this case is the metabolic replicator model ([Könnyű et al. 2008; Könnyű and Czárán 2013; Czárán et al. 2015](#)). A metabolic replicator is any ribozyme that increases the local rate of

replication by the r reaction. It has been shown that systems with multiple types of metabolic replicators that contribute in different ways to increasing the replication rate can evolve together in a surface-based model. Szostak (2012) has reviewed the possibility that RNA replication could be sustained by the r reaction and has also pointed out that it is possible for metabolic ribozymes to arise before polymerases in this case. He envisages RNA replication inside protocells and therefore suggests that a ribozyme catalyzing lipid synthesis would confer a benefit on the protocells that contain it.

If r is sufficient for only short oligomers to replicate, then it is still possible for chemical evolution of the short oligomers to occur. However, if replication of metabolic ribozymes is to be sustained by the r reaction, then the r reaction must function efficiently for sequences that are long enough to be ribozymes. These other ribozymes are potentially as long and as sensitive to mutational error as a polymerase would be. Thus, even if r is high, we cannot avoid the necessity to accurately replicate long sequences.

In the low- r case, the polymerase can spread under its own k reaction. Therefore, it can spread into environments where there is no s or r reaction at all. The example in [Figure 6.2.4a](#) shows a polymerase cluster spreading under the k reaction in the case where s and r are zero. In contrast, in the high- r case, replication is provided “for free” by the chemistry of the r reaction. Therefore, other metabolic functions can evolve without a polymerase, but the system will be constrained to the environment in which $r > r_{min}$, unless it subsequently evolves a polymerase. We have discussed the possibility that other ribozymes could evolve first in the high- r case. But it could also be the case that a polymerase evolves first in the high- r case too. [Figure 6.2.4b](#) shows a simulation in which a single polymerase is added into a region of non-functional strands replicating via the r reaction in the high- r case. A cluster of polymerases and complements is able to spread and displace the non-functional strands.

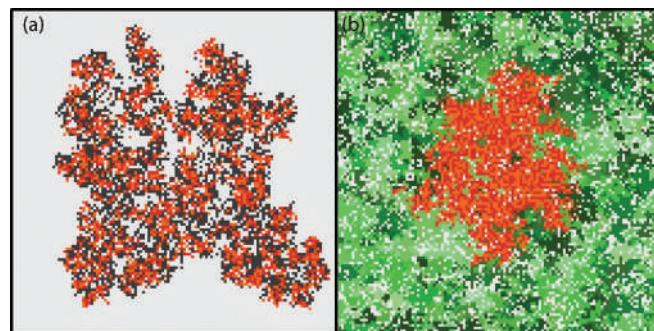

FIGURE 6.2.4 (a) Spread of a polymerase in an environment where s and r are zero. The polymerase must survive against non-functional parasites (black) that arise by deleterious mutation. In this example, $M = 12\%$. (b) Spread of a polymerase into an environment with $s = 0.01$ and $r = 5$. The polymerase must outcompete non-functional strands (green) created by chemistry, which are common in this case.

6.2.5 COOPERATION IN RNA SYSTEMS

An essential point for evolution in the RNA World is that a polymerase ribozyme can copy another template strand but cannot copy itself. The survival of the polymerases therefore requires cooperation between a group of molecules that replicate one another. Non-functional strands act as parasites of polymerases because polymerases spend their time replicating the non-functional strands, instead of replicating other polymerases, and because non-functional strands consume resources (monomers and space *etc.*) that could otherwise be used by the polymerases. There are two distinct ways in which non-functional strands arise, illustrated in [Figure 6.2.4](#). In the low- r case, the density of random strands created by s and r reactions is low. The principal source of non-functional strands is deleterious mutations. In [Figure 6.2.4a](#), s and r are zero, so the only non-functional strands are deleterious mutations (shown in black), which are created with a mutation probability $M = 12\%$ on replication of either a polymerase or complement. In the high- r case in [Figure 6.2.4b](#), the density of random strands made by s and r reactions is high (shown in green). This example has $M = 0$, so the only non-functional strands are made by chemical synthesis and not by mutation (although mutation could easily be added to this simulation as well). Recall that whether the main source of diversity came from chemical synthesis or mutation was a key factor used in [Sections 6.2.3](#) and [6.2.4](#) to distinguish chemical and biological evolution. In both parts of [Figure 6.2.4](#), the polymerases are functioning as cooperators in the evolutionary sense. Each polymerase benefits its neighbors and does not directly benefit itself. We now consider the factors that allow the evolution of cooperative polymerases.

The simplest description of a chemical reaction system is “well-mixed,” *that is*, molecules encounter one another randomly in proportion to their concentration. For the case of polymerases, complements, and parasites that we are discussing, a set of time-dependent differential equations for the concentrations in the well-mixed case can be easily written down (Shay et al. 2015; Kim and Higgs 2016). However, this approach leads to the conclusion that, unless the mutation rate is exactly zero, parasite strands always drive the polymerases to extinction. If s and r are zero, then replication of the parasites depends on the polymerases; hence, the parasites also become extinct if the polymerases disappear. This result depends on the assumption that the polymerase replicates parasite and functional strands at an equal rate but that mutation always favors the parasites. The latter point is true because it is easy for errors in replication of functional strands to create non-functional parasites but very unlikely that a beneficial mutation in a random strand will create a functional polymerase. Thus, for any $M > 0$, the parasites always accumulate and destroy the system. Any real molecular replication process would never be perfectly accurate, but even if we do set M to zero in the model, a polymerase is only neutral with respect to other non-functional strands, because the benefit it provides to the other strands is equal to the benefit that it provides to itself. Hence, a polymerase cannot spread by natural selection in a well-mixed system.

In order for a polymerase to survive and spread, it needs to encounter other polymerases more frequently than it would in a well-mixed system. Spatial structure is one way in which this can occur. In the two-dimensional surface models shown in [Figures 6.2.2–6.2.4](#), a newly synthesized strand is placed on a neighboring site to the template strand. This means that there is clustering of polymerases and templates. Polymerases are more likely to be next to other polymerases and complements and less likely to be next to parasites. Hence, clustering gives an advantage to polymerases that can outweigh the mutational disadvantage. In spatial models, a polymerase can survive as long as M is less than some critical error rate M_{max} .

The term error threshold is usually used to denote the maximum error rate at which a functional replicator can survive (Eigen et al. 1988). The original theory describes independent replicators (equivalent to the r reaction in our terminology). In this case, the advantage of the functional sequence is that it has a higher r rate. In the RNA polymerase models that we are discussing here, replication is via the k reaction and the advantage of the polymerase comes from spatial clustering, not from faster replication. These two cases are qualitatively similar, so we will also use the error threshold term. We have discussed the details of error thresholds in polymerase models elsewhere (Shay et al. 2015; Kim and Higgs 2016; Tupper and Higgs 2017). [Figure 6.2.4a](#) illustrates a case where $M < M_{max}$. The polymerases can spread, although there is always a finite concentration of parasites mixed in, because parasites are continually being created by mutation. [Figure 6.2.4b](#) illustrates the case where $M = 0$. Parasites are present due to the r reaction. The polymerase spreads because of the advantage of spatial clustering, whereas it would be only neutral in the well-mixed case.

There are many other two-dimensional computational models that predict that cooperative replicators can survive as a result of clustering and spatial pattern formation (Boerlijst and Hogeweg 1991; McCaskill et al. 2001; Szabo et al. 2002; Takeuchi and Hogeweg 2009, 2012). It should be realized, however, that there is nothing special about two dimensions. A three-dimensional lattice model would behave in a similar way (although would be more difficult to visualize). What is important is that spatial clustering only builds up if diffusion is slow. In previous papers, we have allowed diffusion of strands into neighboring sites. If diffusion becomes faster than the birth and death of strands, then the system becomes well mixed and the parasites destroy the system (Shay et al. 2015; Kim and Higgs 2016). It seems reasonable to envisage two-dimensional systems where strands are bound to surfaces and where diffusion along the surface might be slow. A mineral surface might actually catalyze the RNA polymerization process, as is known in experiments with Montmorillonite clay (Huang and Ferris 2006; Joshi et al. 2009). Systems of RNA between stacked lipid bilayers are close to two-dimensional systems (Rajamani et al. 2008; Mungi and Rajamani 2015). It might also be possible to envisage three-dimensional systems where diffusion would be slow, such as a network of pores in a rock (Koonin and Martin 2005). However, in an open-water system in three dimensions, diffusion would lead to mixing on a scale faster than replication.

Other aspects of the parasite problem are that shorter sequences will replicate faster and there will be a tendency for short parasites to arise that replicate much faster than full-length functional polymerases. This is reminiscent of the experiments in which Q β RNA is replicated in vitro by a polymerase protein (Mills et al. 1967), where short RNAs arise that are rapidly copied by the protein but have lost the information on the original viral genome. We have simulated a case in which termination of replication can occur prior to the end of the sequence (Tupper and Higgs 2017). This creates parasites of all lengths shorter than the polymerase. The polymerase is still able to survive in a spatial model, and we observe interesting traveling wave patterns in which parasites chase polymerases but do not manage to destroy them. The error threshold for termination errors (which create short parasites) is much lower than for point mutations (which create parasites of equal length to the polymerases).

One way in which a polymerase might lessen the impact of parasites is to use a tag (Wu et al. 2017), which is a short sequence at the beginning of a strand, recognized by the polymerase. Only sequences that begin with the tag sequence are replicated. The complement of the tag sequence has to be at the end of the strand, so that the complementary strand also has the tag at the beginning. This mechanism makes almost no difference to parasites generated by point mutations, because the tags will inevitably be much shorter than the functional part of the ribozyme and any parasite that has a mutation in the main part of the sequence will still have the tags. However, for short parasites created by termination errors, the end tag would be missing and the complementary strand of the parasite would not be recognized by the polymerase. Thus, the tag mechanism would go a long way toward stabilizing the polymerase against short parasites that have arisen via termination errors.

An alternative way in which polymerases can survive against parasites is via compartmentalization in protocells (lipid vesicles). In protocell models, strands within the same compartment are well mixed, but they do not interact with strands in other compartments. Protocells divide randomly when they reach a specified maximum size. The time taken to reach this size depends on the composition. Hence, compartments with few parasitic strands will grow and divide faster than compartments that are overrun with parasites. Group selection at the protocell level benefits polymerases and can outweigh individual selection at the molecular level, which would benefit parasites. Once again, a variety of computational models shows that compartmentalization allows the survival of cooperative replicators (Szathmáry et al. 2005; Takeuchi and Hogeweg 2009; Zintzaras et al. 2010; Bianconi et al. 2013). This effect has also been realized in experimental systems involving vesicles containing RNAs that are replicated by a protein polymerase (Matsumura et al. 2016).

The evolution of cooperation is a very broad field in evolutionary biology, because it spans many different levels, from molecules to cells, to multicellular organisms, to social groups. The major transitions in evolution are important stages in the history of life on Earth in which entities of higher complexity have arisen via cooperation of entities at a lower

level (Szathmáry and Maynard Smith 1995). A system of five mechanisms for the evolution of cooperation has been proposed (Nowak 2006), and RNA polymerase systems exhibit several of these mechanisms.

In addition to the cooperation between groups of polymerases discussed so far, RNAs can also exhibit cooperation in two other senses (Higgs and Lehman 2015). First, we can envisage the formation of an autocatalytic set of mutually dependent strands, where no single strand can replicate itself but the set as a whole can replicate. Experimental systems of this nature have been realized with RNAs (Lincoln and Joyce 2009; Vaidya et al. 2012; Mathis et al. 2017). These examples are close to the general theoretical models of autocatalytic sets (Hordijk and Steel 2013). Second, strands that assemble into a larger complex via secondary structure formation are cooperative if the complex has a function but none of the component strands has a function on its own, for example, recombinase ribozymes assembled from smaller strands (Hayden et al. 2008).

6.2.6 EVOLUTIONARY QUESTIONS

In this section, we will consider how RNA replicators might evolve toward modern organisms. It should be realized that, although modern organisms contain complex genetic networks, these do not resemble the networks of reactions in autocatalytic sets. In autocatalytic set models, each type of strand catalyzes a specific reaction that is required for replication of the set. Each strand in these models is part of the replication process, even though none of them can replicate independently. In contrast, in the genetic systems of modern organisms, there is one system for DNA replication that can replicate the whole genome. Only a very small number of genes are directly connected to replication. The majority of genes have functions related to metabolism or structure of the organism. These genes contribute to fitness, but they are not part of the replication machinery. If we want to understand the pathway from RNA replicators to modern organisms, then we are led to consider a system of multiple ribozymes having different functions, only one of which is a polymerase. If an RNA polymerase that works with general template sequences has already arisen, then it is possible for ribozymes with different functions to work in cooperation with the polymerase, because all these other ribozymes would be copied by the same polymerase.

[Figure 6.2.5](#) shows a hypothetical schematic network of chemical reactions that would be required to generate a supply of nucleotides from small molecules that are abundant in the environment. There would presumably be many reaction steps (thick straight arrows) involving organic molecules that are precursors to nucleotide synthesis. In order for the RNA World to get going at all, all these steps must have occurred chemically to some extent in the environment in which life evolved. Thin curly arrows indicate ribozymes that catalyze some or all of these steps. A polymerase ribozyme would catalyze the last of these steps: synthesis of new strands from nucleotides. If any of the steps was catalyzed by ribozymes, it would lead to faster replication by one means or another.

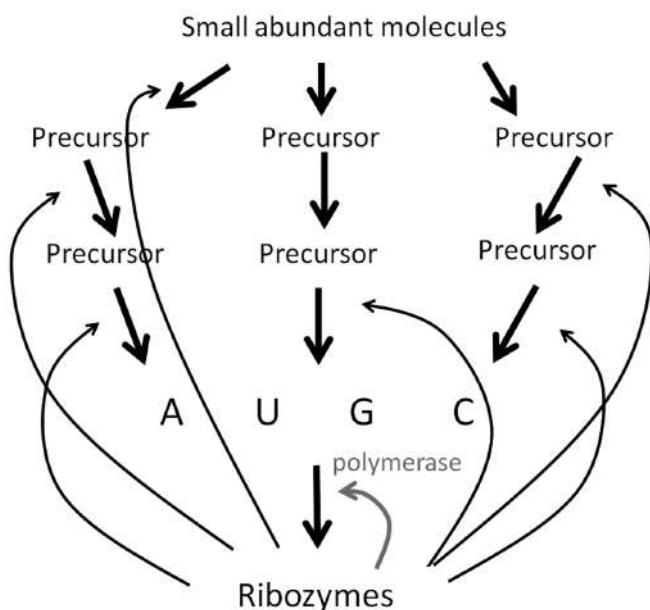

FIGURE 6.2.5 Can we envisage a system of many different cooperating ribozymes? Only one of these ribozymes needs be a polymerase. The others would be metabolic ribozymes that control all the steps of nucleic acid synthesis.

There is a long-standing debate about whether life arose via metabolism or replication first. The evolutionary definition of life requires Darwinian evolution, which means that the origin of life is more or less synonymous with the origin of sequence replication. This is especially true if we use the criterion of biological evolution that I have proposed (Higgs 2017), which requires that there must be molecules sufficiently long that they can only be synthesized by copying previous molecules and not by spontaneous synthesis. Under this definition, proposals of compositional evolution of small molecules that might occur without sequence information (Markovitch and Lancet 2012) would not qualify as life. However, the real scientific question here is not whether a small molecule reaction network should be defined as living but what was the nature of the small molecule reaction network that generated RNAs. It is clear that many steps are required to build up nucleotides. It has often been proposed that this can arise only if there is a small molecule metabolism preceding replication (Shapiro 2000, 2006), but this still has little experimental support (Anet 2004). Although some kind of reaction network must have existed, the reaction network that created nucleotides need not have been autocatalytic or evolving—it simply needed to make lots of nucleotides in a repeatable way, until sequences that initiated the autocatalysis were eventually formed. In my view, therefore, autocatalysis and life begin at the point where replication of autocatalytic sequences is possible and metabolism begins at the point where a significant number of reaction steps in the precursor network become catalyzed by ribozymes.

In Section 6.2.4, we argued that it is most likely that the polymerase was first, according to the low- r picture, whereas according to the high- r picture, a ribozyme that

catalyzed either polymerization or any of the metabolic steps could have been selected first, if its effects were sufficiently localized to benefit itself. If a network such as Figure 6.2.5 is to evolve, it must be possible to build it up by stepwise addition of new ribozymes. We have started to do this by studying the conditions under which a nucleotide synthetase can be added to a replicating system controlled by a polymerase (Kim and Higgs 2016). The two ribozymes are on separate strands, and each one is subject to deleterious mutations that create non-functional parasites. It is clear that the functions of these two ribozymes are complementary, as the nucleotide synthetase produces monomers that speed up the polymerization rate and the polymerase copies the synthetase. If there is a supply of monomers by chemical synthesis, then the polymerase can survive on its own (as in all the examples in the figures of this chapter). If there is no chemical supply of monomers, then the only monomers present are those created by the synthetase. In this case, each ribozyme is completely dependent on the other. We have shown (Kim and Higgs 2016) that there are parameter ranges where the two independent cooperating ribozymes can coexist, including cases where there is no chemical supply of monomers. This demonstrates that building up more complex ribozyme systems in a surface model is possible in principle. It also shows that the two-ribozyme system could move into environments where the single-polymerase system could not go alone. Other computational models (Ma et al. 2007, 2010; Ma and Hu 2012) have also considered replicating RNA systems controlled by a variety of different kinds of ribozyme functioning singly or in association and have emphasized the important role that nucleotide synthetases could have played.

However, there are considerable difficulties associated with getting ribozymes to work together, even when they have complementary functions (Kim and Higgs 2016). First, we have shown that the nucleotide synthetase can coexist with the polymerase only if its length is within a range that is comparable to the length of the polymerase. If the synthetase is too long, it replicates too slowly and dies out, leaving the polymerase working alone. If the synthetase is too short, it replicates too fast, which causes the extinction of both ribozymes. Another important factor is the diffusion rate of the monomers produced by the synthetase. If monomers diffuse rapidly, they benefit non-functional synthetases as much as functional ones. In this case, the functional synthetases are destroyed by parasites. If monomers diffuse too slowly, they do not reach the sites where the polymerase can use them. We have not yet tried to simulate a system with more than two independent ribozymes, but we expect that it will become increasingly difficult to find regions of coexistence as more ribozymes are added. Other studies of metabolic replicators (Könnyű et al. 2008; Könnyű and Czárán 2013; Czárán et al. 2015) have found coexistence of multiple ribozymes in surface-based models. However, these models do not have a polymerase (replication is r not k), so there is no requirement for metabolic ribozymes to occupy neighboring sites to the polymerase, as there is in our model of polymerases plus synthetases.

A quick glance at real biology gives us two important clues as to how life solved the problem of building up genetic systems with multiple functions: cells and chromosomes. We are currently investigating protocell models in order to compare these systems with surface models. Our work in progress suggests that it is considerably easier to get independent replicators to coexist in compartments than on surfaces. It also appears that error thresholds are higher in protocell models than in equivalent surface models. Protocell models also solve many of the problems related to diffusion of small molecules such as monomers and metabolites, as there is free mixing within the compartment, but useful molecules produced within one compartment do not benefit other compartments. The existence of membranes in the protocell brings additional problems, however. There needs to be a way to synthesize the lipids of the membranes (unless these are already present in large amounts from prebiotic chemistry), and there needs to be a way to transport small polar molecules across membranes, when required. The other important factor seen in biology is linkage of genes onto chromosomes. If we link two genes with complementary functions together, there is an advantage that they are always found together when needed together, but there is a disadvantage that a longer strand replicates more slowly than a shorter one. Mathematical models have previously shown (Maynard Smith and Szathmary 1993) that linkage can be favored in protocell models. We also expect that linkage can be favored in surface models. There are a lot of remaining questions about how chromosomes with multiple genes can be built up and whether this requires a compartmentalized protocell system to be already in operation.

The usual view of the RNA World is that it sowed the seeds of its own downfall, *that is*, ribozymes were doing just fine until ribosomes evolved and protein synthesis began, at which point proteins took over the catalytic roles and nucleic acids retained the genetic role. However, from the relics of the RNA World remaining in modern organisms (Jeffares et al. 1998), there is little evidence about how wide a range of metabolic functions might have been possessed by the RNA World. When we consider an RNA-based organism with a metabolic network such as [Figure 6.2.5](#), we are speculating without any direct evidence from modern biology that these ribozymes existed. If we begin with a comparative evolutionary study of extant organisms, then we are immediately struck by the fact that there is one very obvious ribozyme—the ribosome—shared by all forms of cellular life. Ribosomal RNA genes, together with a few protein-coding genes closely associated with translation, are almost the only genes that are homologous across all domains of life. It is therefore clear that the ribosome appeared very early in evolution. I want to finish this section by considering the hypothesis that the ribosome could have evolved without needing to pass through a stage with RNA-catalyzed RNA replication.

Fox and co-workers studying the evolution of the ribosome have noted that both the peptidyl transferase center (the core part of the ribosome that catalyzes peptide bond formation) and tRNAs are less than 100 nucleotides in length and that

“their importance supports the notion that the translation machinery was originally a discovery of the RNA World” (Fox 2010). They have proposed that a protoribosome, having the ability to synthesize peptides, may have been one of the first ribozymes and that “the peptides produced by the protoribosome may have acquired the ability to replicate RNA before RNA-based RNA replicases could evolve in the RNA World. Alternatively, an RNA-peptide complex may have been the first to accomplish the task. In either case, the transition from the RNA World to an RNA-Protein World may have occurred much more rapidly and easily than is traditionally thought” (Fox et al. 2012). This hypothesis acknowledges that RNA was important early on and that some kinds of ribozymes existed (in particular the protoribosome), but it argues that there was never an RNA polymerase composed solely of RNA. This view has been elaborated recently by (Bowman et al. 2015), who propose that “There simply were not any sophisticated enzymes (ribozymes or other catalytic polymers) predating the emergence of the ribosome. In this scenario, the ancestral ribosome arose when building blocks for RNA, or proto-RNA, were provided by abiotic processes.”

When evaluating this hypothesis from the perspective of a theoretical biologist, my first question is to ask whether I could get a computational model to work in this way. I have not actually done this, but I am fairly sure that I could. The model would be rather similar to the high-*r* scenario, where the nucleotide synthetase evolves first. We would need to propose a ribozyme (the protoribosome) that synthesizes peptides. The replication of the ribozyme would have to be by the *r* reaction, because there is no polymerase. The peptides produced by the ribozyme would have to benefit the ribozyme somehow. With a nucleotide synthetase, it is clear that the increased concentration of monomers makes the replication go faster. With peptides, it is less clear what the benefit is. We could propose that peptides bind to RNA strands in their neighborhood and protect them from degradation—making their life time longer. Or, we could propose that peptides bind to double-stranded pieces of RNA in a non-specific way, making the rate of polymerization faster (this would be a primitive kind of peptide polymerase). Either of these things could be put into a model, and I am pretty sure that we could demonstrate survival and spread of the protoribosome within the model.

However, even though this scenario seems to pass the evolutionary logic test, it still appears unlikely. It should be remembered that this will only work if the *r* reaction is fast enough and accurate enough to replicate strands long enough to be ribozymes and that we do not have clear evidence that random peptides do benefit RNA strands in either of the ways proposed above. It is important that the mechanism has to work with random peptides and not with encoded proteins. While it is clear that specific encoded protein sequences could bind and stabilize the protoribosome and that specific proteins could act as RNA polymerases, it seems highly unlikely that a mixture of random peptides—all different from one another—could do these things. If we hypothesize that the protoribosome was actually decoding mRNAs, then we dramatically increase the complexity of the

protoribosome. It would have to have parts that associate with tRNAs and mRNAs and would have to move processively along the mRNA. There would have to be a set of tRNAs and a way of charging them with specific amino acids. All these different RNA strands would have to be replicated without a polymerase. Any argument that requires the whole translation system and genetic code to come into being simultaneously seems untenable. So, any argument that puts the peptidyl transferase center before (or instead of) an RNA polymerase would have to establish that random peptides give a direct benefit to the ribozyme.

In conclusion, let us remember how simple it would be if there were a single ribozyme that could increase the rate of RNA polymerization in some way. The first polymerase does not need to be processive. Given that the *r* reaction must be happening, there will be sites where short oligomers are bound to a longer template. Maybe the first polymerase simply binds to regions of double strands and stabilizes them for long enough to enable subsequent oligomers to join to the end of the strand. Maybe it recognizes places where the ends of two short oligomers are side by side on the same template, and it stabilizes this configuration until the bond is formed. These would be relatively simple mechanisms by which the first ribozyme with a *k*-type function might operate. It should also be remembered that the *r* reaction enables the evolution of specific RNA sequences that are selected for function, whereas the scenarios in which peptides act as polymerases (as in the above quote from Fox et al. 2012) would have to work with random peptides.

6.2.7 GETTING BACK TO REAL CHEMISTRY

Although a lot can be concluded from simulations of simple models, for these results to be meaningful, it is necessary to establish that real molecules can do the things assumed in the simulations. We wish to emphasize that there is experimental support for all three of the reactions we have called *s*, *r*, and *k*.

Spontaneous RNA synthesis is difficult in aqueous solution because hydrolysis tends to proceed faster than polymerization. The balance can be tipped by using monomers activated with triphosphates or imidazoles, and there has been significant success with clay-catalyzed polymerization of activated nucleotides (Huang and Ferris 2006; Joshi et al. 2009; Burcar et al. 2015). There has been considerable recent interest in the idea that the origin of life might be in hydrothermal pools on land rather than in the deep sea (Damer and Deamer 2015; Pearce et al. 2017). Under such conditions, wetting and drying cycles can drive polymerization (DeGuzman et al. 2014; Mamajanov et al. 2014; Da Silva et al. 2015; Forsythe et al. 2015). While dry conditions favor polymerization via condensation reactions, molecules become immobile under completely dry conditions, in which case the reactions cannot occur. In the wet phase of the cycle, hydrolysis is faster than polymerization, but diffusion brings new molecules into proximity, which can then react in the next dry phase. Simulations show that this mechanism gives longer polymers than could be formed in either the wet or the dry phase alone (Higgs 2016). X-ray scattering analysis of nucleotides trapped between lipid bilayers also helps to illustrate the influence of

the lipid layers on RNA polymerization during wetting and drying cycles (Toppozini et al. 2013; Himbert et al. 2016).

Non-enzymatic template-directed replication has also been observed in the laboratory (Deck et al. 2011; Olasagasti et al. 2011). An important issue here is the relative rates of incorporation of correctly matching Watson-Crick pairs, GU wobble pairs, and mismatch errors. These rates have also been measured experimentally (Rajamani et al. 2010; Leu et al. 2011, 2013). Another important factor associated with non-enzymatic replication is that it will tend to give rise to stable double helices. Repeated replication therefore requires a mechanism to separate the strands, and it seems likely that temperature cycling could have played a role (Szostak 2012), and possibly also wet-dry cycling, as in the experiments with spontaneous polymerization. Cycling conditions of either kind keep the reactions out of equilibrium, which is probably important in creating long strands.

We have also studied the kinetics of templating reactions (Tupper et al. 2017) and proposed that templating can solve three types of problems associated with the RNA World by the same mechanism: the origin of homochirality, the selection of a limited set of ribonucleotides, and the regioselectivity of the backbone. The common feature of these problems is that uniform strands are better templates than non-uniform ones. Firstly, in the chirality problem, strands composed of only one of the two enantiomers are good templates, but mixed chirality strands are not. When the template-directed synthesis rate is high, the racemic mixture becomes unstable and chiral symmetry breaking occurs, resulting in a system dominated by one enantiomer or the other. Secondly, templating leads to the selection of a small alphabet of monomers with a particular backbone chemistry, for example, four kinds of nucleotides built from ribose sugars, rather than some random mixture of other sugars that would be expected in prebiotic chemical synthesis. Thirdly, templating favors strands with uniform bond structure (such as the regular 3'-5' bonds, rather than the mixtures of 2'-5' and 3'-5' bonds). We have shown that these latter two cases are closely analogous to the problem of chiral symmetry breaking (Tupper et al. 2017).

Ribozyme-catalyzed replication (*k* reaction) has also been studied experimentally, with gradual progress in the development of polymerases by *in vitro* evolution (Johnston et al. 2001; Lawrence and Bartel 2005; Zaher and Unrau 2007; Wochner et al. 2011; Attwater et al. 2013). Beyond polymerases, the list of functions that can be catalyzed by nucleic acids continues to expand (Breaker and Joyce 2014). The current situations with regard to the *s*, *r*, and *k* reactions seem to be rather similar: there is experimental support for all three, but there is not a cast-iron demonstration of any of them, and important problems remain. For the *s* reaction—can we show that wet-dry cycling can be done under conditions that do not lead to depurination of nucleotides? For the *r* reaction—can we achieve accurate replication of long strands on a time scale faster than hydrolysis of the strand? For the *k* reaction—can we find a polymerase that will replicate a template strand with its own sequence? Although the evidence is incomplete, the RNA World hypothesis has

much greater experimental and theoretical support than any of the alternatives. Therefore, personally, I am sticking to an “orthodox” RNA World point of view. That means it really was RNA first, not some alternative polymer; there really was a polymerase ribozyme; and the essential step for the origin of life was the origin of ribozyme-catalyzed RNA replication. Let us hope that concrete experimental information will lead either to more firm support of this view or to a well-supported alternative hypothesis in the not-too-distant future.

6.3.1 INTRODUCTION

6.3.1.1 SYSTEMS CHEMISTRY OF BIOMOLECULES

One of the most obvious relationships between biomolecular classes in living cells is the mutual interaction between nucleic acids and proteins. Of course, there is a plethora of interaction networks on the small molecule-metabolic level, and a mind-boggling spatio-temporal organization of all molecules and ions on a supra-supramolecular level of any living cell. These include “crowds” of membrane-affine macromolecules that are located in the vicinity of, or anchored to a surface of, the cell or some cellular organelle, all of which creates ion-conducting transport channels and three-dimensional (3D) spaces for the enrichment of crucial, chemically more or less labile metabolites (Spitzer and Poolman 2009; Spitzer 2011, see [Chapter 6.6](#)). However, all “nodes” of these metabolic transformation networks are kinetically strongly favored over other, in consequence, kinetically suppressed chemical reaction networks by proteins. A number of very slow chemical transformations are actually made possible by proteins, but many reactions are not nil without enzymes, only much slower, thence confronted with a much fiercer competition of unproductive “side reactions.”

Nucleic acids are synthesized by proteins where the polymerization process is driven by nucleoside triphosphate (NTP) alcoholysis, that is, when pyrophosphate anions in triphosphoric anhydrides of NTPs are replaced by 3'-hydroxy groups of mono-, oligo-, or polynucleotides. In order to prevent the reversed reaction, the system makes sure that pyrophosphate is permanently hydrolyzed to phosphate. Proteins are synthesized by nucleic acids, and their production is *indirectly* dynamically controlled through RNA-dependent gene regulation and by catalytically active RNA. By far, the most

abundant *direct* RNA catalysis is the ribosomal biosynthesis of proteins, being at its core a carboxyester aminolysis termed “peptidyl transfer” (PT) reaction (cf. [Sections 5.2.1.3](#) and [5.2.3.2](#)). The modern-day biosynthesis of proteins depends on the universal genetic code, also termed “primary code.” The “secondary code” is much less straightforward but prerequisite for the primary code to be operative, since it warrants for the attachment of all proteinogenic amino acids to their “cognate” (appropriate) transfer RNAs. This process is catalyzed by 20 different amino acid-specific proteins, aminoacyl RNA synthetases (ARS), that all recognize and bind their set of “isoaccepting” transfer RNAs, but also require, bind, and hydrolyze a high-energy metabolite, adenosine 5'-triphosphate (ATP). Ribosomes require another high-energy metabolite, guanosine triphosphate (GTP), in order to proceed reasonably error-free in the “wanted” (functional) direction. The ATP is produced by the membrane protein ATP synthase and is driven by a proton concentration difference being maintained across the membrane. Other NTPs are produced from many different enzymatically catalyzed reactions, one of which is a phosphate exchange with ATP. Hence, the mutual control between nucleic acids and proteins through the genetic code is connected to all other actors of the living cell through high-energy metabolites that need to be constantly “replenished” (re-phosphorylated). Many small metabolites, irrespective of whether they are phosphorylated or not, are composed of a distinct and well-controlled number of reduced carbon atoms—reduced with respect to the oxidation number +IV of carbon dioxide being the thermodynamically most stable form of carbon in the presence of other elements.

The chemical reaction networks realized by all small molecules, that is, metabolites of higher or lower chemical energy, guarantee for a stepwise controlled management of the cell’s

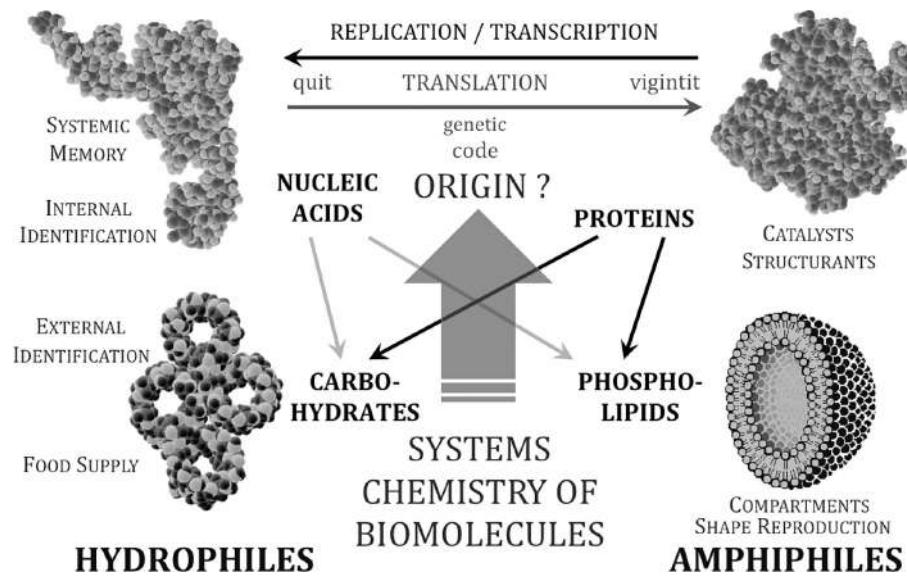

FIGURE 6.3.1 Four principal macromolecular compound classes, their interrelationships, and their main functions in living systems. Left: Hydrophiles. Right: Amphiphiles. Arrows indicate control by (begin) over synthesis of (end). Quit = quaternary digit (polymer); vigintit = 20 digit (polymer), cf. [Section 5.2.1.3](#). All processes are coupled to metabolic cycles (not shown).

carbon atoms and energy household. These reaction networks help the cells to remain reasonably robust against changes and, to varying degrees, independent of the surroundings, including other cells and the non-cellular environment. The fundaments of both the cellular energy household and the intercellular communication are composed of smaller and larger carbohydrates, respectively. For example, the transformation of critical, and easily “digestible,” monosaccharides is catalyzed by the enzymes of the Calvin cycle. On the macromolecular level, oligosaccharides in the form of glycoproteins and glycolipids serve as extracellular antennae by which cells are more or less roughly identified from the outside. Inside a cell, a very special kind of carbohydrate congener, the nucleic acids, serves to precisely identify any cell from within. The “splendid isolation” of the cellular inside from the environmental outside of any cell is provided by a semipermeable membrane composed of a phospholipid bilayer spherically closed into a vesicular shape; this *per se* quite flexible boundary is stabilized by cell wall carbohydrates (“glycans”) and membrane proteins. The supramolecular aggregation property of relatively small and multicompositional phospholipids furnishes a direct physico-chemical means of spontaneous shape replication through a process termed “growth and division.”

This extremely reductionist compositional and systemic view of the organization of any living cell holds true, without significant amendments, ever since Francis Crick and his comrades of the time—late 1950s—began to formulate and elaborate on the main message of the Central Dogma (Cobb 2017). A dogma of any variety and language, be it the “Central Dogma,” “Dogme 95” (von Trier et al. 1995), or “Dogma 13” (Strazewski 2014), is by definition firmly linked to infallibility, being in turn, and also by self-definition, reserved for non-scientists and non-artists. Therefore, this specific wording from the mouth, feather, or paintbrush of a scientist or artist

needs, again by definition, to be taken with a dash of humor. Nonetheless, the “basic assumption” (Crick 1970) on the flow direction of information in a living cell persists like Einstein’s Relativity Theory—with and without humor. The questions here are, how can such a systemic network of biomolecules, as a matter of fact, of any kind of molecules (Cronin and Walker 2016) arise spontaneously, that is, originate from “dead” matter? And how can any genetic code, universal or not, get established spontaneously by itself ([Figure 6.3.1](#))?

6.3.1.2 METAPHORS VERSUS REAL THINGS

The above questions set us back to a definition problem, namely what do we mean by saying “dead or alive”? Erwin Schrödinger’s dead *and* alive cat was originally meant to be of sub-atomic size, but twenty-first-century experimental physics and chemistry teach us that the “wave character,” that is, the property of constructive and destructive interference, thus superposition of different states, can be clearly observed on the molecular and macromolecular size scales of objects. In principle, all nature should be seen as a “superposition of multiple states” being very delicate and easy to disturb—they readily “decohere” upon the slightest disturbance (Haroche and Wineland 2012). Physics does not give us other than probabilistic grounds, for which of all possible decisions is taken by nature when a superposition of multiple states decoheres. It is pure chance that decides about the fate of things coming into being, that is, becoming observable and “real.”

Let us use the above metaphor of the superposition of a dead and alive cat. From a human observer’s point of view, nature is gaining momentum, far from probabilistic, as time goes by, from inanimate (inert) to animate (alive) and from abiotic to biotic, provided the conditions such as temperature, pressure, energy source, and fluctuations are appropriate. Therefore,

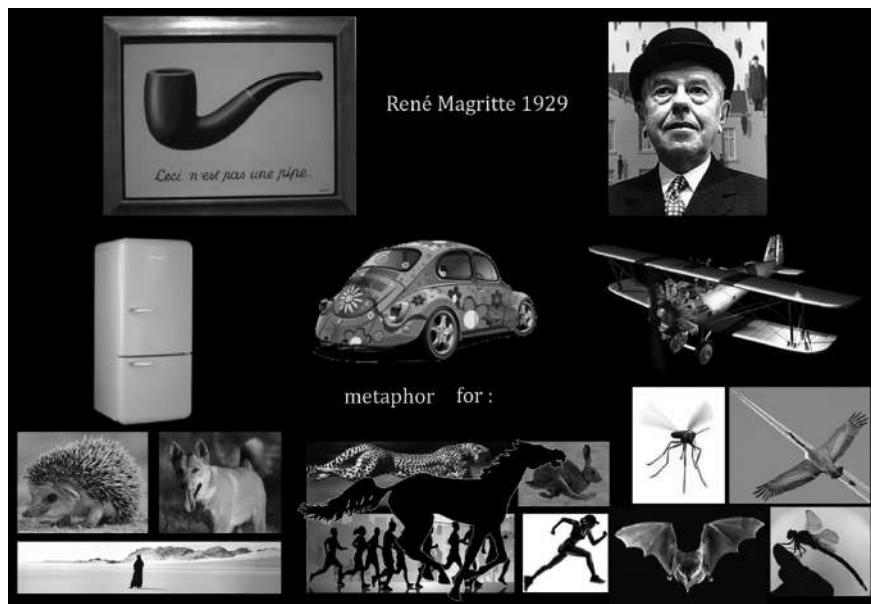

FIGURE 6.3.2 The difference between models of the reality and reality itself. *Ceci n'est pas une pipe* (Magritte 1929) translates into: “This is not a pipe,” meaning “you cannot smoke with this pipe.” The fact that the photographic image of René Magritte (upper right) cannot and did not paint this picture (upper left © ADAGP, Paris and DACS, London 2018) should be neglected for the sake of the argument (see text). Creating models of the reality (machines) is not the same as creating the reality. (Source: Reproduced with the permission of Artimage DACS © ADAGP, Paris and DACS, London 2018.)

I should like to illustrate here how I usually introduce to my students the difference between dead and alive (Figure 6.3.2). It is based on the vision of René Magritte, a Belgian painter of the early twentieth century (1898–1967), who unequivocally illustrated that we should not confuse a metaphor with the reality.

The metaphor that I am using to get to my point is that, if inanimate matter is a purposefully designed metaphor, then animate matter is self-emergent reality. For instance, a fridge, a mechanically reasonably solid and hopefully long-lasting electric machine, is an *inanimate model* (a metaphor) for any warm-blooded animal—like a desert hedgehog, a dingo, or a person that lives in a hot desert—specialized in transforming chemical energy into exported heat, which is closely linked to a “function,” that is, the purpose of keeping an interior comparatively cool and thermostated, when the outside is ferociously hot. Animals are long-lasting, too, albeit thermodynamically sometimes less stable than many man-made machines. The difference between the “model” and the “real thing” is that you need somebody from the outside to reproduce a fridge, while animals reproduce themselves, without any external designer. Reproduction of itself is the way of how thermodynamically less stable but alive “fridges” stay long-lasting. Individually, we may be short-lasting, but we self-reproduce and our *genre* is long-lasting. The same concept and difference can be applied to other functions and machines, such as motor cars being metaphors for fast running-animals and airplanes for flying animals and so forth. One necessity of this fundamental dichotomy is that, probably (unproven but intuitive), self-reproducing matter cannot be, at the same time, thermodynamically very stable, or else, it could not be dynamically self-evolvable and thus could not adequately and rapidly adapt

to changing surroundings. When sometimes, challenged by the odd student, I must respond to the question: “What about self-repairing robots?”—note that to “re-pair” could mean to “re-make one (whole) out of two (parts)”—I usually answer: “Show me a robot that self-reproduces by somehow giving birth to at least one similar but slightly different and also self-reproducible baby robot—hence, a robot that makes at least two out of one—and I’ll be happy to call her alive.”

The main reason for the above, perhaps bizarre, introduction into the concepts of life is the important fact that we humans, scientists, and chemists just *adore metaphors*. We are not listening to René Magritte and are definitely in danger of confusing models with the reality.

6.3.1.3 SYNTHETIC CELLS VERSUS ABIOTENESIS

Of course, there is a very good reason for why many scientists prefer to produce and study models. It is much easier to understand the functioning of a good model than to decipher, for example, all the mechanisms taking place in a living creature or even unravel a few mechanisms being part of a much more complex chemical system. Sometimes, it is clearly impossible to do otherwise. A cosmologist or experimental particle physicist won’t desire—perhaps only in his or her wildest dreams—to create a real, not *in silico*, “synthetic universe.” Given our fervor for an early “inflationary,” spontaneous and sudden cosmic expansion of the total space volume over at least 26 orders of magnitude, it may be too dangerous to do so at this stage of research. There are physicists that would like to produce, in a particle accelerator, small experimental mini-black holes, which should be very

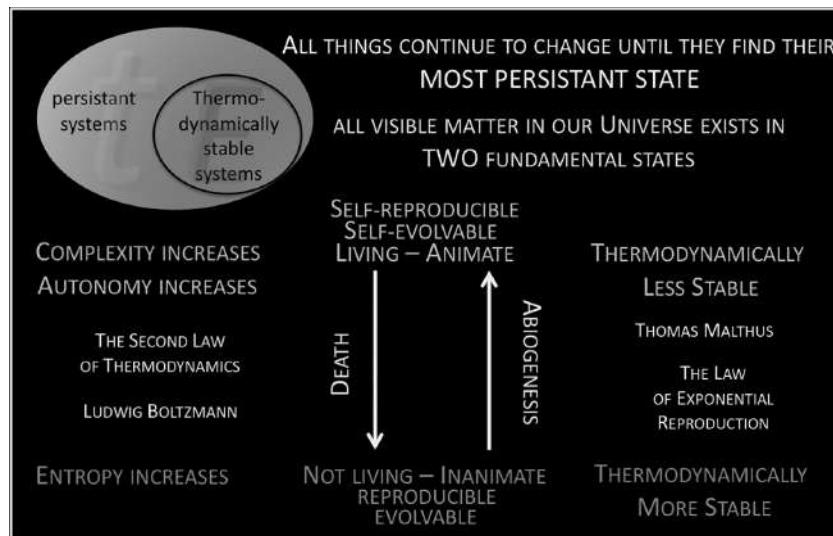

FIGURE 6.3.3 Two fundamental states of visible matter, their interrelationships, and their driving forces in the physical reality. Upper left: There are more ways of persisting over a long period of time than being thermodynamically stable (Pascal and Pross 2015). Absolute qualities, such as “long,” “short,” “high,” “low,” and so forth, are avoided and replaced by relative descriptions, such as “increase,” “decrease,” “more,” and “less.”

short-living, if possible at all. Usually, cosmologists and particle physicists hardly ever confuse a model with the reality; too different are the looks of both.

Things look different on a less energetic scale of experimentation. Living individuals die relatively easily. From what we know about biotic nature on Earth, we can be quite certain that the same holds true for any extraterrestrial life within our universe. As mentioned earlier, the persistence of animate matter over long periods of time is based on the strategy to self-reproduce, provided the surrounding conditions permit productive (fertile) self-reproduction. This strategy is not based on thermodynamic stability, quite on the contrary (Figure 6.3.3).

Evidently, a piece of cloth, wood, coal, granite, iron, or lead is less persistent than a slowly radiating black hole; so is a barrel of petrol when compared with the same amount of water. Yet, all are thermodynamically quite stable, can persist due to their stability over long periods of time under reasonably isolated conditions, and are, despite their very different provenance, definitely inanimate. The “lifetime” of inanimate matter should be compared with that of a living species, not with an individual.

Two open questions arise from this holistic view of physics, one is the difficulty of quantification of complexity, autonomy, and the precise lifetime of a species when compared with that of thermodynamic stability and entropy of inanimate matter. The main reason for this difficulty is the lack of any reference system for animate matter, owing to the permanent change of both organisms and surrounding environment.

The other open question is the obvious disparity between the ways of transformation. Although the mathematical rules that drive both ways (arrows in Figure 6.3.3) are known since long (Malthus 1798; Boltzmann 1877), experimentally, only one way, the transformation from the animate to the inanimate states, death, has been and is being explored and studied many times. The other direction, abiogenesis,

still awaits experimental proof. My personal conviction on the importance of truly knowing both ways of transformation is the ultimate reason for writing this book chapter. I think that abiogenesis reconstructed by humans would not only be the greatest-ever achievement in the history of the natural sciences. Also, it is a necessity for modern society to be able to make a great leap forward in its development and a responsibility for ourselves and for all non-humans, including inanimate matter (see also Section III of this handbook). We humans need to show it to ourselves by experiment that life can emerge from inanimate matter. Maybe this is not really the place for personal opinions of the non-scientific kind, but, since it may be the only occasion for me to write down this opinion, let me state here that, in a society where experimental, that is, synthetic abiogenesis will be known for let's say two generations, our grand-grand children won't be astonished anymore about how actually quite easy it is to animate from the truly inanimate and how extremely delicate such an emergent synthetic life is—given the enormous extant biotic competition and the lack of eons of self-evolution for the establishment of a new biosphere. Concerning exobiology and astrobiology, creating, on purpose, life from the inanimate might be an option to survive in some form elsewhere. Most importantly for us, in the not-so-far future, when a majority of human society knows about this possibility and can now and again remake life in laboratories—outside, I believe, our biotic life is too strong to let any new life persist—the major reason for religious wars will become naturally extinct and definitely obsolete. Other ways of solving problems will impose themselves; this archetype will become history, and religion will gain the importance and character of taste: extremely important in everyday life (“I like marmalade,” “I hate oysters”) but no reason at all for violent behavior against others (“You must hate oysters or I'll kill you”). This should change the world quite a bit.

I am not a philosopher, but it seems quite evident that at least the lucky part of society that has rejoiced over two or more generations the absence of wars on its territories is, by virtue of a highly and globally developed technology, at the verge of a “big leap,” not unlike the ancient Greek society more than 2400 years ago, when the first European philosophers (Parmenides, Aristotle, Theophrastus, Diogenes, Socrates, and Plato) wrote about the reality; not unlike during the Renaissance, when the need of careful and analytical dissection of corpses emerged from pure curiosity (Leonardo da Vinci), became first allowed and then established (Andreas Vesalius), and gave the grounds for the development of modern medicine; and not unlike during the era of Enlightenment, when human curiosity and the confidence in oneself had been encouraged against current opinion for a long-enough time (Francis Bacon, René Descartes, John Locke, and Baruch Spinoza), so that the construction of machines could gain significant momentum, which paved the way to modern technology. These three phases can be roughly circumscribed and extremely reduced to “observation” (meaning mainly theoretical analysis), “analysis” (meaning experimental analysis), and “synthesis,” respectively, where each activity is prerequisite for, and permanently accompanies, the next. Of course, there are anxieties; of course, we make mistakes. One mistake that we should work out a little bit more is related to our natural desire to control the design as much as possible, while not being able to control the outcome in a way that would correspond to the effort put into the design. Highly complex, especially animate systems are alas! highly non-predictable as well.

My temper was sometimes violent, and my passions vehement; but by some law in my temperature they were turned not towards childish pursuits but to an eager desire to learn, and not to learn all things indiscriminately. I confess that neither the structure of languages, nor the code of governments, nor the politics of various states possessed attractions for me. It was the secrets of heaven and earth that I desired to learn; and whether it was the outward substance of things or the inner spirit of nature and the mysterious soul of man that occupied me, still my inquiries were directed to the metaphysical, or in its highest sense, the physical secrets of the world... (Wollstonecraft Godwin Shelley 1818, Chapter 2)

He held up the curtain of the bed; and his eyes, if eyes they may be called, were fixed on me. His jaws opened, and he muttered some inarticulate sounds, while a grin wrinkled his cheeks. He might have spoken, but I did not hear; one hand was stretched out, seemingly to detain me, but I escaped and rushed downstairs. I took refuge in the courtyard belonging to the house which I inhabited, where I remained during the rest of the night, walking up and down in the greatest agitation, listening attentively, catching and fearing each sound as if it were to announce the approach of the demoniacal corpse to which I had so miserably given life. (Wollstonecraft Godwin Shelley 1818, Chapter 5).

To end this introduction, and to round up what was unwound in seeming digressions, let us take a brief look from a distance at the research strategies that synthetic biology, systems biology, and systems chemistry have chosen in the past 15 years.

Much has been undertaken by following a top-down approach in building more and more complex *models* of cells that are capable of producing designed components through designed genetic-control circuits. Such artificial cells are either very close to natural living cells or stripped off their non-essential genes to survive as so-called minimal cells, but they are not living for many generations. The top-down approach of synthetic biology is considered as designed assembly of artificial cells from components of once-animate origins.

A pioneering vision for the creation from bottom-up of living synthetic cells was published by Szostak, Bartel, and Luisi in 2001. The authors proceeded from designing a protocell, providing it with a synthetic RNA replicase and furnishing the RNA with the ability of catalyzing the synthesis of vesicle membrane components:

The first challenge on the path to a synthetic life form is to imagine a collection of molecules that is simple enough to form by self-assembly, yet sufficiently complex to take on the essential properties of a living organism... We believe that within this framework structures can be found that are both indisputably alive and yet simple enough to be amenable to total synthesis. We note that solutions found in the laboratory need not be chemically similar or even directly relevant to the actual molecular assemblies that led to the origin of life on Earth [...] The first major synthetic intermediates are an RNA replicase and a self-replicating vesicle [...] Such simple protocells would be nearly, but not quite, alive. When fed small-molecule precursors for membrane and RNA synthesis, they would grow and divide, and improved replicases would evolve. However, a vesicle carrying an improved replicase would itself not have improved capacity for survival or reproduction. For this to happen, an RNA-coded activity is needed that imparts an advantage in survival, growth or replication for the membrane component. A simple example would be a ribozyme that synthesizes amphipathic lipids and so enables the membrane to grow. (Szostak et al. 2001)

This bold plan seems to be rooted in creating an autopoietic system (Maturana and Varela 1980) with implementations of the concept of the chemoton (Gánti 1971, 2003) and notwithstanding the hypothesis of an “RNA World.” More than 15 years of experimental research after this idea have taught us to be critical and to constantly re-think the “best” initial conditions of such an endeavor (Blain and Szostak 2014; Buddingh and van Hest 2017). In particular, it seems now that even this inventive bottom-up approach probably bears too much human design and is reaching too far into some desired future that might prove different from what we would expect at a first sight.

It is still true, of course, that, in order to be conceived as “alive” in a conventional sense and consensus, protocells have to contain some kind of readable information-carrying “memory polymer” (Section 5.2.1.3), parts of which, at least, need to be reproduced, that is, their sequence of digits “replicated” and spread over the dividing cells. However, there is no need for self-replication, as beautiful and “simple” such a property appears. It is perfectly acceptable, when the memory polymer is replicated by some other molecule(s), even by some other

molecular class of compounds. What counts is the mere replication rate k and spreading of a set of “sequence of digits” upon every cell division, resulting in an exponentially growing ($p = 1$) population density x with time t (Equation 6.3.1).

$$\frac{dx}{dt} = k \cdot x^p \quad (6.3.1)$$

Exponential growth rates are mandatory for a so-called Darwinian evolution to set in, according to which different reproducing populations compete with each other when sharing the same ecological niche, thus competing at least partly for the same resources. Under initial conditions, when the resources can be considered unlimited and the degradation, decay, or individual “death” rates are negligible, a faster replicating population can completely outcompete and make extinct a slower-replicating population only if the growth rates of reproducing populations are exponential or higher than exponential $1 \leq p \leq 2$ (Equation 6.3.1), that is, hyperbolic with time (Lotka 1921; Volterra 1938; Eigen and Schuster 1979; Szathmáry 1991; Szathmáry and Maynard Smith 1997; von Kiedrowski and Szathmáry 2012; Szilágyi et al. 2013, 2017). Under subexponential initial (resource-rich) growth conditions $0 < p < 1$ (termed parabolic), a “survival of everyone” regime is sustained and no Darwinian selection is possible. The selection rules in these three growth order regimes are independent of the stoichiometry of growth (1 parent gives 1, 2, 3 or more children) and include changes in the fitness landscape (fertility, health). Exponential growth order means that, overall and on the average, every new generation produces the same number of offspring as the previous generation per parent. Hyperbolic growth, such as the human race is supporting right now, is when every generation gives off, on the average, more fertile progeny than the previous generation per parent. Parabolic growth means, of course, that the brood becomes on the average fewer and fewer per parent. Enzyme-free template-directed (e.g., RNA) replication follows parabolic growth dynamics, owing to the fact that newly grown strands “scavenge” their complementary single strands through stable base pairing, thus inhibiting somewhat their templating ability. The extinction of a sub-population within competing parabolic replicator systems can only be caused by a below-critical abundance (concentration or density), sequence-selective decay rates, or a separation into different ecological niches, for example, a complete spatial separation of the competitors. In that case, the absence of a competitor in a given area is of course not due to its extinction. Irrespective of whether systemic memory carriers, such as RNA, are self-replicating or being replicated by someone else, an inanimate mixture of a great many of different compounds and different compartments must first somehow segregate, “demix,” and diminish its *chemical diversity*, or else, a living state of matter will never be achieved. Conversely, once early replicators, that is, chemical systems that are driven by the doubling of memory polymers, have become operative, the coexistence of populations of different replicators is prerequisite for the maintenance of a sufficient amount of *inheritable diversity* of, at first, highly mutable (unstable) digital information, or

else, the survival of such replicators under early biotic environmental conditions can hardly be sustained over long periods of time and many generations (Szilágyi et al. 2017). One of the current difficulties in modeling evolutionary population dynamics is to properly outline the scope of “selectability” of replicators, the emergence of Darwinian selection through the extinction of competing sub-populations of coexisting replicators while maintaining the survivors stable, for example, stable against parasites, yet still evolvable over space and time in the sense that the survivors may integrate more different replicating (memory) polymers, without making the whole system collapse. It turns out from the research of the past decade that spatially explicit systems of cooperating replicators that are irrevocably coupled to (“fed by”) metabolic reaction networks are incomparably more robust than replicators devoid of metabolism.

However, a memory polymer that cannot carry out or give rise to a function that is of use for the survival of the whole system, is not much of a memory polymer. This is the reason why the RNA World hypothesis was so attractive over a long period of time. Experiments on the “ribozyme” activity of many RNA molecules have shown a plethora of different catalytic promises of this compound class. When we look closer at these fantastic experimental achievements, including ribozymic RNA copying, aminoacylation of RNA, and limited (without turnover) aminoacyl transfer, some of us still cannot help scratching our heads. Synthetic catalytic RNA still seems to be best at catalyzing the cleavage of RNA “in cis” (intramolecularly, self-cleaving) and second-best, when appropriately designed, at catalyzing cleavage “in trans.” Intermolecular RNA strand cleavage works only upon sufficient base-pair-stabilized hybridization between the ribozyme and the substrate RNA. All other ribozymic catalyses, such as the reversed ligation reaction or the above-mentioned (trans)aminoacylation ribozymes, are comparably less well performing. The typical catalytic rates of RNA self-cleavage that can be achieved *in vitro* with synthetic ribozymes are worrying, since the rate constants at 25°C under optimized conditions, that is, high divalent salt concentrations, including magnesium, manganese, and calcium salts, are in the range of one cleavage event per hour to one event per week, per molecule of ribozyme.

The chemical nature of RNA and similar nucleic acids—the facts that they are periodically polyanionic and very well water soluble at virtually any nucleotide length and that they do fold upon themselves quite readily without the need of a complementary strand, as in double-stranded DNA, is advocating against the RNA World, meaning against a self-contained functioning and copying of nucleic acids, without the need of peptides or proteins. Nucleic acids are good at hybridizing with nucleic acids. Nucleic acids are bad at “denaturing,” that is, unfolding nucleic acids. Hybridizing and folding through base pairing is the opposite of denaturing and unfolding. But, to be amenable to both intermolecular “cross” catalysis and RNA strand copying, unfolding and exposing its nucleotide sequence is prerequisite. No unfolding, no readout—“no” may be replaced with “slow.” In extant biotic systems, all nucleic

acid denaturing work is executed by proteins. Most of these proteins are “helicase” or “unwindase” enzymes of some sort. However, not only highly evolved and well ordered (folded) enzymes are known to unfold nucleic acids. An intrinsically disordered protein assembling in organelle-like liquid droplets has been identified as being able to efficiently stabilize single-stranded DNA and RNA (Nott et al. 2016). There is only one exception to this unique dehybridizing property of proteins. The binding of messenger RNA and exposure of two codons for peptidyl- and aminoacyl-tRNA anticodon readout is carried out by the “decoding center” located at the “neck” of the small ribosomal subunit termed 30S subunit in bacterial and 40S subunit in eukaryotic ribosomes (Demeshkina et al. 2012). The decisive molecular contacts between the mRNA codons and the 30S/40S subunit are mediated by ribosomal RNA, 16S rRNA in bacteria and 18S rRNA in eukarya. However, when mRNAs are partly self-folded, in spite of the degeneracy of the genetic code, which allows for a certain choice of nucleotides that all code for the same protein, then these folded parts may constitute a problem for the ribosome—ribosomal “stalling” during translation is a commonly observed phenomenon. It is of note that the main catalytic function of RNA is executed by folded tRNA and folded rRNA (see also Chapter 6.4), whereby the covalent chemistry of peptide bond formation is carried out at the single-stranded 2',3'-terminus of tRNA. It is also of note that the ribosome depends on many ribosomal proteins; 52 bacterial and 82 eukaryotic different ribosomal proteins enhance its structural integrity, and even more proteins are needed for its proper functioning. Not only are all ARS enzymes proteins, so are the “elongation factors” that make sure that hydrolytically labile aminoacyl-tRNAs are safely transported from their ARS to the ribosome and are reliably selected for the cognate codon. The ribosome will only produce proteins in a processive manner when it always moves “translocates” forward and never backward, which would otherwise catalyze the cleavage of the nascent peptide bonds, instead of their synthesis. This translocation is guaranteed by a protein (an elongation factor) that mimics the shape of a tRNA being bound to another elongation factor. The correct final disconnection of the nascent protein from the last tRNA can only occur thanks to protein enzymes, “termination factors.” Most of these translational protein enzymes are binding and hydrolyzing GTP as a thermodynamic driving force. The attachment of whole ribosomes to the lipid membranes again is mediated by proteins, through which the nascent protein moves to the other side of the membrane of the corresponding organelle, the “rough” part of the endoplasmic reticulum (ER). There, the nascent proteins are most often captured and isolated from their immediate environment by protein chaperones called “chaperonins,” until they slowly but safely fold into their “native” conformation being usually required for their function, and so, they won’t be degraded too early by protein-degrading proteins. This cellular work and mutual dependence between RNA and proteins seem so extremely interwoven and intimate that it is really hard to imagine how one compound class could ever do without the other (Carter 2015). Any purist vision of a “protein-only” or “RNA-only” or, for that matter, “anything-only” world looks

like an act of desperation for order rather than a theory based on experimental scientific work.

In addition, we should take into account a realistic prebiotic situation, on the early Earth or elsewhere, where amino acids are always chemically more stable and more persistent than nucleotides. It is very likely that, at an early stage of molecular complexification, both prebiotic synthetic pathways shared the same chemical transformation routes, namely, from the first C-C-bond-forming reactions to the point where α -aminonitriles diverge to α -amino acids and α -hydroxyaldehydes, that is, small carbohydrates (cf. Section 5.2.2). If this is the case, a pure or even less pure RNA World seems even more improbable. Instead of stubbornly clinching to this sharp “RNA World blade” that is swimming over deep waters, we should take much more care of how any spontaneous RNA-catalyzed synthesis of peptides from the amino acids can emerge, in order to get hold of useful primordial functions provided by such first peptides. We should try to convince ourselves by experiment that it might indeed be possible to let first self-evolve a kind of primitive RNA-driven protein or peptide production before the advent of RNA replication. Given the initial absence of any systemic memory that would require RNA replication, a protocellular approximate (error-prone) reproduction would indeed ensue the provision of the same RNA molecules over long time periods and many protocellular generations over and over again and of the same amino acids and other small molecules as well. But no dogma forbids this highly “heterotrophic” scenario devoid, at first, of any systemic memory. Compartmented protometabolic reaction cycles thus gain importance, not because they provide the first building blocks—being the essence of an “autotrophic” origin of protocells—and *not yet* for the dynamic stabilization of cooperating parabolic replicators (*vide supra*), but for the upkeep of a sufficient level of compartmented chemical energy, in order to maintain good growth conditions, for instance, for compartmented peptides from internal aminoacyl-RNA. The upside of this “no memory-scenario” is that, once RNA-driven peptides would fold into structures capable of unfolding RNA and generating hydrophobic “pockets” around short parts of single-stranded RNA, then an RNA-dependent RNA polymerase activity would be within close reach, if chemical energy from, for example, NTPs, could be coupled into this process. When such a mutual protein-RNA cross-catalysis—peptides from RNA catalysis, RNA from protein catalysis—emerges, then eventually, a huge acceleration of population growth of compartments that would host these activities is expected to literally shoot off exponentially from the throng of no-memory compartments.

Finally, it is true that a point must be reached where the membrane components should be synthesized by the system itself (Gánti 1971, 2003; Szostak et al. 2001), in order to become reasonably independent of external lipid sources. However, to join glycerol monophosphate with fatty acids, or phosphate-containing polar headgroups with diacylglycerols, or any such dehydration reaction that would generate a strong amphiphile, is by far easier to catalyze in water than to actually polymerize methylene groups (CH_2) into long

hydrophobic chains, which is at the heart of any membranogenic amphiphile. A minimal length of the hydrophobic zone in an amphiphile, for its stable assembly into bilayer membranes that could close into vesicles, is at least 9 or 10 carbon atoms long. In a biotic system, this C–C bond-forming oligomerization process is carried out and cycled, for a fatty acid chain length of C₂₄, up to two dozens of times consecutively. The fatty acid synthetase machinery is huge in size (2.6 MDa, 260 × 230 Å, 100% protein), slightly larger than the bacterial ribosome (2.5 MDa, 250 Å diameter hemisphere, 65 weight % rRNA and 35 weight % ribosomal proteins) and is highly elaborated, cooperative, and genetically streamlined to make sure that a controlled “homeostatic” mixture of different phospholipids and glycolipids is provided from within a cell to feed into its membranes.

There is thus far no chemically reasonable enzyme-free process known to work under conditions that would synthesize membranogenic hydrophobic carbon chains *and* support the presence of RNA. Fischer-Tropsch-type processes, which generate in water carbon chain lengths of the required size, necessitate temperatures between 150°C and 250°C (McCollom et al. 1998). Of course, once the carbon chains are “heterotrophically” fed from the outside, a protein or even ribozyme might be able to attach through condensation, that is, dehydration, one or two alkanols or alkanoic acids to glycerol or glycerol phosphate. But the extant degree of autonomy, that is, independence of macromolecular food from the outside, can, for chemical reasons, only be a late “Darwinian” achievement, as far as our current knowledge stands now. Unless, of course, some bright chemist will come up with a mild fatty-acid-like enzyme-free synthesis from acetate C₂ and CO₂ to give malonate C₃, that reacts with acetate to produce back CO₂ and acetoacetate C₄, that gets reduced to β-hydroxybuturate, then dehydrated and reduced to give butyrate, and so forth: C₄ + C₃ – C₁ = C₆; C₆ + C₃ – C₁ = C₈; C₈ + C₃ – C₁ = C₁₀ etc., perhaps in the presence of peptide-stabilized iron-sulfur clusters (Bonfio et al. 2017), yet still in water and, most importantly, without hydrophobic aggregation *en route* that would stop the whole process before it formed long enough chains that could assemble into membranes. They say that miracles happen, but I would not bet on it (Fry et al. 2017), but, of course, never say never.

To conclude on this introduction, I tried to show that the times are ripe for chemists to investigate the transformation of matter from the inanimate to an animate state by laboratory experiment. Such experiments should not be confused with the production of artificial or synthetic cells. While the latter efforts are extremely important for us to understand the detailed mechanisms that take place in living organisms, it is highly unlikely that we can generate through this “high-design” approach actually living and self-evolving cells *de novo* that could survive over many generations in an appropriate environment being well isolated from extant biotic life, on some other habitable planet, for instance, or in the laboratory. For reasons that are beyond mere scientific curiosity, which include the belief in full human responsibility over all domains of our perceived reality, we should convince ourselves that it is indeed possible to create life

truly *ex inanimo*. For this endeavor to be successful, we cannot keep patching up and energizing “dead but not yet degraded” formerly living material, or else, we will not overcome the “Frankenstein threshold,” below which no reproductive self-evolution can emerge. We need to start from conditions that are less complex and preclude far-less-designed properties that would supposedly provide “functions.” However, it is true that we cannot start yet another historical origin of life beginning either with metal oxides, graphite, sulfur, phosphorous, hydrogen, and nitrogen gases at temperatures above 2000°C, or even with carbon monoxide, formaldehyde, acetylene, ammonia, hydrogen cyanide, sulfide, phosphate, and water between 1000°C and 100°C (cf. Section 5.2.2.1). We simply do not have this kind of timescale at our disposal.

A major issue is, therefore, to figure out by experiment what kinds of initial functions, that is, a minimal set of functions, are needed to make and keep a complex chemical mixture alive. In my opinion, we should not assume *a priori* that replication belongs to the minimal set of functions, even less so the self-consistent synthesis of cell membranes. Both functions are indeed absolutely required for an autopoietic, self-reproducing state of matter, but they still could be *emergent rather than prerequisite*. So, what are the functions that can be considered to belong to the minimal set of a self-reproducing system? This question can be boiled down to the minimal autonomy needed for a sustainable complex chemical compartmented mixture devoid of any systemic memory. What kind of complexity of matter needs to be inanimate provided long, constantly, or regularly enough for a systemic memory to emerge? Let us consider a working hypothesis that states that, when bits and pieces of oligonucleotides and oligopeptides can be kept compartmented under conditions that allow them to grow in chain length, thus sequential diversity, then, after some time shorter than the average life time of a researcher, a translational code will emerge between the two classes of compounds that will keep particularly useful peptide and RNA sequences more abundant than the background abundance carried over from dividing mother cells to daughter cells. This, in turn, will keep some of the compartments that harbor such “selected” RNA and peptides more and more persistent and abundant, when compared with the other compartments that do not. There is growing experimental evidence that peptides and nucleic acids—those that do interact with lipids—can render membranes more resistant and robust against mechanical and osmotic stress. Lipophilic peptides, which may form spontaneously without any instruction or catalysis by RNA, are quite likely to firmly interact with lipidic vesicles, whereas the lipophobicity of many kinds of nucleic acids, most prominently RNA, precludes any significant interaction with lipid membranes (cf. Section 5.2.3.2), unless considerable human intervention and design are involved (Kurokawa et al. 2017). Therefore, one primordial function prerequisite for not replicating but *quasi* self-reproductive protocells might be the selection of those peptides, out of the astronomical number of abiotic oligopeptide sequences, that are able to import RNA into the interior of lipidic vesicles and perhaps anchor them to the inner surface of the membrane. Since vesicles that harbor

imported RNA and lipophilic peptides are not yet alive and do not yet harbor replicating RNA, the terms “function” and “selection” are a bit of a stretch. But the experimental abiogenesis is a bit of a stretch, too, between inanimate chemistry and animate biology.

6.3.2 EXPERIMENTAL ABIOTGENESIS

Most important in this experimental setup is the fact that we start with a mixture of chemically different compounds, rather than beginning with merely one kind of compound, for example RNA, and only one kind of amphiphile, or perhaps a uniform and rigid physical barrier, where the compound can evolve in micro- or nano-compartments. (Strazewski 2015, p. 853)

The experimental conditions need to keep the macromolecules, RNA and peptides, under hydrolytic stress and, at the same time, the compartments under mechanical and/or osmotic stress, for example. This could be achieved when giant lipid vesicles (GVs) are kept on a membrane filter that can be dipped into an aqueous phase containing any kind of molecules and into which any kind of solid or aqueous liquid solution can be added from above (Figure 6.3.4). In addition, the population of GVs should be submitted to changing temperatures and atmospheric conditions and therefore be placed in a convenient incubator.

6.3.2.1 DYNAMIC COMPARTMENTS

Above everything else, always provide the system with many possible variants—variants in chemical composition, property, reactivity, but also in shape and size—so it can choose whatever is best in a given situation or phase of development, “best” being whatever leads to longer persistence of the vesicles “over time. With respect to the extent of replicative property at the beginning, I think that we can start with virtually none whatsoever. We should not provide a system with ribozymes that already know how to copy certain RNA sequences once

or twice, and try to evolve replicators from there. It suffices to start with the most simple physico-chemical replicative property, the one of spontaneously reproducible shape. Lipid-like amphiphiles do organise themselves into compartments, and other supramolecular architectures, spontaneously. When the compartments are fed with more lipids, they reproduce more of those shapes already being present. Grow and divide is at the same time an intrinsic physico-chemical property of lipidic supramolecular architectures (vesicular, hexagonal, cubic, etc.) and an ubiquitous cellular behaviour in the living domain.” (Strazewski 2015, p. 853)

6.3.2.2 FUEL

A chemical energy gradient of the maximally atom-sparing kind is needed for keeping the system environment locally out of thermodynamic equilibrium. Through compartmentation we seek to economise on all macromolecules, viz. avoid any “organised waste” of large elaborate compounds including the added amphiphiles that make up the compartments of the system. We prefer to recycle them. But we shall not compromise on the delivered amounts and waste of small-molecular-weight-high-energy compounds, the fuel that keeps the system running. Such fuel should show a prebiotically plausible identity, in other words, should be composed of geologically and geochemically feasible minerals and compounds. They should not be too reactive, not too destructive when brought into contact with the macromolecules and compartments of the system. Basically, they should be “anhydrides” of some sort (not to be understood uniquely as organic chemical anhydride functional groups) that mostly hydrolyse into small diffusible waste products. Only mostly, because the residual fraction of fuel compounds, the one that will not react directly with water but rather eliminate water molecules from organic compounds, shall be the motor of the self-evolving process, a motor of quite low energy conversion efficiency at first. But this motor, too, should be able to self-evolve. (Strazewski 2015, p. 853)

6.3.2.3 FOOD

“We shall feed the compartments with more than lipids and chemical energy: with amino acids, peptides, nucleosides, nucleotides and” carbohydrates, the ad hoc assumption being “that all these compound classes were available from natural prebiotic reservoirs and could locally accumulate at the same time and space for certain time periods once water was present.” (Strazewski 2015, p. 854)

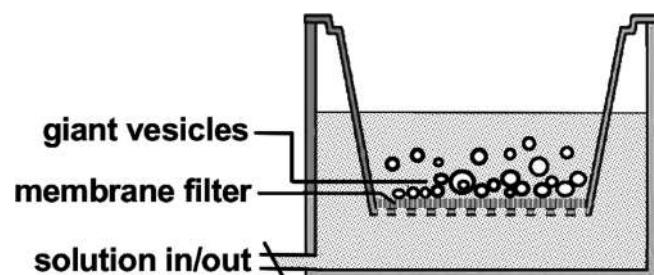

FIGURE 6.3.4 Fueling and feeding giant vesicles. Schematic drawing that should allow for (a) the growth and division of giant lipid vesicles when fed with lipid mixtures, and (b) growth of biomolecules that are encapsulated, when fed with the corresponding monomers and fueled with large amounts of dehydrating agents that can pass through the membrane. Stresses imposed on the system can be any leakage of molecules from the inside, osmotic pressures, shearing forces due to filtration, pH difference between the inside and outside of the vesicles, high salt concentrations, and so forth, in the absence or presence of oxygen and/or carbon dioxide gases at varying temperatures and humidity.

In view of the stunning success of the first enzyme-free protometabolic reactions in water, catalyzed by iron, zinc, and other transition metal salts (Muchowska et al. 2017), compound mixtures belonging to the Krebs cycle, that is, acetate, pyruvate, oxaloacetate, malate, fumarate, succinate, α -ketoglutarate, oxalosuccinate, isocitrate, aconitate, and citrate, could also be periodically fed. We should keep in mind that too high transition metal concentrations may be detrimental to the GVs but that a limited amount of this kind of “chemical stress” might permit to generate more robust populations. One way or another, protometabolic networks need to be coupled into the system (Bonfio et al. 2017).

6.3.2.4 RNA-DIRECTED PEPTIDE SYNTHESIS IN THE LIPID BILAYER

At this point, usually, or let's say quite often, some of my colleagues begin to have serious scientific doubts in the feasibility of such experiments—not to say, they are probably rolling their eyes behind my back. Especially in grant applications, anonymous reviewers are asking for reasons why RNA-directed peptide synthesis should emerge from the experiment? For an obvious purpose, I try to satisfy such longings, although I think that the main reason for myself is not explicable on a molecular level. Any chemical rationale should not evidently contradict any solid knowledge on molecular chemistry and, of course, physics. I imagine that if Harold Urey and Stanley Miller had been asked, in advance of their experiments, why they think that α -amino acids would form from methane and ammonia when submitted to spark discharges, they would, maybe, not argue with their real main reason—in the sense of motivation—but rather come up with the possibility of transiently formed aldehydes and ammonium cyanide undergoing the Strecker reaction. Who knows.

It is of course an open question how exactly RNA can start producing peptides from chemically activated α -amino acids without instruction from a proto-messenger RNA and without catalysis by a proto-ribosome. One of my own imaginations on how on a molecular level this could come about was described in considerable detail in Strazewski (2015). That “mechanism” replaces some of the function of a future protoribosome with a lipid bilayer and therefore places the primordial PT reaction two-dimensionally bounded and reversibly immobilized to the inner part of vesicle membranes. The immersion of the reactive atoms, that is, the nucleophilic α -amino group of an aminoacyl-RNA and the α -carboxyester function of a close-by peptidyl-RNA, into the hydrophobic phase of a lipid membrane should strongly enhance the reactivity of the locally desolvated reactive sites and lead to spontaneous and sequential aminolyses of ribonucleotidyl ester bonds to give peptide bonds. Since this mechanism is biomimetic but purely putative, I would like to direct the interested reader to this article and concentrate here on what arguments and thoughts have found their way into this hypothesis since 2015, albeit all of it still stands on purely hypothetical grounds and absolutely needs experimental testing.

Hence, despite early successes in the spontaneous aminoacylation of nucleoside-5'-phosphates (Biron et al. 2005), the last few years have shown that the C-terminal esterification of α -amino acids with ribonucleotides does not lead to peptide bonds that are in any way directed by RNA. The chemically activated amino acids do get esterified with nucleotides but re-hydrolyze too rapidly and, during their chemical activation, form peptides independently of the nucleotides (Liu et al. 2014). On the other hand, plausibly prebiotic reaction conditions have been found, where chemically activated α -amino acids react with nucleoside-5'-phosphates to form N-terminally linked nucleotidyl amino acid phosphoramidates (Jauker et

al. 2015; Griesser et al. 2017). What's more, such nucleotidyl amino acid phosphoramidates grow peptide chains and, comparably slowly, short RNA chains on this first “composite monomer.” Experimentally, thus far, the access to N-terminally linked peptido-RNA is more readily achieved than to the more biomimetic C-terminally linked peptidyl-RNA. The current efforts concentrate now on finding reaction conditions that permit the rearrangement from peptido-RNA to peptidyl-RNA. Second, the evolution of a RNA-driven PT reaction at protocellular membranes might well be accompanied by the growth of unbound RNA chains within the vesicles' lumen that could step by step take over the hosting role of the membrane in promoting the PT reaction. Thus, a proto-ribosomal RNA activity could emerge and considerably accelerate the membrane-associated PT reactions. However, these are all hypotheses, not yet confirmed by experiment. The literature is full of unproven hypotheses, and the above hypothesis is only one more. This is why I wish to get back to my main argument that experimental abiogenesis with minimal initial design and open-ended expected results must be the way to obtain the answers to our questions on the origin of life: We need to create life in order to really understand it, as Richard Feynman wrote on his blackboard shortly before his death: “What I cannot create, I do not understand.”

“Let us not forget that inside the GV s the system continues to produce longer peptides and longer RNAs” at ever increasing “crowded” concentrations, “and that both compound families bear useful functionalities in their populations. In such dynamic-flow off-equilibrium experiments anything that proves useful for the GV hosts, for example peptide pores that facilitate the import of useful and export of harmful compounds, becomes noticeable as an enhanced persistence of the corresponding GVs. It all depends on the food delivered by the environment. This at first total dependence of the GVs on sustainable food (heterotrophism in a biotic world) contrasts true autopoiesis. The lack of robustness is potentially lethal. The permanent danger diminishes sharply with the appearance of a ‘systemic memory.’ The passing-on of inherited information can only be functional and robust for the whole system after a genetic code has established. Proto-ribosomes, proto-ARS and proto-RNA polymerases can then better self-evolve; also proto-fatty acid and nucleoside triphosphate synthetases. Eventually, true protocells, living cells are expected to appear” ex inanimo. [...]

The farther we get carried away with deriving in a chemically logical sequence what might happen, the more divergent territory we are occupying. Nonetheless, divergence is what we are ultimately seeking for. I am not particularly fond of skating on thin predictive ice. Instead of hypothesizing on the order of foreseeable events, on whether a ribosome (RNA-dependent amino acid polymerase) has to be ribozymic, a RNA polymerase or ARS must be proteic, what comes first, what second and why our genetic code is as it is, I much prefer to see what actually happens, and how far I can get, and how different the results will be when we restart the same way with a new batch, or after we restart racemically instead of enantiomerically pure, and so forth. (Strazewski 2015, p. 857)

6.3.3 SUMMARY

The importance of being able to create truly self-evolving cells *ex inanimo* cannot be underestimated, for our knowledge on the natural sciences and, should the necessity arise, for being able to safely seed extraterrestrial life, in particular farther away than on Mars. Current research on artificial and synthetic cells concentrates more on designed approaches than on actually animating inanimate complex chemical systems. A bottom-up and more pro-active approach would be to test a general experimental setup, as proposed here. Its aim is to work in the laboratory toward self-evolvable chemical systems that, according to what we know about life's chemical processes, should eventually become alive. The experiment is based on reasonably complex molecular compound classes that are known from extant biotic life: amino acids, peptides, nucleotides, lipids, and small organic molecules. The most challenging realistic goals are the observation of the emergence of one or several "genetic" codes and of "genetic" replication.

ACKNOWLEDGMENTS

I thank the Volkswagen Foundation for the funding of the research program "Molecular Life" within their call *Life?—A Fresh Scientific Approach to the Basic Principles of Life*. I hope that closer funding agencies will start opening their funds to experimental abiogenesis proposals in the nearest possible future.

6.4.1 CATIONS IN WATER: RELEVANCE TO ORIGIN OF LIFE AND EVOLUTION ON EARTH

Inorganic metal cations are abundant in cells and are essential to life on Earth. Metal cations are vital for a variety of biological processes. Fundamental biological processes such as electron transfer, photosynthesis, and respiration require these ions (Bertini et al. 2007). Cations stabilize transition states in the replication of DNA, transcription of DNA to RNA, and ligation and cleavage of the nucleic acids by both proteins and ribozymes (Lykke-Andersen and Christiansen 1998; Steitz 1999; Doherty and Dafforn 2000; Lee et al. 2000; Yin and Steitz 2004; Ellenberger and Tomkinson 2008). Protein sequences encoded in messenger RNA are translated by amino-acid-bearing tRNAs at the ribosome, neither of which are transcribed, folded, assembled, or functional in the absence of inorganic cations. Few natural biological manipulations of the nucleic acid phosphodiester backbone proceed *in vitro* without divalent cations, and none are known to proceed in the absence of monovalent cations. Divalent cations stabilize three-dimensional structures of proteins, catalyze redox reactions, stabilize cell membranes, and transmit electrical current in the nervous system. Here, we focus on the interactions of metal ions with nucleic acids and explain their role in the translation system.

The earliest available data suggests that translation, one of the most central processes of life, originated with dependence on inorganic cations. The catalytic center of the ribosomal

large subunit (LSU), responsible for peptide bond formation, is stabilized by Mg²⁺. Within 20 Å of this center, about 20% of the phosphate oxygens of the RNA phosphodiester backbone interact directly with Mg²⁺ (Klein et al. 2004; Hsiao et al. 2009). Mg²⁺ bridges RNA nucleotides from disparate regions of the RNA sequence to form a structure that is inaccessible with monovalent cations alone (Hsiao and Williams 2009; Lenz et al. 2017). These Mg²⁺-RNA bridges are highly conserved in position and structure through all three major evolutionary branches of life, suggesting that they preceded, or at least coincided with, the last universal common ancestor (LUCA).

The availability of biologically useful inorganic ions is dependent on the existence of certain minerals and on their solubility in water. The composition of the atmosphere affects cation solubility, especially partial pressures of O_{2(g)} and CO_{2(g)}. An influx of O_{2(g)} to an aqueous system diminishes the solubility of redox-sensitive ions such as Cu²⁺, Fe²⁺, and Mn²⁺. Similarly, CO_{2(g)} decreases pH, mobilizing ions such as Ca²⁺ and Na⁺ from soils and precipitants. Fe²⁺ has been proposed and demonstrated to be a functional early Earth analogue for Mg²⁺ in nucleic-acid-processing steps, due to its similarity in size and charge density (Athavale et al. 2012; Okafor et al. 2017). Yet, in the pH range that sustains most life, Fe^{2+(aq)} precipitates as Fe(OH)_{2(s)} (Morgan and Lahav 2007) or Fe(III)_(s) species (Derry 2015) in a complex mechanism and at a rate that is dependent on the concentration of dissolved O_{2(g)}. Together with well-documented substitutions of Cu²⁺, Zn²⁺, and Mn²⁺ for Fe²⁺ in catalytic proteins (Torrents et al. 2002;

Wolfe-Simon et al. 2006; Anjem et al. 2009; Cotruvo and Stubbe 2011; Martin and Imlay 2011; Ushizaka et al. 2011; Aguirre and Culotta 2012; Harel et al. 2014), these observations suggest that changes in Earth's atmosphere over evolution may have altered the ions of key ion-dependent biological processes.

Water's interactions with ions are as important to biology as the ions themselves. Cations observed at the atomic level in three-dimensional molecular structures are almost always at least partially hydrated. Water molecules are coordinated, oriented, polarized, and acidified by ions in a manner that depends on the properties of the ion—mainly size and charge density (Hribar et al. 2002; Collins et al. 2007). Hydrated cations mitigate the negative charge on nucleic acids by long-range electrostatic and shorter-range hydrogen-bonding interactions with backbone phosphates. Partial dehydration allows direct coordination of the cation by phosphates (up to four for Mg^{2+}) of the nucleic acid backbone, while remaining cation-coordinated water molecules are available to participate in hydrogen bonding. Cation hydration mitigates the thermodynamic favorability of direct coordination by phosphodiesters by requiring unfavorable dehydration. Together, these interactions provide access to a range of complex and finely tunable conformational states of the RNA. The functional roles of cations in extant biology are interdependent with the unique properties of water.

6.4.2 HYDRATED CATIONS

6.4.2.1 COORDINATION BY WATER

Water molecules are oriented and polarized by cations, forming acidic metal hydrates ($Me(H_2O)_x^{n+}$) with elevated potential for participation in hydrogen bonding and function in enzymatic activity and proton donation. The extent of attraction between a cation and water molecules is given by the cation's hydration enthalpy. A large, negative hydration enthalpy indicates a stronger attraction than a small, negative one. The hydration enthalpies of cations vary in magnitude by cation identity, roughly based on size and charge. Hydration

enthalpies of Zn^{2+} and Mg^{2+} , for example, are large in magnitude (~−450 kcal/mol) compared with those of Na^{2+} and K^+ (~−100 kcal/mol) (Rashin and Honig 1985).

Biologically relevant metal hydrates include those of Ca^{2+} , Fe^{2+} , K^+ , Mg^{2+} , Mn^{2+} , Na^+ , and Zn^{2+} . These cations are coordinated by multiple water molecules in their hydrate form. The inherent polarity of each water molecule is increased by coordination with a cation, increasing the acidity of the water hydrogens. Experimentally derived $pK_{a\text{,}}$ (Table 6.4.1) indicate a relative hydrate acidity of $Zn^{2+} > Fe^{2+} > Mn^{2+} > Mg^{2+} > Ca^{2+} > Na^+ > K^+$ (Baes and Mesmer 1976; Stumm and Morgan 1996; Mähler and Persson 2012; Jackson et al. 2015), where the most acidic hydrate $[Zn(H_2O)_6]^{2+}$ has, by definition, the largest relative abundance of potentially reactive oxyanion species in water near physiological pH (~7.4). All of these hydrates are more acidic than bulk water (pK_a 15.7) (Baes and Mesmer 1976). The standard free energy for ionization of an uncoordinated water molecule ($H_2O \rightarrow OH^- + H^+$) is large and positive (382.8 kcal/mol); coordination in a hexahydrate of Mg^{2+} , Mn^{2+} , or Zn^{2+} reduces the energy of ionization by more than half (Bock et al. 1999).

Cations constrain water molecules to specific geometries. Though the number of water ligands for a hydrated cation is not fixed, especially when considering the dynamics of water molecules in solution, crystallographic structures reveal dominant coordination numbers (Table 6.4.1). Coordination by water ligands compresses metal ions: hydration decreases the effective ionic radius of the cation progressively with each water molecule added, while metal-oxygen bond distances increase (Shannon 1976; Bock et al. 1999). The effective ionic radius of a hexahydrated cation is also related to spin state and cation identity. Comparison of ionic radii, assuming hexahydrate coordination and low spin, yields relative atomic sizes $Fe^{2+} < Mn^{2+} < Mg^{2+} \leq Zn^{2+} < Ca^{2+} \leq Na^+ < K^+$ (Shannon 1976). The radius of a hexahydrated Fe^{2+} ion is less than half the radius of a hexahydrated K^+ ion. With the exception of Zn^{2+} , the radii of cation hexahydrates mentioned here correlate inversely with hydrate acidity. The availability of d-orbital electrons in the transition metals (Fe^{2+} , Mn^{2+} , and Zn^{2+}) is known to affect hydrate pK_a (Roychowdhury-Saha and Burke 2006).

TABLE 6.4.1
Properties of a Subset of Biologically Relevant Hydrated Cations

Cation	Effective Ionic Radii (Å) in a Hexahydrate (Shannon 1976)	Common Hydrate Coordination (Baes and Mesmer 1976; Jackson et al. 2015)	Experimentally Derived pK_a (Baes and Mesmer 1976; Jackson et al. 2015)
Fe^{2+}	0.61 ^a , 0.78 ^b	$[Fe(H_2O)_6]^{2+}$	9.3–9.5
Mn^{2+}	0.67 ^a , 0.83 ^b	$[Mn(H_2O)_6]^{2+}$	10.6–11.0
Mg^{2+}	0.72	$[Mg(H_2O)_6]^{2+}$	11.2–11.4
Zn^{2+}	0.74	$[Zn(H_2O)_6]^{2+}$	9.0
Ca^{2+}	1.00	$[Ca(H_2O)_8]^{2+}$	12.7–12.9
Na^+	1.02	$[Na(H_2O)_{6-8}]^+$	14.2
K^+	1.38	$[K(H_2O)_{6-8}]^+$	14.5

^a Low spin (estimate);

^b High spin.

Water molecule dynamics are suppressed by cations. The lifetime of a water molecule in the first coordination shell of a cation is generally longest for ions with the greatest charge density (e.g., highly charged with small ionic radius) (Diebler et al. 1969). It may be expected, based on ionic radii alone, that the relative exchange rate for the cations of Table 6.4.1 is $\text{Fe}^{2+} < \text{Mn}^{2+} < \text{Mg}^{2+} \cong \text{Zn}^{2+} < \text{Ca}^{2+} \cong \text{Na}^+ < \text{K}^+$. Exchange rates have been estimated experimentally as $\text{Mg}^{2+} < \text{Fe}^{2+} \cong \text{Mn}^{2+} < \text{Zn}^{2+} < \text{Ca}^{2+} \cong \text{Na}^+ < \text{K}^+$ (Diebler et al. 1969), where rates within one order of magnitude are considered within the range of uncertainty. The rate of exchange of water from the first coordination shell of K^+ (on the order of $\sim 10^9$ waters per second) occurs four orders of magnitude faster than from the first shell of Mg^{2+} (Diebler et al. 1969).

Ions affect water enthalpically and entropically. In pure water, intramolecular interactions are dominated by hydrogen bonds. Hydrogens and electron lone pairs on each water participate in hydrogen-bonding interactions with surrounding water molecules. The high electronegativity of the oxygen makes each water molecule a dipole, with partial negative and positive charges. The partially negative oxygen of a water dipole interacts electrostatically with adjacent cations. Conversely, the partially positive charge of the dipole (bearing two hydrogens) interacts electrostatically with anions. Ions organize first-shell water molecules, affecting surrounding water molecules. The geometric perturbation of waters around an ion in aqueous solution reflects the outcome of competition between the ion and surrounding water molecules (or between electrostatic and hydrogen-bonding interactions) for the ion-constrained water. Theoretical studies suggest that the outcome of this competition strongly favors electrostatic interactions when a cation is small and densely charged, which disrupts canonical water-water hydrogen bonds (Hribar et al. 2002). Large, less-charge-dense cations have a greater tendency to share their most proximal

water molecules with other water molecules and even promote canonical hydrogen bonding among surrounding waters (Hribar et al. 2002). The combined result is a difference in the distance of propagation of ion-induced organization of water. One report suggests that small, charge-dense cations reorganize up to two layers of water molecules around the ion ($< 5 \text{ \AA}$), whereas large, less-charge-dense cations perturb only one layer (Collins et al. 2007). Differences in the organization of water around ions may explain, if only in part, the lack of interchangeability of ions in some biochemical processes.

6.4.2.2 DEHYDRATION BY PHOSPHATE OXYANIONS

Biology employs partially hydrated cations that constrain ligands other than water in the first coordination shell. Ligand binding to hexahydrated Mg^{2+} , for example, displaces a water molecule in the reaction (Mayaan et al. 2004):

Single substitution of a water molecule for an alternate first-shell ligand type alters the structure of the Mg^{2+} hydrate (Mayaan et al. 2004). If the ligand (L) is the oxyanion OH^- , for example, the interatomic distance between Mg^{2+} and the oxygen atom of L is slightly less than the distance between Mg^{2+} and each of its remaining five water oxygens in $[\text{Mg}(\text{H}_2\text{O})_5(\text{OH})]^{+}$. In addition, the interatomic distance between Mg^{2+} and the remaining five water oxygens increases slightly relative to $[\text{Mg}(\text{H}_2\text{O})_6]^{2+}$. That is, the oxyanion ligand OH^- is held more tightly by Mg^{2+} than the neutral waters in $[\text{Mg}(\text{H}_2\text{O})_5(\text{OH})]^{+}$, and the neutral waters are less constrained (and possibly less acidic) than those in hexahydrated Mg^{2+} (Figure 6.4.1).

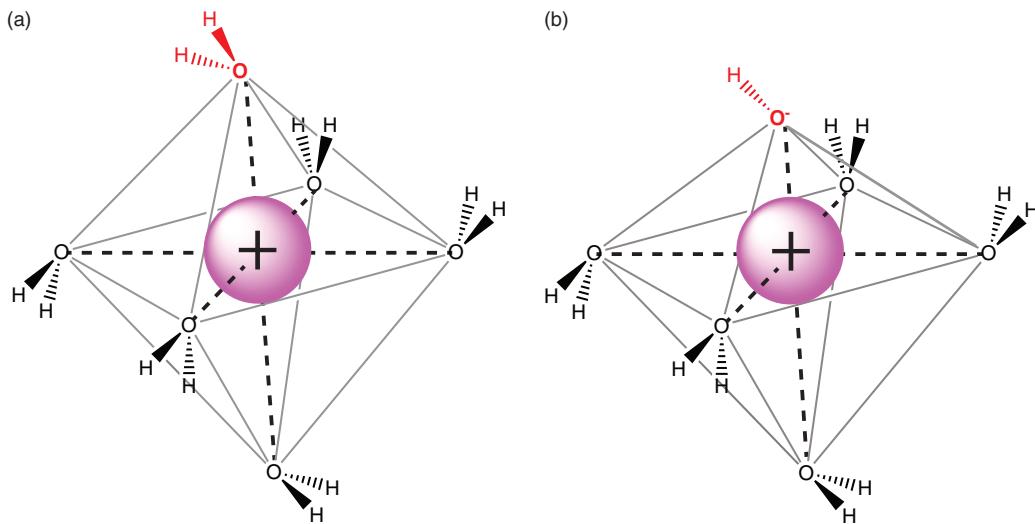

FIGURE 6.4.1 Small oxyanion ligands of cations are held more tightly than neutral water. A conceptual model of the difference in interatomic distances between a charge-dense cation and a water ligand or oxyanion ligand. (a) A hexahydrated cation with octahedral coordination geometry and six roughly equal cation-water oxygen interatomic distances. (b) The interatomic distance between the cation and an oxyanion ligand, in this case OH^- , is less than remaining cation-water distances. The magenta sphere is a generic charge-dense cation. Neutral water ligand and oxyanion ligand are shown in red font. Remaining cation-water distances are increased slightly in panel B, relative to panel A. The change in bond length is exaggerated for clarity.

Phosphates and phosphate esters are common first-shell ligands of cations in biology. Like water, they are oriented, polarized, and constrained by cations. Most biological phosphate is covalently bound in adenosine mono-, di-, or tri-phosphate (AMP, ADP, or ATP); deoxyribonucleic acid (DNA); or ribonucleic acid (RNA) (Figure 6.4.2), and these molecules are well-documented partners of cations, especially Mg^{2+} . The transition states in condensation of

the nucleic acid phosphodiester backbone by polymerases, ligases, and ribozymes, for example, are directly stabilized by divalent cations (Lykke-Andersen and Christiansen 1998; Steitz 1999; Doherty and Dafforn 2000; Lee et al. 2000; Yin and Steitz 2004; Ellenberger and Tomkinson 2008; Butcher 2011; Johnson-Buck et al. 2011).

Computation suggests that Mg^{2+} binds phosphate or phosphate esters more tightly than water molecules. In work by

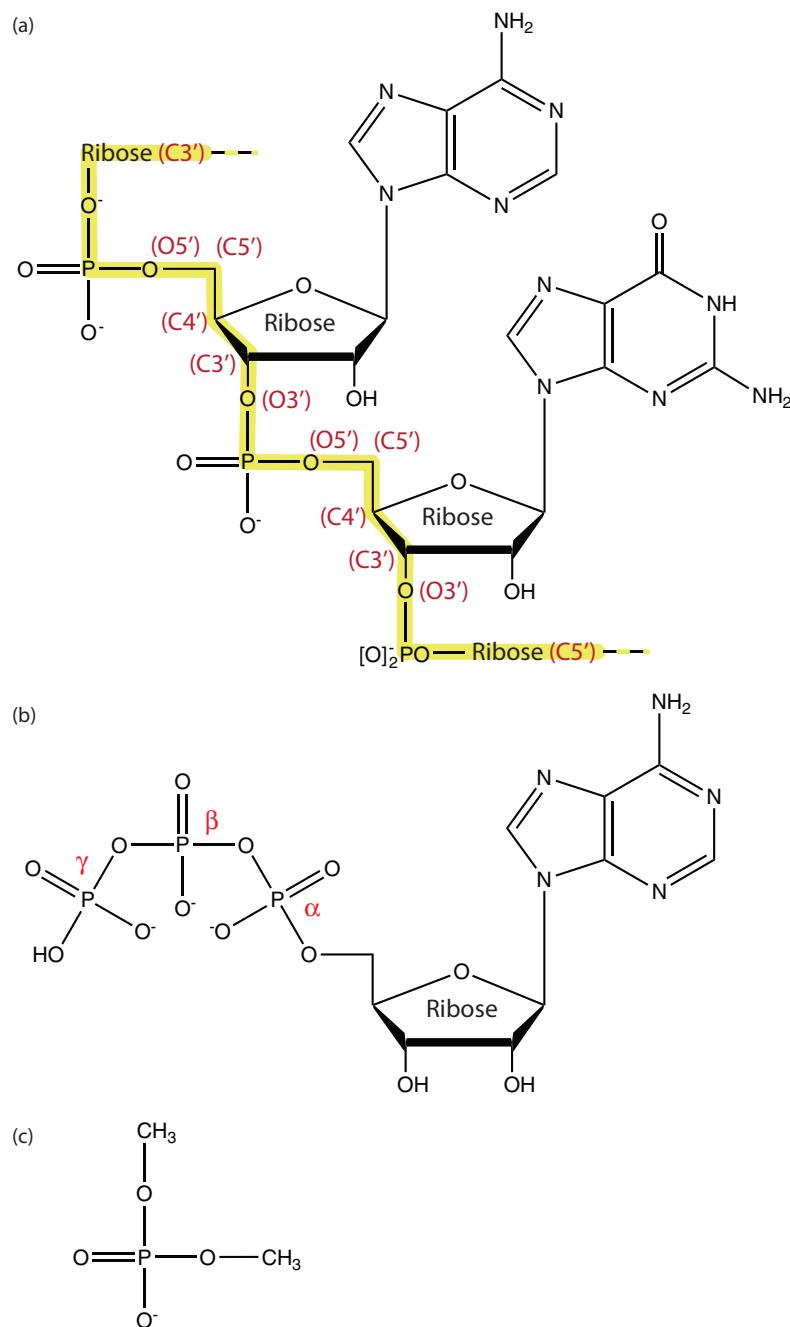

FIGURE 6.4.2 Common biological ligands of cations. (a) Two monomers of RNA connected by the phosphodiester backbone (yellow highlight), with conventional ribose atom designations in parentheses. (b) Adenosine triphosphate (ATP) with conventional phosphate designations. (c) Dimethyl phosphate. Dimethyl phosphate, as discussed, is a molecular model representing the phosphodiester connecting unit of the nucleic acid backbone. Hydrogens on the ribose sugars of panels (a) and (b) have been omitted for clarity.

Mayaan et al. (2004), substitution of a single water molecule in Mg²⁺ hexahydrate for a biologically derived ligand resulted in ligand-dependent changes in Mg²⁺-ligand interatomic distances and remaining cation-water interatomic distances, consistent with Figure 6.4.1. Mg²⁺ coordinated all evaluated small oxygen- and phosphate-bearing ligands with shorter cation-ligand oxygen interatomic distances than cation-water oxygen interatomic distances in single-substitution reactions (Mayaan et al. 2004). These ligands included free phosphate species hydrogen phosphate (HPO₄²⁻) and dihydrogen phosphate (H₂PO₄⁻), which dominate at physiological pH of 7.4, and dimethyl phosphate. Since the electronic structure of dihydrogen phosphate is somewhat different than phosphodiester, the dimethyl-phosphate anion (CH₃—O—PO₂—O—CH₃)⁻ (Figure 6.4.2) is often used as a model system representing the phosphodiester connection between the base-bearing sugars of nucleic acids. In dimethyl phosphate, one methyl group is an analogue for the 3' ribose carbon and the other an analogue for the 5' carbon of the adjacent ribose sugar. Reported relative coordination distances for Mg²⁺ are OH- < dimethyl phosphate < free phosphate species < water (Mayaan et al. 2004). In other words, Mg²⁺ binds to dimethyl phosphate more tightly than to free phosphate or water.

The geometry of the nucleic acid backbone is cation-dependent. Work by Panteva et al. aiming, in part, to computationally replicate experimentally derived thermodynamic parameters for the interactions of Mg²⁺, Mn²⁺, or Zn²⁺ with RNA, derived parameters for interactions of these cations with the nucleic acid analogue dimethyl phosphate. Their results suggest that contact and minimum energy distances between cation and phosphate follow a trend in which dimethyl phosphate oxyanion-Mg²⁺ and -Zn²⁺ distances are approximately equal and less than that of Mn²⁺ (Panteva et al. 2015), suggesting that dimethyl phosphate binds more tightly to Mg²⁺ and Zn²⁺ than to Mn²⁺. Fujimoto et al. (1994) reported cation-dependent variations in the nucleic acid hydrodynamic radius, in which Na⁺ slightly decreased while divalent cations Mg²⁺ and Mn²⁺ substantially increased the hydrodynamic radius of DNA. These observations suggest cation-specific structural changes in nucleic acids, perhaps phosphodiester bond stabilization and/or changes in hydration.

Mg²⁺ polarizes first-shell phosphate ligands, shortening phosphodiester bonds and leaving phosphorus more susceptible to nucleophilic attack. Upon substitution of a Mg²⁺-constrained first-shell water with dimethyl phosphate in computational analyses, Mayaan et al. (2004) observed corresponding changes in the phosphate ligand. While the interatomic bond distance between phosphorus and the phosphate oxygen interacting with Mg²⁺ increased, bond distances between the phosphorus atom and phosphate oxygens covalently bound to the methyl groups decreased, suggesting that Mg²⁺ polarizes phosphate, drawing negative charge away from phosphate oxygens not directly coordinated by the cation. The magnitude of decrease in the length of the phosphodiester bonds of dimethyl phosphate has been calculated to be cation-specific, where the change induced by Ni²⁺ > Mg²⁺ > Na⁺ (Zhang et al. 2015). Application of this observation to

nucleic acids suggests that first-shell coordination of a backbone phosphate with cations may increase the reactivity of phosphorus while rigidifying the backbone by shortening the phosphodiester bonds in a cation-dependent manner. The expected change in bond lengths based on these calculations are within the range of precision of most nucleic acid structures but are believed to be corroborated by a few very-high-resolution structures.

6.4.3 CATIONS AS RNA LIGANDS

6.4.3.1 CONCEPTUAL FRAMEWORKS FOR BINDING

Cations stabilize RNA through a continuum of associations, not just first-shell interactions. Williams and co-workers classified cation interactions with RNA as chelated, condensed, glassy, or diffuse, based on six criteria: relative population, number of first-shell RNA ligands, extent of mobility, dimensionality of mobility, contribution to RNA thermodynamic stability, and contribution to non-canonical RNA structure (Bowman et al. 2012).

The most populous ions in solutions of RNA are diffuse ions, which are fully hydrated without first-shell or first-shell water interactions with RNA and are no more restricted in mobility than bulk water. Diffuse cations are much more abundant than partially hydrated cations that directly coordinate RNA. The phosphodiester backbone of RNA is negatively charged and therefore self-repellent; diffuse cations electrostatically neutralize the RNA backbone. They interact with RNA by numerous weak, long-range electrostatic interactions (Manning 1969), contributing to the overall thermodynamic stability of nucleic acids and their complexes. These ions are undetectable in crystallographic structures in part due to their positional disorder. Diffuse ions do not stabilize specific non-canonical RNA structures.

Condensed ions (Manning 1969) have slightly attenuated mobility due to electrostatic or hydrogen-bonding interactions of one or more ion-coordinated waters with RNA or an RNA ligand. Their relative population and rate and dimensionality of diffusion are less than that of diffuse ions but are greater than glassy ions. Condensed ions neutralize charge that is more localized to the RNA than diffuse ions. Their population is sensitive to a local base pairing of nucleic acids and affects the geometry and conformational dynamics of the nucleic acid grooves (Lavery and Pullman 1981). Condensed ions can be visualized as a shell or coating on the surface of a three-dimensional RNA, extending beyond the van der Waals radius of the RNA.

Glassy cations have at least one first-shell RNA ligand and restricted mobility. They are typically found in the interior of the RNA, encased within the external three-dimensional surface of the native structure, such that the dimensionality of diffusion is reduced. The mobility of glassy cations is less than that of condensed cations. Glassy cations may contribute to stabilization of specific RNA structural states that are inaccessible in their absence. Divalent ions, especially Mg²⁺, play a special role in the stability of RNA, due to their ability

to mediate strong tertiary interactions. Charge-dense Mg^{2+} is glassy, with one first-shell RNA ligand, while less-charge-dense cations such as Na^+ and K^+ require four to five first-shell RNA ligands to similarly restrict diffusion.

Chelated cations, bearing more than one first-shell RNA ligand in the case of Mg^{2+} , are the least frequent ions in RNA structures but often have the most significance for the structure-function relationship. Chelated cations are typically at the interior of the three-dimensional surface of the native RNA. Their rate of diffusion is dependent on the number of first-shell RNA ligands. These cations are the least mobile of the four classes and, being rigidly bound by the RNA, are difficult to remove *in vitro* without disturbing the RNA structure.

The mode of Mg^{2+} -RNA interaction is influenced by local RNA structure. Experimental work suggests that sites of Mg^{2+} chelation in RNAs are not random. Linear RNAs are less likely than folded RNAs to form first-shell interactions with Mg^{2+} , suggesting secondary structure and even sequence dependence (Porschke 1979). However, Mg^{2+} forms first-shell interactions less readily with double-stranded RNA than with compact single-stranded RNA (Kankia 2003, 2004). In many cases, site-specific Mg^{2+} binding and RNA conformation are interdependent: the conformational space in which an RNA achieves its native structure, including chelation of Mg^{2+} , is not available without Mg^{2+} , even with high concentration of monovalent cations (Draper et al. 2005; Grilley et al. 2006).

6.4.3.2 A QUANTUM MECHANICAL PERSPECTIVE ON FIRST-SHELL RNA-CATION INTERACTIONS

First-shell RNA- Mg^{2+} complexes occur so frequently in ribosome and ribozyme x-ray structures that they appear to be fundamental units of RNA folding (Petrov et al. 2011). These complexes often appear in a singular and defined geometry, referred to here as the bidentate chelation complex (or bidentate clamp, Figure 6.4.3). Bidentate clamps are characterized by a 10-membered ring system ($Mg^{2+}-O^- - P - O5' - C5' - C4' - C3' - O3' - P - O^-$), which includes a single Mg^{2+} chelated by phosphates of adjacent nucleotides (Hsiao et al. 2008; Hsiao and Williams 2009). Tri- and tetra-dentate RNA- Mg^{2+} chelates have been noted (Hsiao et al. 2008).

Petrov et al. (2011) characterized the energetics of bidentate RNA- Mg^{2+} clamps computationally using density functional theory (DFT). This work explains a special role of magnesium ions in the formation of tertiary interactions with RNA due to magnesium's enhanced binding ability with phosphodiester linkages and nucleobases. The Mg^{2+} -RNA interactions are amplified quantum effects of polarization and charge transfer due to high charge to radius ratio, which is the highest of all alkali and alkaline earth cations, making magnesium a unique ion in this group.

Bidentate chelation refers to cation association with two anions of the same ligand (in this case, the oxyanions of RNA phosphates) in the first coordination shell of the cation. The defined geometry and high stability of RNA- Mg^{2+} bidentate clamps have been attributed to the tightly packed octahedral structure of the Mg^{2+} first coordination shell (Brown 1992;

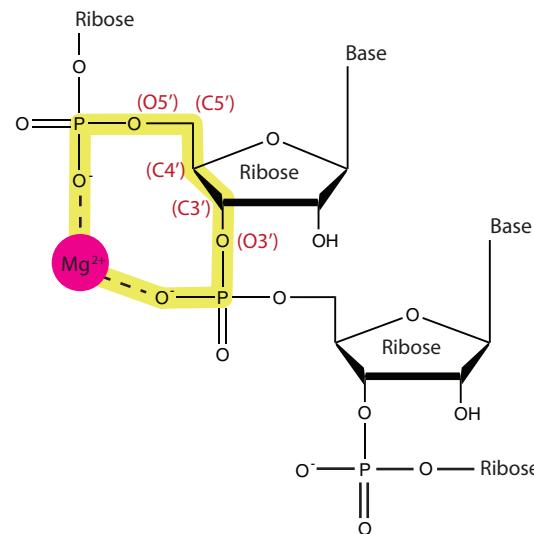

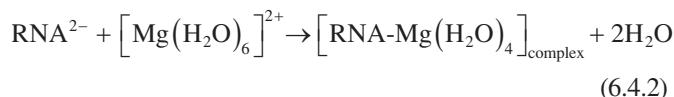

FIGURE 6.4.3 The bidentate clamp characterized by a 10-membered ring system ($Mg^{2+}-O^- - P - O5' - C5' - C4' - C3' - O3' - P - O^-$), which includes a single Mg^{2+} chelated by phosphates of adjacent nucleotides. (From Petrov et al. 2011; Hsiao, C. et al., Complexes of nucleic acids with group I and II cations, in *Nucleic Acid Metal Ion Interactions*, edited by N. Hud, pp. 1–35, The Royal Society of Chemistry, London, UK, 2008; Hsiao, C. and Williams, L.D., *Nucleic Acids Res.*, 37, 3134–3142, 2009.)

Bock et al. 1999) and to the resulting non-canonical RNA backbone confirmation (Klein et al. 2004; Hsiao et al. 2008; Hsiao and Williams 2009). Using DFT, Petrov et al. explored the reaction:

In this reaction, two waters of hexahydrated magnesium are displaced as the cation is chelated by phosphate oxyanions on consecutive RNA nucleotides. Petrov et al. modeled the reaction by computationally optimizing the RNA structure in the absence and presence of $[\text{Mg}(\text{H}_2\text{O})_6]^{2+}$, followed by optimization of the bidentate RNA- $\text{Mg}(\text{H}_2\text{O})_4$ complex. Optimization was repeated with $[\text{Na}(\text{H}_2\text{O})_6]^{+}$ or $[\text{Ca}(\text{H}_2\text{O})_6]^{2+}$ in place of the Mg^{2+} hexahydrate, with the objective of understanding the uniqueness of the role of Mg^{2+} in complex stability.

RNA forms a more stable bidentate chelation complex with Mg^{2+} than with Na^+ or Ca^{2+} (Petrov et al. 2011). The RNA- $\text{Mg}(\text{H}_2\text{O})_4$ complex is ~10 kcal/mol more stable than the RNA- $\text{Ca}(\text{H}_2\text{O})_4$ complex. The $[\text{RNA-Na}(\text{H}_2\text{O})_4]^-$ complex approaches neutral interaction energy and is unstable. The ionic radius of hexahydrated $Mg^{2+} < Ca^{2+} < Na^+$, therefore Mg^{2+} forces first-shell oxyanion RNA ligands closer together than Ca^{2+} or Na^+ . The close proximity of the RNA oxyanions coordinated by Mg^{2+} incurs an electrostatic penalty of ~10 kcal/mol from the opposing negative charges on the two oxygens; this is mitigated by other favorable energy components.

The octahedral coordination geometry of hexahydrate metals is distorted by RNA phosphate oxyanion ligands.

Distances from metal to oxygen are smaller for RNA phosphates than for water in Mg²⁺ and Ca²⁺ RNA chelation complexes. The metal-to-RNA phosphate oxyanion interatomic distances in the Na⁺ RNA chelation complex are polymorphic. Optimization with Na⁺ yields a monodentate structure with only one RNA phosphate oxyanion ligand in the first coordination shell of Na⁺.

Energies of binding are substantial for small, charge-dense Mg²⁺ complexes but are less so for Ca²⁺ due to its larger size and for Na⁺ due to its smaller charge. Decomposition of the interaction energy of bidentate clamps reveals that, for all cations modeled, electrostatic components make the greatest contributions to complex stability, followed by polarization (of the RNA phosphates) and charge transfer. There is a ~20 kcal/mol difference in the electrostatic contribution to bidentate clamp stability by Mg²⁺ compared with Ca²⁺; and a ~220 kcal/mol difference by Na⁺ compared with Mg²⁺. The polarization component is less than half of the electrostatic contribution for all cations. Charge transfer components include a net reduction of positive charge on each cation (Mg²⁺: 0.2 e⁻ > Ca²⁺: 0.1 e⁻ > Na⁺: 0.1 e⁻) (Petrov et al. 2011).

Magnesium's high charge density brings phosphate oxyanions of adjacent RNA nucleotides into closer proximity than Ca²⁺ or Na⁺, inducing non-canonical RNA backbone conformations found especially in catalytic RNAs. Complex formation may be driven, in part, by magnesium's preference for RNA's negatively charged and polarizable phosphate oxyanions over water. Though electrostatic energy components dominate stability, polarization and charge transfer components are not negligible. The small size of Mg²⁺ creates a symmetrical distortion of the metal's octahedral coordination geometry, in which phosphate oxyanions are bound more tightly than water oxygens.

6.4.4 STRUCTURAL ROLES IN THE RIBOSOME

6.4.4.1 A Mg²⁺ SCAFFOLD FOR THE RIBOSOME PEPTIDYL TRANSFERASE CENTER

All proteins of living organisms are synthesized by the ribosome, a highly conserved and ancient RNA-protein enzyme. The ribosome is the site of execution of the genetic code. With the help of aminoacyl tRNA synthetases and transfer RNAs, messenger RNA is decoded at the small subunit (SSU), while peptide bonds are made in the ribosomal LSU at the catalytic center, the peptidyl transferase center (PTC). The bacterial LSU contains two ribosomal RNA (rRNA) polymers, the 23S rRNA and the 5S rRNA, as well as numerous ribosomal proteins. The LSU rRNA of *Thermus thermophilus* is made up of more than 2,900 nucleotides, subdivided into seven domains (Domains 0, I, II, III, IV, V, and VI; Figure 6.4.4), based on the native structure common to all ribosomes (Petrov et al. 2014). Bokov, Steitz, Williams, and others observed that the occurrence of Mg²⁺ in the LSU is greatest in Domain V near the PTC (Hansen et al. 2001; Klein et al. 2004; Bokov and Steinberg 2009; Hsiao et al. 2009).

Hsiao and Williams (2009) reported a framework of highly conserved Mg²⁺ microclusters in the LSU. These microclusters include the 10-membered Mg²⁺-RNA ring structure (Figure 6.4.3), modeled using DFT by Petrov et al. (2011), but in microclusters, the Mg²⁺ ion is one of a pair of Mg²⁺ ions chelated by a common bridging phosphate. The bridging phosphate, which has the form Mg²⁺_a-O⁻-P-O⁻-Mg²⁺_b, is part of the 10-membered chelation ring (Mg²⁺_a-O⁻-P-O⁻-C5'-C4'-C3'-O3'-P-O⁻) (Hsiao and Williams 2009). As in Petrov et al. (2011), the phosphates of the chelation ring are contributed by adjacent nucleotides, but in a microcluster, at least one additional phosphate oxyanion interacts with at least one of the Mg²⁺ ions.

Mg²⁺-RNA microclusters support long-range intra- and inter-domain interactions relevant to the global structure of the ribosome. Hsiao and Williams (2009) found three ancient Mg²⁺-RNA microclusters supporting the PTC and a fourth located near the LSU exit tunnel (Figure 6.4.4). These microclusters are conserved among archaea (represented by *Haloarcula marismortui*), bacteria (represented by *T. thermophilus*), eukarya, and mitochondria. Two of the ancient microclusters make intra-domain nucleotide connections, while the other two connect very remote rRNA nucleotides of multiple domains of the LSU. References to specific nucleotides are given as *T. thermophilus* residues in the *Escherichia coli* numbering convention.

Microcluster D2 connects Domain V of the LSU, near the PTC, to Domain II of the LSU (Figure 6.4.5). Here, the 10-membered ring is made of up of the phosphate groups and ribose atoms of A783 and A784 in Domain II. One Mg²⁺ of this microcluster interconnects these nucleotides to the phosphate of A2589 in Domain V near the PTC. The other Mg²⁺ links the phosphate of A784 to the phosphate of G2588. Five phosphate oxygens of four nucleotides representing two disparate locations in the rRNA sequence are bridged by these two Mg²⁺.

Microcluster D4 connects Domain IV of the LSU to Domain II (Figure 6.4.6). There are two 10-membered rings in this microcluster. One ring is made up of the phosphate groups and ribose atoms of C1782 and A1783; the other is made up of the phosphate groups and ribose atoms of A1783 and A1784. All of these nucleotides are in LSU Domain IV. The phosphate of A1780, a non-consecutive nucleotide of Domain IV, chelates one of these Mg²⁺. One Mg²⁺ of this microcluster is also chelated by the phosphate of U740 in Domain II.

Microclusters D1 and D3 make long-range intra-domain connections of the rRNA (Figure 6.4.4). Microcluster D1 links RNA nucleotides of Domain V that are not adjacent in the linear sequence or secondary structure; microcluster D3 links non-adjacent nucleotides of Domain III. In microcluster D1, the 10-membered ring is made of up of the phosphate groups and ribose atoms of C2498 and C2499. The phosphate of A2448 (50 nucleotides away in the primary sequence) bridges both of the microcluster magnesiums. In microcluster D3, located near the exit tunnel, the 10-membered ring is made of up of the phosphate groups and ribose atoms of

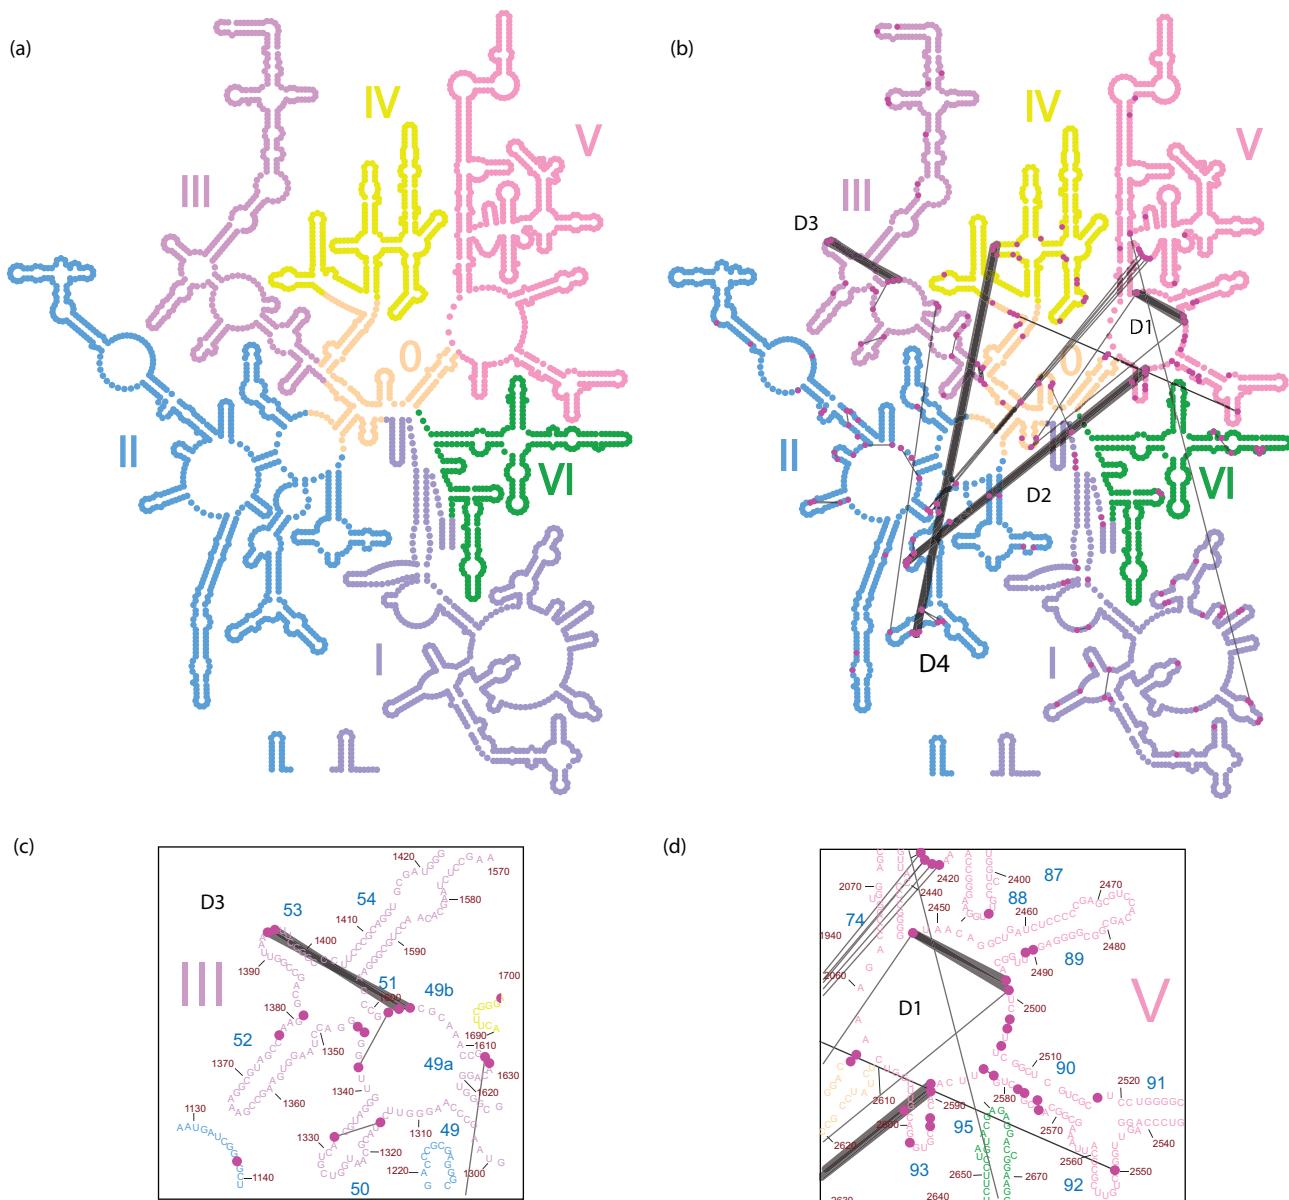

FIGURE 6.4.4 Ancient Mg²⁺ microclusters interconnect domains of 23S rRNA in the LSU. (a) Divisions in rRNA secondary structure. Domains 0, I, II, III, IV, V, and VI are represented by changes in nucleotide color. (b) Microclusters D1, D2, D3, and D4 are shown as thick gray lines connecting nucleotide phosphates sharing a common first-shell Mg²⁺. Other first-shell Mg²⁺ interactions are shown as thin gray or black lines (some have been omitted for clarity). Nucleotides are colored spheres. Mg²⁺ ions are magenta spheres. (c) Mg²⁺ microcluster D3 of Domain III. (d) Mg²⁺ microcluster D1 of Domain V. Secondary structure data generated with RiboVision (Bernier et al. 2014); microcluster data from Hsiao. (From Hsiao, C. and Williams, L.D., *Nucleic Acids Res.*, 37, 3134–3142, 2009.)

A1603, along with the phosphate group of C1604. Phosphates of U1394 and U1395 chelate the Mg²⁺ of this microcluster.

Mg²⁺ microclusters cause bases to unstack, priming them for short- and long-range rRNA interactions. Microcluster D2 unstacks base A784 of Domain II, which forms a pocket for ribosomal protein L2, and base A2587 of Domain V, which intercalates with unstacked bases C1782 and A1783 from microcluster D4 of Domain IV (Figure 6.4.5). Microcluster D4 induces a large array of unstacked bases in Domain IV, some of which intercalate with A2587 (unstacked in D2) of Domain V (Figure 6.4.6). Microcluster D1 unstacks G2447 from A2448 and A2497 from C2498 in Domain V.

Microcluster D3 unstacks base U1602 from A1603 and base A1393 from U1394 in Domain III.

The Mg²⁺-RNA microcluster appears to be an ancient motif, with roles in rRNA folding and function, though it does not participate directly in peptide bond formation. The microclusters and rRNA elements linked by microclusters are conserved over evolution among archaea, bacteria, eukarya, and mitochondrial rRNA. Mg²⁺-RNA microclusters have been identified in other rRNAs, including the bacterial SSU rRNA (Wimberly et al. 2000), and the P4-P6 domain of the *Tetrahymena thermophila* Group I intron ribozyme (Cate et al. 1997).

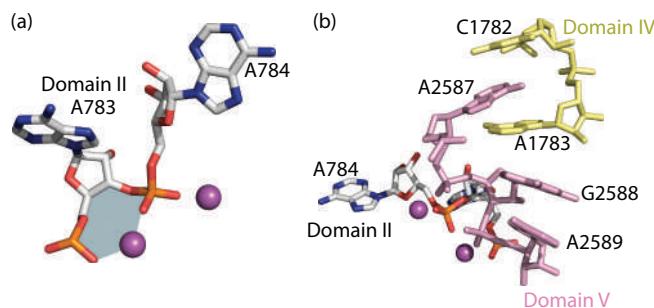

FIGURE 6.4.5 Inter-domain Mg^{2+} -RNA microcluster D2 of 23S rRNA. (a) The D2 microcluster is a 10-membered ring (composed of a single Mg^{2+} , the phosphate and ribose backbone atoms of nucleotide A783, and the phosphate of A784) and a second Mg^{2+} ion bridged by the common phosphate of A784. The area of the 10-membered ring is shown gray. RNA carbons are light gray, oxygens red, phosphorus orange, and nitrogen blue. Magnesium ions are magenta spheres. D2 microcluster nucleotides A783 and A784 are in Domain II of the 23S rRNA secondary structure. (b) The D2 microcluster mediates short- and long-range interactions in the 23S rRNA. The two Mg^{2+} of D2 are chelated by nucleotide phosphates of Domain II (atoms colored as in panel [a]) and Domain V rRNA (pink). Microcluster formation induces a non-canonical RNA backbone conformation, unstacking A2587 of Domain V, which intercalates with C1782 and A1783 of Domain IV (yellow). Structure of *T. thermophilus* [PDB 2J01 (obsolete). Superseded by 4V51]; microcluster data from Hsiao. (From Hsiao, C. and Williams, L.D., *Nucleic Acids Res.*, 37, 3134–3142, 2009.)

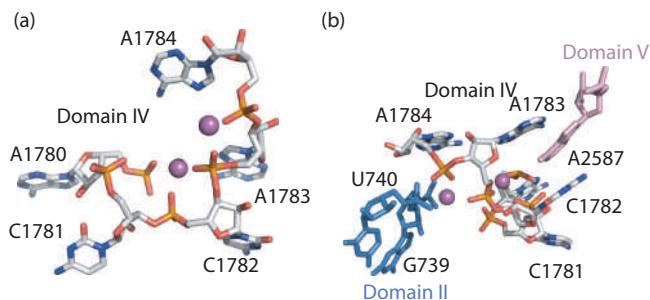

FIGURE 6.4.6 Inter-domain Mg^{2+} -RNA microcluster D4 of 23S rRNA. (a) The D4 microcluster has two consecutive 10-membered rings composed of two Mg^{2+} and the phosphate and ribose backbone atoms of nucleotides C1782 and A1783, and A1783 and A1784. The phosphate of A1780 also chelates one of the Mg^{2+} . (b) The D4 microcluster mediates short- and long-range interactions in the 23S rRNA. One Mg^{2+} of D4 is chelated by the phosphate of U740 of Domain II (blue). C1782 and A1783 intercalate with A2587 of Domain V (pink). Structure of *T. thermophilus* [PDB 2J01 (obsolete). Superseded by 4V51]; microcluster data from Hsiao. (From Hsiao, C. and Williams, L.D., *Nucleic Acids Res.*, 37, 3134–3142, 2009.)

6.4.4.2 RIBOSOMAL RNA FOLDING IN THE ABSENCE OF PROTEINS

The 23S rRNA of the ribosome LSU is a single polymer, thousands of nucleotides in length. Folding of the native ribosome to its catalytic state *in vivo* occurs with cations, including Mg^{2+} ; many ribosomal proteins; and post-transcriptional modifications.

It has been shown that the 23S rRNA, without ribosomal proteins or post-transcriptional modifications, can fold to form RNA-RNA interactions resembling those of the native ribosome (Lenz et al. 2017). Lenz et al. used a chemical footprinting technique called Selective 2' Hydroxyl Acylation Analyzed by Primer Extension (SHAPE) (Mortimer and Weeks 2007) to assess the reactivity of each ribose 2'-OH in the 23S rRNA sequence to an electrophile. SHAPE reactivity can be viewed as a measure of a nucleotide's mobility or tendency to adopt a reactive conformation, meaning that the least-reactive nucleotides are the most likely participants in canonical hydrogen-bonding interactions.

Lenz et al. (2017) found that Na^+ alone supports formation of native-like rRNA secondary structure in the 23S rRNA. In other

words, regions of rRNA such as helices, which are base-paired in the x-ray crystallographic structure, show minimal reactivity by SHAPE, whereas bases in or near the bulges and loops of rRNA, which should be more mobile and/or unpaired, are reactive.

Structural collapse of 23S rRNA to form the tertiary interactions of the native ribosome LSU requires Mg^{2+} (Lenz et al. 2017). Addition of Mg^{2+} alters the pattern of reactivity, observed with Na^+ alone. Some bases or regions of bases at or near bulges and loops become more, and others less, reactive in the presence of Mg^{2+} and Na^+ than in the presence of Na^+ alone. The reactivities in helical regions, unreactive in the presence of Na^+ alone, are largely unaltered in the presence of Mg^{2+} . However, non-helical regions showed changes in reactivity upon addition of Mg^{2+} . Inspection of regions of crystallographic structures of native ribosomes showing altered reactivity by SHAPE suggests that these regions are largely associated with or are proximal to (1) known RNA-RNA tertiary interactions or (2) known RNA-protein interactions. Regions of altered reactivity are not limited to nucleotides expected to form first-shell tertiary interactions with Mg^{2+} , as observed by Hsiao and Williams (2009).

Magnesium-induced tertiary interactions include formation of an intricate inter-domain rRNA interaction network. Nucleotides within secondary structure domains come into close proximity in three-dimensional space on folding and formation of the native 23S rRNA structure, interacting, in part, via base-pairing, base stacking, and phosphate-Mg²⁺ interactions. Of the 21 possible combinations of domain-to-domain interactions, the native 23S rRNA (as represented by bacterium *T. thermophilus*) has 14 interactions. Lenz et al. (2017) found that 12 of the 14 domain-domain interactions are detectable as Mg²⁺-induced by SHAPE in the absence of ribosomal proteins. Here, one domain-domain interaction may be represented by a series of nucleotide-nucleotide or nucleotide-Mg²⁺ interactions.

Mg²⁺ appears necessary to position rRNA nucleotides for native interactions with ribosomal proteins and form a catalytic structure. Folding of the LSU 23S rRNA in the presence of Mg²⁺ induces a native-like structure in which the rRNA has collapsed to form much of the essential inter-domain architecture.

6.4.4.3 RIBOSOMAL RNA FOLDING IN THE PRESENCE OF PROTEINS

Divalent cation-rRNA backbone interactions induce conformational changes that accommodate other ligands. Magnesium-microcluster D2 forms a pocket in the ribosome for ribosomal protein L2 (now known as uL2; Ban et al. 2014). Hsiao et al. found that Mg²⁺-microcluster D2 connects Domain V of the 23S rRNA, near the PTC, to Domain II of the 23S rRNA (Hsiao and Williams 2009). The 10-membered ring of this microcluster is made of up A783 and A784 in Domain II. One Mg²⁺ forms a phosphate-mediated tertiary interaction with A2589 in Domain V near the PTC. The other Mg²⁺ forms a phosphate-mediated tertiary interaction with G2588 of Domain V. The D2 microcluster unstacks base A784 of Domain II, forming a pocket for ribosomal protein uL2 (Figure 6.4.5).

Ribosomal protein uL2 is unique in that its interaction with 23S rRNA appears to be more extensively mediated by Mg²⁺ than the interactions of other LSU proteins. The two Mg²⁺ ions of the D2 microcluster have (in sum) 12 first-shell ligands: five RNA phosphate oxyanions and seven waters (Petrov et al. 2012). Protein uL2 interacts directly with four of these waters through two highly conserved amino acids, alanine (or valine) and asparagine, interposed by a conserved methionine. The conserved uL2 sequence is most frequently alanine-methionine-asparagine (AMN) (Petrov et al. 2012). In *T. thermophilus*, these are residues Ala225, Met226, and Asn227 (Figure 6.4.7).

The observed interaction at the D2 microcluster is protein-water-Mg²⁺-RNA, where the protein-water components interact via hydrogen bonds between a protein carbonyl and an acidic Mg²⁺-bound water. In addition to directly coordinating the phosphates of A783, G784, G2588 and A2589 of the D2 microcluster, the Mg²⁺ ions, through their water ligands, interact with lone pairs of electrons on the backbone carbonyl of Ala225 and the side-chain carbonyl of Asn227 (Figure 6.4.7). Petrov et al. (2012) dissected and examined the stability of

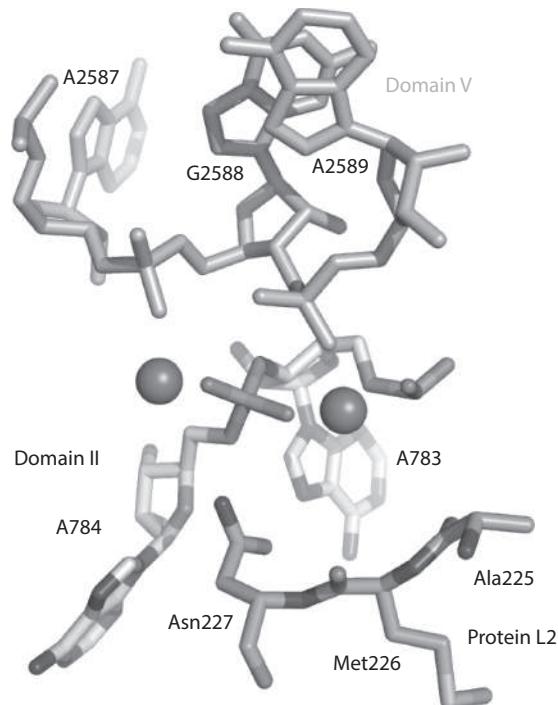

FIGURE 6.4.7 The microcluster D2-ribosomal protein L2 interaction, an RNA-Mg²⁺-water-protein interaction. Phosphates of A783, A784, G2588, and A2589 coordinate two Mg²⁺ ions and form microcluster D2. These magnesium ions are also chelated by the backbone carbonyl of Ala225 and the side-chain carbonyl of Asn227. Structure of *T. thermophilus* [PDB 2J01 (obsolete). Superseded by 4V51] adapted from Petrov, A.S. et al., *J. Phys. Chem. B*, 116, 8113–8120, 2012.)

each component of the D2 microcluster protein-water-Mg²⁺-RNA interaction by using quantum methods.

In Mg²⁺ microcluster D2, the Mg²⁺ ions stabilize amino acid-water interactions, while the RNA ligands of the Mg²⁺ attenuate them slightly. Though Ala225 and Asn227 each have favorable and roughly equal interaction energies with water alone, interaction energies with water bound to Mg²⁺ in a hexahydrate (e.g., [Mg(H₂O)₆]²⁺) are four-fold more favorable. The charge transfer component of the interaction energies implies that the charge on the amino acid carbonyl is transferred to the Mg²⁺ by polarization of the mediating water. To understand the effect of the RNA phosphates on the stability of the complex, two dimethyl phosphate molecules (Figure 6.4.2) were used to simulate chelation of [Mg(H₂O)₄]²⁺ by the RNA bidentate clamp. Chelation of the metal by the RNA analog decreases the overall stability of the amino acid-water-Mg²⁺-RNA complex by roughly one third, though interaction energies remained favorable. In other words, chelation of the Mg²⁺ by the phosphates of the RNA analog decreases polarization of the remaining water ligands of the Mg²⁺ and thus the acidity of the protein-mediating water, slightly attenuating the strength of the water-protein interaction. Even so, the amino acid-water-Mg²⁺-RNA complex remains more than two-fold more stable than the amino acid-water complex, and the charge transfer component of the interaction energy remains strong enough to

infer that some charge from the amino acid carbonyl remains with the Mg²⁺.

The D2 microcluster stabilizes a segment of protein uL2 through orientation and polarization of water molecules. The AMN segment of protein uL2 interacts with the D2 microcluster through six hydrogen bonds. Four of these are with Mg²⁺-polarized water molecules. The backbone carbonyl oxyanion of Ala225 hydrogen bonds (H-bonds) with two Mg²⁺-bound waters of the same D2 Mg²⁺ and one 2'OH of rRNA A782. The side-chain carbonyl of Asn227 H-bonds with one water of each D2 Mg²⁺, while the side-chain amine of Asn227 shares a hydrogen with a phosphate oxyanion of A784. To determine the role of the Mg²⁺ in supporting this interaction, Petrov et al. (2012) used DFT to examine the stability of the hydrated L2 segment, AMN-water, with and without the Mg²⁺ and RNA of the D2 microcluster. The AMN-water-Mg²⁺-RNA complex is four-fold more stable than AMN-water, even though AMN does not interact directly with the Mg²⁺. In the case of uL2, neither Mg²⁺ nor RNA alone stabilizes the interaction with ribosomal protein; it is rather the orientation and polarization of the water molecules by Mg²⁺ that enhance stability.

6.4.5 RIBOZYME FUNCTION

6.4.5.1 RIBOZYMES WITH Mg²⁺, Fe²⁺, AND OTHER CATIONS

Cations in the LSU play, to current knowledge, strictly structural roles in their support of the peptidyl transfer reaction. Although Mg²⁺ is necessary for folding and function of the LSU, there is not a direct role for any Mg²⁺ ion in the mechanism of peptidyl transferase (Noller et al. 1992). This is not the case for all catalytic RNAs.

The transition states of many ribozymes (see also Chapters 6.4 and 6.6) are directly stabilized by divalent metals (Butcher 2011; Johnson-Buck et al. 2011). In the activity of the *in vitro* evolved L1 ligase ribozyme (Robertson and Scott 2007), for example, the 5' α-phosphate of a nucleotide triphosphate (Figure 6.4.2) is polarized by a Mg²⁺ ion, priming the α-phosphorus for nucleophilic attack by an acidic 3'-OH of the adjacent nucleotide. Nucleophilic attack of the 3'-OH on the 5' α-phosphate completes the phosphodiester bond necessary for backbone ligation, generating a pyrophosphate leaving group (Robertson and Scott 2007). In the hammerhead ribozyme, an acidic metal-coordinated water at the active site is believed to donate a hydrogen, stabilizing the oxyanion leaving group during cleavage (Scott et al. 1995; Murray et al. 1998; Scott 2007). Unlike the L1 ligase ribozyme, which requires the divalent metal for activity, the hammerhead ribozyme retains some activity in the absence of divalent metals in high (e.g., >1.0 M) Na⁺ concentration (Nakano et al. 2014) or low Na⁺ concentration (100 mM) at freezing temperature (Lie and Wartell 2015).

The hammerhead ribozyme, in particular, has a promiscuous relationship with cations. Computed barriers in the free-energy landscapes of “metal migration” within the active site of the self-cleaving hammerhead ribozyme are generally

larger for Mg²⁺ and Zn²⁺ than for Mn²⁺ (Panteva et al. 2015). This observation is consistent with experimental work showing that at pH 7, in the presence of 0.1 M NaCl, the catalytic rate of self-cleavage by the hammerhead is greater with Mn²⁺ than with Mg²⁺ (Hunsicker and DeRose 2000).

Compaction and formation of secondary structure in the Group I intron P4-P6 domain ribozyme of *T. thermophila* are supported by Na⁺ alone, but divalent cations are needed to induce tertiary structure (Cate et al. 1997; Deras et al. 2000). Athavale et al. (2012) used SHAPE to probe the P4-P6 domain in the presence of Na⁺ and observed low SHAPE reactivity, indicative of canonical base pairing, in regions observed in the crystallographic structure to be helical, while loop regions (unpaired in the structure) tended to be much more reactive. Addition of mM concentrations of Mg²⁺ caused distinct changes in SHAPE reactivity, suggestive of specific magnesium binding and formation of tertiary RNA structure (Figure 6.4.8).

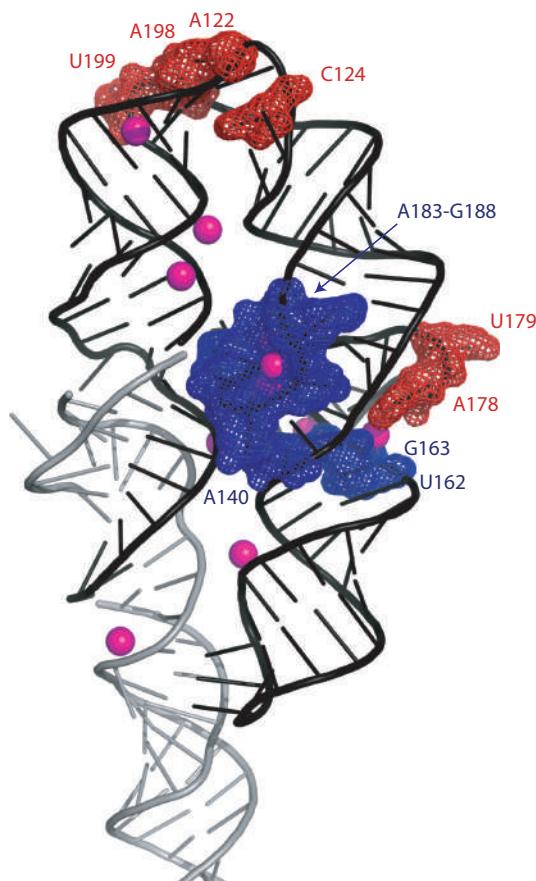

FIGURE 6.4.8 SHAPE reactivity of the Group I intron P4-P6 domain ribozyme of *T. thermophila* is altered in the presence of Mg²⁺ or Fe²⁺. Sites of pronounced increases in SHAPE reactivity in the presence of Mg²⁺ or Fe²⁺ and Na⁺ (compared with Na⁺ alone) are red; decreases are blue. RNA for which there is moderate to no change in SHAPE reactivity with Mg²⁺ or Fe²⁺ is black. RNA for which SHAPE data are not available is shown in gray. Mg²⁺ ions are magenta spheres. SHAPE data are adapted from Athavale et al. (2012), displayed on PDB 1GID (Cate et al. 1996). The structure was crystallized in the presence of Co²⁺ (not shown), which was not present in SHAPE reactions by Athavale et al. (From Athavale, S.S. et al., *PLoS One*, 7, e38024, 2012.)

Most of the residues having an increase in SHAPE reactivity in the presence of Mg²⁺ (compared with Na⁺ alone) bear a C2'-endo sugar pucker in structure PDB 1GID (Cate et al. 1996). This geometry of the ribose, typical of DNA, but rare and restricted to non-helical regions of RNA structures (Auffinger and Westhof 1997), was previously demonstrated to have enhanced reactivity by SHAPE (Cate et al. 1996; Vicens et al. 2007). The region with a decrease in SHAPE reactivity in the presence Mg²⁺ is consistent with packing of phosphates by Mg²⁺ in a core inaccessible to solvent (Cate et al. 1997). Mg²⁺ microclusters are present in this region of the P4-P6 RNA (Cate et al. 1997; Hsiao and Williams 2009).

Fe²⁺_(aq) oxidizes and precipitates rapidly in the presence of atmospheric oxygen, but under anoxic conditions, it induces folding of P4-P6 domain RNA to a near-native state. Athavale et al. (2012) demonstrated that the pattern of SHAPE reactivity in P4-P6 domain RNA in the presence of Fe²⁺ under anoxic conditions closely resembles that in the presence of Mg²⁺. Regions of RNA with pronounced increases in SHAPE reactivity upon the addition of Mg²⁺ (compared with Na⁺ alone) also increase in reactivity upon addition of Fe²⁺. Parallel decreases in SHAPE reactivity were also observed in other regions of the RNA, suggesting that, in anoxia, Fe²⁺ replaces Mg²⁺, without perturbation of the native structure of the P4-P6 ribozyme.

Catalysis by the L1 ligase or hammerhead ribozyme occurs at an enhanced rate in the presence of Fe²⁺. Athavale et al. (2012) compared the catalytic rate of the L1 ligase ribozyme in Na⁺, Na⁺/Mg²⁺, and Na⁺/Fe²⁺. As expected, the L1 ligase was inactive in Na⁺ alone. Micromolar concentrations of Mg²⁺ or Fe²⁺ induced catalytic activity. Surprisingly, the rate of Fe²⁺-induced catalysis was 25 times that of Mg²⁺-induced catalysis. A similar effect was observed for the hammerhead ribozyme: catalysis in the presence of Fe²⁺ initiated at a rate three times higher than in the presence of Mg²⁺. The interchangeability of Mg²⁺ and Fe²⁺ in RNA folding and function is supported by theoretical computational analyses that revealed only subtle differences in the coordination geometries of these RNA-divalent metal (RNA-M²⁺) complexes. Furthermore, the calculations demonstrated that stability of RNA-M²⁺ complexes is enhanced when Mg²⁺ is replaced with Fe²⁺ (Petrov et al. 2011; Athavale et al. 2012), possibly due to the availability of d-orbitals in Fe²⁺.

6.5.6 CONCLUSIONS

Fundamental biochemical processes of life as we know it depend on inorganic cations. Inorganic cations in association with RNA are always hydrated to some extent, and the importance of water in their interactions cannot be overstated. The unique properties of each cation—principally size and charge—alter the mobility and physicochemical properties of first-shell waters, which in turn affect surrounding water and non-water molecules. The energetic penalties associated with cation dehydration are a part of the net energy of reaction for every first-shell interaction with a biological ligand.

Inorganic cations have a special relationship with the phosphodiester backbone of nucleic acids. Backbone phosphates are anionic and highly polarizable, coordinating some cations with more compact geometry than others. The intricacies of a cation's individual properties can be viewed as magnified by interactions with phosphate esters, due to phosphate's enhanced polarizability relative to water. Magnesium stabilizes RNA through a continuum of associations, from neutralization of bulk negative charge in solution by mobile hexahydrates to compact first-shell coordination of up to four RNA backbone phosphates, while the range of associations of Na⁺ and other large, monovalent cations is less diverse (Bowman et al. 2012).

The role of inorganic cations in protein translation provides an essential perspective on their importance in biology and relevance to the origin of life. Multiple high-resolution crystal structures of the ribosome reveal that the core structure of the LSU is essentially unchanged throughout extant life, including the locations of cations and their binding sites' geometries (Hsiao and Williams 2009). When compared with other functional RNAs (ribozymes), the rRNA of the LSU is immense in length and complexity. An understanding of the principles underlying folding of such a large RNA to the universal conformation of peptide bond synthesis informs our understanding of LUCA and the constraints under which it might have evolved.

The LSU provides every indication that it has been dependent on Mg²⁺ or Mg²⁺-like divalent cations for folding and function since, and likely before, LUCA. Reoccurring motifs of rRNA in first-shell interactions with Mg²⁺ help to organize the three-dimensional structure of the LSU, though Mg²⁺ does not participate in catalysis directly. A recent study suggests that Mg²⁺ may also play an indirect role in stabilization of pre- and post-peptidyl transfer states (Polikanov et al. 2014). For perspective, Mg²⁺ ions observed in a crystal structure of the ribosome are shown in Figure 6.4.9.

These motifs include the bidentate RNA-Mg²⁺ clamps and Mg²⁺ microclusters (Hsiao and Williams 2009; Petrov et al. 2011). In an RNA-Mg²⁺ clamp, the phosphates of two consecutive nucleotides chelate a single Mg²⁺, altering the geometry of the metal hydrate and in turn the local properties of the RNA. Computation suggests that Na⁺ is incapable of stabilizing this type of RNA geometry. In a Mg²⁺ microcluster, one phosphate of an RNA-Mg²⁺ clamp serves as a bridge to a second Mg²⁺ ion, which, in three-dimensional structures, coordinates and restrains the phosphate of nucleotide(s) that are hundreds to more than a thousand nucleotides away in the primary sequence. Mg²⁺ microclusters induce non-canonical geometries to RNA bases, priming them for interaction with nucleotides from other domains and ribosomal proteins. Twelve of the 14 inter-domain interactions in the LSU 23S rRNA of *T. thermophilus* are Mg²⁺-induced (Lenz et al. 2017).

The Mg²⁺ dependencies of the LSU extend to interactions of first-shell waters with rRNA and ribosomal proteins. The first-shell waters of Mg²⁺ also stabilize the LSU. In one case, waters coordinating the Mg²⁺ of the D2 microcluster participate in hydrogen-bonding interactions with side-chain and backbone carbonyls of two highly conserved residues

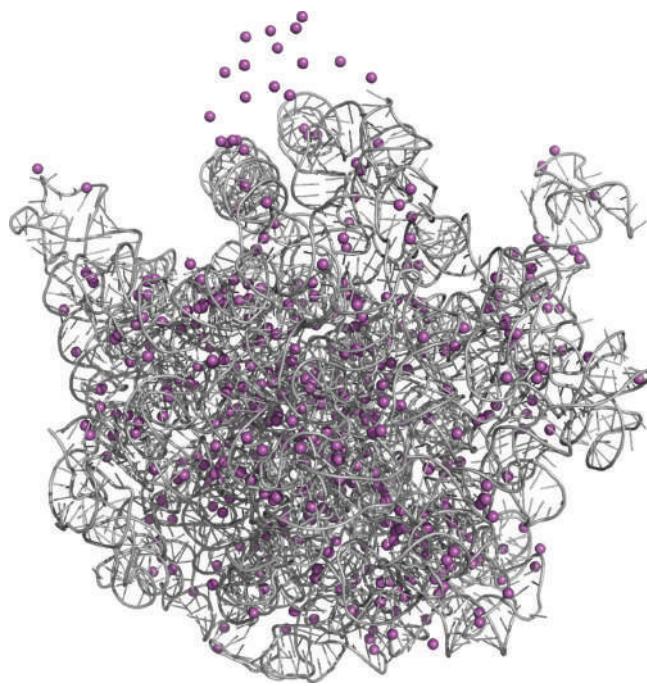

FIGURE 6.4.9 Prevalence of Mg^{2+} (magenta spheres) in the 23S rRNA crystal structure. Structure of *T. thermophilus* [PDB 2J01 (obsolete). Superseded by 4V51].

of ribosomal protein uL2 (Petrov et al. 2012). Mg^{2+} substantially increases the favorability and stability of the uL2-water interactions through orientation and polarization of the water molecules.

The ribosome is our telescope to origins and evolution of life (Gutell et al. 1994). Evolution appears to have perpetuated inorganic ion-dependent mechanisms that are essential and somewhat resilient to ion substitution. Three of the four ribozymes discussed, the Group I Intron P4-P6 domain, the hammerhead, and the ribosome LSU, are natural ribozymes. The P4-P6 domain and hammerhead ribozymes accommodate a broader range of cations in function and folding than the *in vitro* selected L1 ligase (Hunsicker and DeRose 2000; Doudna and Cech 2002; Travers et al. 2007; Athavale et al. 2012), yet the most central ribozyme of life, the ribosome, has just recently been shown to catalyze peptidyl transferase with a cation other than Mg^{2+} (Bray et al. submitted). Fe^{2+} , which has been largely insoluble and toxic to life in the absence of protein chaperones since the Great Oxidation Event, appears to be a capable and, in some cases, an even superior substitute for Mg^{2+} in RNA folding and function.

Cation substitutions over evolution extend beyond nucleic acids. An almost-singular mechanism with transition states stabilized by divalent cations underpins a variety of nucleic-acid-processing proteins (Lykke-Andersen and Christiansen 1998; Steitz 1999; Doherty and Dafforn 2000; Lee et al. 2000; Yin and Steitz 2004; Ellenberger and Tomkinson 2008). As a group, but with species-specific

exceptions, these enzymes generally tolerate partial to complete substitutions of Mg^{2+} for Mn^{2+} and occasionally other cations. One analysis ties the early evolution of eukaryotes to an oxic Earth and prokaryotes to an anoxic one, based on trends in metal substitutions in metallo-proteins (Dupont et al. 2006). Another result of this work is that the overall abundance of metallo-proteins was found to scale with proteome size, suggesting that biology's dependence on inorganic cations is not vestigial.

ACKNOWLEDGMENTS

We thank Roger M. Wartell for critical review of an early version of the manuscript and Afrah Ghauri and Chieri Ito for careful editorial review. This work was supported by the National Aeronautics and Space Administration (NNX16AJ29G and NNX16AJ28G) and the National Science Foundation (1724274).

6.5.1 INTRODUCTION

The question of the origin of life is among the most difficult problems faced by science today. Evaluating what might have been the chemistry of life’s emergence around 4 billion years ago involves inherent uncertainties. Thus, the scientific goal is to reconstruct a possible scenario, under assumed prebiotic environmental conditions, that could have led to the first living systems. Optimistically, as Earth science, astronomy, and other relevant fields of science gain more knowledge about conditions on the primordial Earth, the gap between the

possible and the actual will become narrower. Various scenarios delineating possible mechanisms of emergence are being raised by researchers, but none of them has as yet gained the consensus of the origin-of-life community and none has as yet been simulated in full in the laboratory. Investigators are nevertheless convinced that the transition from chemical compounds on the primordial Earth to the first living systems was an evolutionary process (Peretó 2012; Szostak 2012a; Pascal et al. 2013). As was asserted by the late Leslie Orgel, among the most prominent researchers in the field, “[A]ny “living” system must come into existence either as a consequence

of a long evolutionary process or a miracle" (Orgel 1973, p. 192). According to what I suggest to call *the evolutionary hypothesis of the origin of life*, the living systems at the origin of biological evolution did not arise through a staggeringly improbable chance event. Rather, they resulted from a long series of stages growing in complexity. Clearly, an evolutionary process prior to the existence of life was different from the process of biological evolution. According to the evolutionary hypothesis suggested in this chapter, prebiotic evolution involved highly constrained physical and chemical processes that led to the rise of chemical infrastructures capable first of "a poor man's natural selection" (Vasas et al. 2012, p. 1) and gradually of full-blown natural selection.

The nature of the chemical structures that could have undergone evolution during the emergence of life and the details of their prebiotic synthesis are still debated. However, theoretical models and experiments conducted in various laboratories point to various physical and chemical factors in specific environmental conditions that could have changed the odds of prebiotically synthesized molecules and molecular systems away from statistical randomness and thus constrained and channeled the emergence process (De Duve 1991, p. 141; Copley et al. 2007, pp. 432–433). The crucial role of prebiotic inorganic and organic catalysts and of physico-chemical selection events in allowing the emergence of evolvable infrastructures and their gradual evolution is noted in various scenarios in the field. Growing understanding in the last few decades of the chemistry and functions of RNA, the study of primitive cellular-like structures and of prebiotic catalysts and their possible role in early metabolism, and the discovery of sites on Earth that might have been conducive to the rise of life, all combined to make the evolutionary hypothesis of the origin of life a robust research framework.

My aim in this paper is to examine major theoretical and empirical lines of investigation based on the heuristic, fruitful value of the evolutionary conception. Various scenarios attack the enormous challenges still facing the field from different perspectives. I will also indicate how they differ in their evaluation of possible evolutionary processes leading to the emergence of life. Chapter 3.1 of this volume examines views rejecting the possibility of evolution prior to the existence of life, most notably, those of the renowned evolutionary biologist Richard Dawkins (1986, pp. 139–145, 2006, pp. 134–141). Dawkins's view that life arose by a highly improbable single-step chance event is not only contested by numerous probability calculations offered by researchers in the field, but also most significantly by the more probable alternatives suggested by the case studies examined here.

6.5.2 A SHORT HISTORICAL BACKGROUND: EARLY EVOLUTIONARY THEORIES OF THE ORIGIN OF LIFE

Several scientists, notably the biochemist Alexander Oparin in the Soviet Union and the geneticist and biochemist J. B. S. Haldane in England, independently published pioneering theories on the origin of life in the 1920s. Their theories (Oparin

1953 [1936], 1967 [1924]; Haldane 1967 [1929]) were based on new developments in biochemistry and genetics, on the chemistry of colloids, and on new data from geochemistry and astronomy. Their heterotrophic hypotheses upheld that organic compounds were synthesized from inorganic molecules in a primordial reducing atmosphere under the impact of various energy sources. They both contended that these organic building blocks that dissolved in the ancient ocean, described by Haldane as "a hot dilute soup" (Haldane 1967, p. 246), were transformed into structures that could have undergone evolutionary processes, leading to "protoorganisms" and later to life (see Fry 2000, pp. 65–78). A lesser-known contribution to the study of the origin of life was made already in the 1910s, in a few papers published by the American physicist and psychophysicist Leonard Thompson Troland (see Muller 1966, pp. 495–498).

As a biochemist, Oparin saw metabolism, supported by interacting enzymatically catalyzed reactions, as the defining characteristic of life. He hypothesized that organic polymers synthesized in the "soup" self-organized into cell-like structures that selectively absorbed organic material from the solution, grew in size, and divided. Oparin saw these structures, the so-called "coacervates," as endowed with metabolism-enabling organization that could have been transmitted from "parents" to "offspring" during these divisions. Based on such "heredity," assured via reproduction through division, and variations among the coacervates, Oparin (1953, pp. 193–195) envisaged primitive processes of natural selection and the evolution of metabolism. Haldane was first and foremost inspired by the rise of genetics and the discovery of viruses and saw self-reproduction as the defining feature of life. He hypothesized that large self-reproducing organic molecules synthesized in the soup (which functioned as a "vast chemical laboratory") were analogous to genes and constituted the first "living or half-living things" (Haldane 1967, p. 247). Leonard Troland's abstract analysis focused on the logic of the emergence of life and represented in a most straightforward way what later came to be called the "replication-first" approach. Moreover, unknowingly, he predicted the future discovery of the ribozymes. He suggested the appearance in the ancient ocean of a "genetic enzyme" capable of catalyzing both its own formation and the synthesis of an envelope around itself. The reproduction of such "enzymes" was also the basis for variation (mutation) and led to natural selection and evolution. Troland acknowledged the high improbability of the spontaneous synthesis of such a "genetic enzyme" but insisted that all that was needed was the appearance of a single copy of such entity, the probability of which was also aided by the vast stretches of time available for the process (Troland 1914, pp. 102–104, 105, 110–112; Fry 2006, p. 27).

Oparin's biochemical conception characterized life as a multi-molecular, multi-functional metabolic system, whereas Haldane's and Troland's genetic theories identified early life with molecular self-reproduction. These two concepts later became the two main lines of research in the origin-of-life field, and the conflict between their supporters grew in intensity, especially with the establishment of molecular biology. These two "camps," the "metabolism-first" and the "gene-first," clearly suggested very different prebiotic evolvable structures.

6.5.2.1 EVOLUTION IN THE TEST TUBE

The discoveries of the structure of DNA by Watson and Crick in the early 1950s and of the mechanisms by which nucleic acids function as the hereditary material transformed the study of evolution and consequently also the study of the emergence of life. Several researchers raised the question whether natural selection and evolution might occur not only in a population of organisms but also in a population of molecules. Beginning in the 1960s and 1970s, experiments carried out in various laboratories demonstrated Darwinian evolution “in the test tube” (*in vitro*) among genetic molecules capable of replicating and mutating. The American molecular biologist Sol Spiegelman and his group isolated a single strand of viral RNA and its replicating enzyme and, upon addition of the four types of nucleotides, showed RNA replication outside the cell (Mills et al. 1967). They also examined the impact of changing the “environmental conditions” in the reaction mixture. For example, when replication was carried under high temperatures or in the presence of an RNA-degrading enzyme, mutants that could form spatial structures more resistant to high temperatures or to a degrading enzyme were selected (Safhill et al. 1970). Extended experiments exploring molecular evolution *in vitro* and its application to the study of the origin of life were also conducted in the laboratory of the German physical chemist Manfred Eigen at the Max Planck Institute in Göttingen (Eigen et al. 1981, pp. 82–85).

The general conclusion from these and later experiments was that any group of entities could evolve by natural selection, provided it conformed to the specific conditions of reproduction, variations, inheritance, relative advantage conferred by some of these variations, and competition (Orgel 1973, pp. 145–159; Cairns-Smith 1986, pp. 2–3). It was nevertheless realized that a realistic model for the origin of life on the ancient Earth cannot involve a sophisticated replicating enzyme like the one isolated by Spiegelman and Eigen from highly evolved cells. The quest was thus for much more primitive systems, more fitting to primordial conditions.

6.5.2.2 THE CHICKEN AND EGG CONUNDRUM—A DEAD-END OR MAYBE NOT?

Researchers searching for such systems were facing a challenge raised by a major discovery of molecular biology—the interdependence of nucleic acids and proteins in terms of their synthesis and function. How could such a “chicken and egg” circle first emerge? Which came first, proteins or nucleic acids? From the early 1960s, origin-of-life scientists explored the two options of nucleic-acid-only (or nucleic-acid-first) and proteins-first, in order to “break the vicious circle” and establish a basis for an evolutionary process. These two options came to be described as the gene-first versus metabolism-first lines of research.

Leslie Orgel and his group at the Salk Institute in California conducted, for many years, experiments aiming to explore the possibility of natural selection and evolution in a system without a replicating enzyme. Although early experiments showed

promise, further results were disappointing. For several empirical reasons, a full cycle of non-enzymatic replication of oligonucleotides could not be achieved (Orgel 1994). Parallel to Orgel’s nucleic-acid-only experiments, an evolutionary protein-first, metabolic scenario was formulated by Sidney Fox. He demonstrated, under supposedly prebiotic conditions, the synthesis of amino acids and peptide-like oligomers, or “proteinoids,” manifesting weak catalytic activity. He also achieved the synthesis of microspheres out of these proteinoids that were engaged in some metabolic activity (Fox and Dose 1977; see, De Duve 2003, pp. 567–568). Fox, similar to several later proponents of metabolic theories, claimed that these cell-like systems could have served as infrastructure for evolution during the emergence of life through Oparin-like alternative processes of inheritance and variation without nucleic acids (see, Fry 2011, pp. 8–9).

Awareness of the implications of the chicken-and-egg problem for attaining a scientific understanding of the emergence of life resulted in diverse reactions in the 1960s and 1970s. A highly pessimistic attitude was adopted by the eminent French biologist Jacques Monod. In his book *Chance and Necessity* published in 1970, Monod described the chicken-and-egg problem as unsolvable and a “veritable enigma” (Monod 1974 [1970], p. 135) and acknowledged that this conclusion precluded a scientific solution to the origin-of-life problem (1974, pp. 135–136). The puzzle of the chicken-and-egg problem motivated a very different reaction, expressed in three seminal publications by Carl Woese (1967), Francis Crick (1968), and Leslie Orgel (1968). All three were committed to evolutionary thinking as means to search for a scientific solution to the origin-of-life problem, including the origin of the genetic code and the mechanism of translation. Crick and Orgel in their papers and Woese in his book examined molecules and mechanisms in extant cells from an evolutionary perspective and raised an unconventional idea that was formulated almost 20 years later as the RNA-world hypothesis (Woese 1967, pp. 179–195). Based on several factors, especially RNA’s tertiary structure, each of them suggested that RNA molecules could have also functioned on the ancient Earth as enzymes (see Crick 1968, pp. 371–372; Orgel 1968, p. 387). And yet, as long as there was no experimental indication suggesting otherwise, the common belief was that only proteins could have functioned as catalysts and nucleic acids acted only as replicators (see Orgel 1968, p. 387). Thus, the chicken-and-egg puzzle continued to cast a huge shadow on efforts to understand the origin of life (see also, Crick 1981, p. 72; Jacob 1982, pp. 305–306; Mayr 1982, pp. 583–584).

6.5.3 THE RNA WORLD: HIGH HOPES, ENORMOUS DIFFICULTIES

In the early 1980s, RNA molecules functioning as enzymes, given the name “ribozymes,” were unexpectedly discovered in extant cells (Kruger et al. 1982; Guerrier-Takada et al. 1983). In 1986, Walter Gilbert coined the term the “RNA World,” referring to a hypothetical ancient chemical “world” in which RNA molecules were both chicken and egg, both

catalysts and replicators, catalyzing their own replication and later also the synthesis of proteins and DNA (Gilbert 1986). The first discovered ribozymes were found to catalyze the cutting and joining of RNA segments. Since then, various ribozymes were also isolated in *in vitro* evolution experiments. Experimental efforts in several laboratories revealed that “the ribosome uses RNA catalysis to perform the key activity of protein synthesis in all extant organisms, so it must have done so in the Last Universal Common Ancestor (LUCA)” (Cech 2012, p. 2). This conclusion is among the strongest indications that an RNA world did exist during the emergence of life (see Benner et al. 2012, p. 4).

It was first optimistically assumed that prebiotic chemistry enabled the synthesis of RNA nucleotides; their assembly into RNA sequences; and the presence in this RNA pool of various ribozymes, especially a self-replicating ribozyme, an RNA replicase. If such was the case, the RNA world would have been indeed “the molecular biologist’s dream,” serving as basis for early evolution through natural selection (Joyce and Orgel 2006, pp. 23–24). This optimistic picture was called into question following several decades of failed experiments to show that the RNA world could have been a “prebiotic product,” that is, the first genetic “world” to emerge on Earth by physico-chemical prebiotic means (Anastasi et al. 2007, p. 721). Though some of the originally anticipated goals, especially the synthesis of oligonucleotides, were achieved to some extent (see Ferris 2005; Monnard 2007; Pino et al. 2008), a failure to demonstrate prebiotic synthesis of activated nucleotides still poses an enormous obstacle. Also, so far, no ribozyme replicase has been found in extant cells or has been evolved *in vitro*. The late Orgel, a veteran proponent of the view that life could have begun only on the basis of the emergence of a replicating system, that is, *the gene-first view*, came to adopt the *RNA-later position*. He and his colleague Joyce described the reality of the *RNA-first option* as “the prebiotic chemist’s nightmare” (Joyce and Orgel 2006, pp. 23–24). Assuming that RNA could not have been a prebiotic product, an earlier, pre-RNA “world” would have required, first, an easier prebiotic synthesis of its components. It should have nevertheless been based on some sort of genetic system; should have involved various catalysts, including a “replicase”; and eventually should have evolved into the RNA world (see Orgel 2003, p. 213). Various pre-RNA candidates were considered (e.g., Nielsen 1993, 2009; Eschenmoser 1999, 2007a, pp. 12823–12827). Some of these candidates do form stable double helices and cross-pair with RNA strands; however, they do not appear to be synthesized prebiotically more readily than RNA (Orgel 2004, pp. 114–115; Anastasi et al. 2007, pp. 733–736).

Insisting on the evolutionary nature of the emergence of life, but viewing organic chemistry in general and nucleotides in particular as prohibitively “high-tech” for prebiotic chemistry, the Scottish physical chemist and crystallographer Graham Cairns-Smith suggested a radical “out of the box” idea. Already in the 1970s, he envisaged a “low-tech” genetic system completely unrelated to RNA, made of clay minerals that were and are among the most ubiquitous materials

on Earth. Constituting a sort of scaffolding, such minerals could have, according to Cairns-Smith, replicated, mutated, and evolved to catalyze the synthesis of organic molecules (Cairns-Smith 1986, 2008). Cairns-Smith’s “scaffolding” conception was a key theoretical and philosophical contribution to the evolutionary conception of the origin of life. Yet, his specific clay scenario was criticized by a number of researchers (Hazen 2005, pp. 160–164; Morowitz 1992, p. 27; Orgel 1994, p. 61, 1998, p. 493; Yarus 2011, p. 3). Most practitioners in the field are convinced of the continuity between primitive life and extant life in terms of organic chemistry and biochemistry (e.g., Morowitz 1992, pp. 90–91; Orgel 2003, p. 213, 2004, p. 100; De Duve 2005a, pp. 17–21; Martin and Russell 2007, p. 1922).

Convinced of the need to find an evolutionary path and to overcome the RNA-nucleotides-prebiotic hurdle, Orgel (2003) also raised an idea of a pre-RNA “organism.” Taking into account the central role of amino acids in biochemistry, combined with the easy synthesis of amino acids and peptides under prebiotic conditions, Orgel (2003, p. 214) suggested that “it is worth exploring the possibility that a self-replicating peptide was a precursor of RNA because it seems to be the only major, biochemistry-based, game in town.” Orgel was inspired by the work of Ulf Diederichsen and colleagues in organic chemistry, who produced self-replicating polymers, in which the monomers were amino acids whose β hydrogen was replaced by a nitrogen base. Specifically, the polymers’ backbone was made of alanines and the substituting bases were guanine and cytosine (Diederichsen 1996, 1997). Orgel pointed to the major achievement of Diederichsen’s work that overcame the structural obstacle posed by forming a pairing structure of two homochiral peptide chains. By synthesizing chains in which L- and D-alanines alternated, a very stable hydrogen-bond interaction between the bases guanine and cytosine was made possible (Orgel 2003, p. 215, 2004, pp. 115–116).

Orgel (2004, p. 116), though indicating that the monomers of alanyl nucleic acid (ANA) play no role in biochemistry, nevertheless found Diederichsen’s ideas attractive in the context of prebiotic chemistry. Not only was the use of the two amino acid enantiomers advantageous in a prebiotic racemic environment, but Orgel (2003, p. 217) also saw the relevance of this work in suggesting “a generic pairing structure.” Thus, in his motivation to find a prebiotically plausible genetic material that would provide a basis for replication and evolution, Orgel also suggested to explore pairing structures made of amino acids with side chains whose specific interactions are based on charge or size. He wondered whether the stability of nucleic acid double helix, provided by the non-specific stacking interactions between bases, could have been achieved without the bases on the surface of a mineral (Orgel 2003, p. 217, 2004, p. 116). Several research groups have demonstrated self-replication of peptides, for example, through the autocatalytic ligation of two shorter peptides (Lee et al. 1996, 1997; Issac and Chmelewski 2002). Orgel (2008, pp. 11–12) noted in his last 2008 paper that this is an interesting direction to explore. However, he questioned the prebiotic relevance

of these and previous experiments on the self-replication of peptides. More recent work demonstrated the ability of short peptides that self-assemble into β -sheet structures to self-replicate (Bourbo et al. 2011; Brack 2014).

It is important to note that despite the enormous challenges still faced by the RNA-first and RNA-later approaches, they are among the most favored lines of research in the field, owing to the evolutionary explanation they provide to the emergence of life (see Schwartz 2013, p. 784).

6.5.3.1 RNA-FIRST, DESPITE IT ALL

6.5.3.1.1 Possible Synthesis of Ribonucleotides

Supporters of the RNA-first option acknowledge the fact that almost half a century of effort by researchers did not lead to a prebiotically plausible generation and oligomerization of activated nucleotides. They claim, however, that a large number of potential chemical routes toward these goals from prebiotic feedstock molecules were not explored yet (Anastasi et al. 2007, pp. 721–722). Furthermore, based on the fact that, so far, convincing pre-RNA candidates were not found (Anastasi et al. 2007, pp. 733–737) and on the clear advantage of the “real thing,” nucleotides and oligonucleotides (James and Ellington 1995, pp. 519–520; see Eschenmoser 2007b, p. 559), it is considered premature to conclude that the RNA-first option is not viable. Expanding on several previous experimental leads (see, Orgel 2004, pp. 105–106), recent work by John Sutherland and colleagues has overcome some of the most difficult problems in a possible prebiotic synthesis of nucleotides (Powner et al. 2009; Sutherland 2010). This line of research questions the long-held “dogma” in prebiotic chemistry that RNA nucleotides were originally assembled from their components, nucleobase, ribose, and phosphate. It is suggested now to replace this dogma by a novel approach, by which free ribose and the free bases are bypassed in the synthetic procedure and are produced from a common precursor. The synthesis of activated pyrimidine ribonucleotides was successfully carried out according to this approach (Powner et al. 2009). Significantly, the synthesis followed the methodology of “systems chemistry,” in which “reactants from different stages of a pathway are allowed to interact” (Szostak 2009, p. 171). In subsequent work, fragments of ribose were synthesized using similar systems chemistry, involving simple prebiotic oxygenous and nitrogenous components (Ritson and Sutherland 2012). So far, however, the synthesis of activated purine ribonucleotides was not achieved (but see Powner et al. 2010). Criticism was raised against “an excessive Deux ex machina” type of prebiotic chemistry assumed in the synthesis of activated pyrimidine ribonucleotides (Benner et al. 2012, p. 7). It was also pointed out that, though overcoming the problem of ribose synthesis, the sequence of reactions suggested by the Sutherland group raised other questions (Schwartz 2013, pp. 784–785).

As will be seen later, several metabolically inclined scenarios suggest that organic compounds in general and nucleobases and nucleotides in particular had a good chance of being synthesized and oligomerized on the surface of minerals and

in interaction with other organic substrates under the conditions at hydrothermal vents (see, e.g., Wächtershäuser 1992; Copley et al. 2007; Martin and Russell 2007). The delivery of nucleobases to Earth, together with other organic compounds, within carbonaceous chondrite meteorites was also proposed (Martin et al. 2008b, but see a more cautious evaluation of the exogeneous-organics claim, Pizzarello and Shock 2010; Damer and Deamer 2015, p. 875).

It might be of interest that following the Sutherland line of study on ribose, mentioned earlier, the Sutherland group engaged in experiments aimed to show that precursors of ribonucleotides, amino acids, and lipids can be commonly derived from hydrogen cyanide and hydrogen sulfide under certain prebiotic conditions. They also suggested a geochemical scenario that could have enabled such a common origin (Patel et al. 2015; Sutherland 2016).

6.5.3.1.2 Experimental Synthesis of Oligonucleotides

Assuming the discovery of a plausible prebiotic mechanism for the synthesis of ribonucleotides, the next stage in an RNA-world scenario must have been the polymerization of these monomers that somehow underwent activation to produce RNA sequences. The work of James Ferris and colleagues during the last decades has yielded a growing body of knowledge on the synthesis of short-, medium-, and longer-size RNA oligomers on the surface of minerals, in particular some montmorillonite clays (Huang and Ferris 2006; Joshi et al. 2009; Brack 2017). Another well-researched method of concentrating and polymerizing activated ribonucleotides uses ice eutectic phases prepared from dilute solutions of monomers and metal ions, Mg^{+2} and Pb^{+2} , which act as catalysts. In such an environment, “two phases co-exist and form the eutectic-phase system: a solid (the ice crystals made of pure water) and a liquid phase containing most solutes” (Monnard and Ziolk 2008, p. 1524). In the experiments performed by Monnard and colleagues, this particular environment allowed for the concentration of the activated nucleotide monomers out of the aqueous medium, and their condensation catalyzed by the metal ions. When this mixture is frozen and maintained for days at $-18^{\circ}C$, that is, below its freezing point, the monomers are concentrated as eutectics in the ice matrix (Monnard et al. 2003; Monnard and Ziolk 2008). Polymerization in this case probably occurs not by adsorption to ice surfaces but in cavities between ice crystals, with monomers and catalysts being highly concentrated. Such experiments are viewed as possible simulation of ice deposits on the primordial Earth that facilitated the synthesis of short- and medium-size RNA or RNA-like sequences (Monnard et al. 2003, pp. 13735, 13738, 13739).

It was reported recently that condensation of activated RNA monomers into short RNA chains was achieved via the catalysis by the dipeptide seryl-histidine (ser-his) in water-ice eutectic phase. As noted by the authors: “Because peptides are much more likely products of spontaneous condensation than nucleotide chains, their potential as catalysts for the formation of RNA is interesting from the origin-of-life perspective” (Wieczorek et al. 2013). The dipeptide ser-his was chosen as

a catalyst of the condensation of activated RNA monomers, based on its record as the smallest known peptide catalyzing the dissociation of peptide and phosphodiester bonds and as a catalyst of the condensation of amino acids. Since “all chemical reactions are in principle reversible,” the possibility of the peptide catalyzing also the condensation of phosphodiester bonds, so far not checked, was put to the test (Wieczorek et al. 2013).

Lipids were also demonstrated to catalyze polymerization of RNA under conditions of wetting and drying cycles (Rajamani et al. 2008). Using a different technique, it was found by Di Mauro and his group that spontaneous ligation of short RNA segments (10–24 monomers) in water at acidic pH and moderate temperatures led to the formation of longer RNA sequences. Under these conditions, short segments capable of forming double-stranded structures tended to ligate at their ends. This mechanism overcomes the problems associated with polymerization in water by monomer addition, which is slow and results in an equilibrium favoring degradation over synthesis (Pino et al. 2008).

Against the contention that the origin of life was a “highly improbable chance event” (see Dawkins 1986, pp. 139–141), it should be indicated that the RNA products of the above-mentioned polymerization and elongation procedures under prebiotic conditions are not statistically random and depend, among other factors, on the monomers involved (see, Miyakawa and Ferris 2003; Monnard 2007, p. 389; Pino et al. 2008). In the framework of their studies of the synthesis of RNA on montmorillonite clays, it was found by Ferris and colleagues that both the sequences, for example, purines versus pyrimidines, and the regioselectivity, 3'-5' versus 2'-5' phosphodiester bonds, followed certain “rules for RNA elongation on montmorillonite” (Miyakawa and Ferris 2003, p. 8204; see also, Brack 2017, pp. 219–220). Most significantly, longer oligomers can form only under catalysis because “the catalyst limits the number of reaction pathways and there are sufficient monomers to make the longer oligomers” (Miyakawa and Ferris 2003, p. 8206). Based on these data, it seems that the prebiotic synthesis of RNA (and in extension, of other polymers that might have been involved in the origin of life) was not statistically random (Miyakawa and Ferris 2003, p. 8202).

6.5.3.1.3 Small-Size Ribozymes?

Recent evaluations of the catalytic functions performed by RNAs in extant organisms in what is referred to as the “contemporary RNA world,” point to “very small RNAs” that can act as ribozymes. It was hypothesized that some of these ribozymes could have functioned similarly in a primordial RNA world (Cech 2012, p. 3). Studies of ribosomal RNA and the functions involved in the mechanism of translation have led to similar conclusions. Harry Noller, a leading contributor to these discoveries, pointed out that only three nucleotides of 16S rRNA constitute the ribosomal structure active in sensing whether Watson-Crick pairing between bases are made. Noller commented that “it is not difficult to imagine assembling such a mechanism from small, rudimentary RNAs of the kind that have been suggested to have populated the

RNA world” (Noller 2012, p. 5). The group of Michael Yarus, another prominent contributor to the field, has isolated a tiny ribozyme, five nucleotides in length, whose active center consists of three nucleotides that catalyze the aminoacylation-of-tRNA reaction performed today by the protein enzymes aminoacyl-tRNA synthetases. This ribozyme also supported peptidyl-tRNA synthesis (Turk et al. 2010). The researchers claimed that these results support the hypothesis that “minuscule RNA enzymes participated in early forms of translation” (Turk et al. 2010, p. 4585).

Clearly, the possibility that small RNAs could have accelerated various reactions on the primordial Earth raises the chance that the RNA world could have been a “prebiotic product” (see probability calculations in Turk et al. 2010, p. 4588). This is even more probably the case if it is taken into account that the assembly of these short RNAs might have involved catalysis by minerals, metal ions, and short peptides. Yarus noted that the most intriguing possibility raised by these results is that a ribozyme catalyzing phosphodiester transfer “...may exist somewhere near this size. *This would make the polymerase/replicase needed to initiate Darwinian evolution of RNAs, the founding event of the RNA world, much more likely*” (Turk et al. 2010, p. 4588, emphasis added). Unlike Yarus’s optimistic evaluation, other researchers doubt whether the structure of such a small ribozyme could have been compatible with the complex functions required of an RNA replicase (Schrum et al. 2010, p. 7).

6.5.3.1.4 Alternative Route to RNA Replicase?

Discussing the many difficulties involved in the *in vitro* evolution of an RNA replicase, Jack Szostak and his colleagues considered seriously the option that it might have been easier and thus more likely for life to begin if “RNA-catalyzed RNA replication could have emerged gradually in a series of simpler steps” (Schrum et al. 2010, p. 8; see also Szostak 2012b, pp. 12–13). They, thus, embarked recently on attempts to replicate RNA chemically, that is, without enzymes, in the “simplest form of genetic replication” (Blain and Szostak 2014, p. 11.3).

This reaction was studied for many years in the Orgel (1994, 2004) laboratory (see, Section 6.5.2.2) and was proved most inefficient. When Orgel began his studies of non-enzymatic replication, he was interested to find out whether replication without a protein enzyme was at all possible. Ribozymes have not yet been discovered. Szostak’s interest today, however, is in the possibility of replication without a polymerizing/replicating ribozyme. Among the many difficulties considered as hindering a full replication of RNA sequences was the fact that the complementary strand produced in the non-enzymatic copying process always contained a random mixture of non-heritable “non-natural” 2'-5' and “natural” 3'-5' phosphodiester linkages, unlike the homogenous 3'-5' linkages in contemporary RNA. After the discovery of ribozymes, it was commonly assumed that a random mixture of 2'-5' and 3'-5' linkages will prevent the spatial folding of the RNA chain needed for ribozyme activity, thus preventing an origin of life based on RNA catalysis (Engelhart et al. 2013, p. 390). And yet, facing the many problems associated with

the emergence of an RNA replicase, revisiting chemical template replication of RNA presented itself as a plausible path (Blain and Szostak 2014, p. 11.13). (As will be seen shortly, this was especially the case in the context of the current research of prebiotic protocells).

In a series of experiments by Szostak and colleagues, it was found that “RNAs containing remarkably high proportion of randomly distributed 2'-5' linkages retain the ability to fold, recognize ligands and catalyze reactions” (Engelhart et al. 2013, p. 391). More specifically, the self-cleavage activity of the hammerhead ribozyme, synthesized to contain various percentages of 2'-5' linkages, retained most of its activity at the prebiotically plausible 10% level, though the rate of reaction was slowed. Though specific point substitutions of 2'-5' linkages in the catalytic core of the ribozyme led to substantial or total decrease of activity, still with a low to moderate level of randomly dispersed 2'-5' linkages, only a fraction in a pool of functional RNAs would be seriously inactivated (Engelhart et al. 2013, p. 392).

Furthermore, heterogeneous mixtures of linkages seemed to overcome another major problem that was encountered by Orgel and others in the studies of non-enzymatic RNA replication. Full replication of an RNA strand, that is, repeated cycles of template copying, depends on the post-copying separation of strands. Due to the thermal stability of long RNA duplexes, strand separation was hard to achieve. It has been known for quite some time that the presence of 2'-5' linkages destabilizes the RNA duplex structure, lowering its “melting” (i.e., separating) temperature. The recent results of the Szostak group indicate that the presence of low to moderate 2'-5' linkages has multiple effects: it effectively lowers the melting temperature of long RNA duplexes while being, at the same time, compatible with non-enzymatic RNA copying and ribozyme activity (Engelhart et al. 2013, p. 393). Thus, contrary to a long-held view, 2'-5' linkages in RNA “*far from being problematic, are, in fact, an essential feature that allowed RNA to emerge as the first genetic polymer of life*” (Engelhart et al. 2013, p. 391, emphasis added).

6.5.4 ORIGIN OF LIFE: COMPARTMENTS AND EVOLUTION

The concept of some sort of “primitive cell” engulfing emerging metabolism characterized metabolism-first theories from the first half of the twentieth century. The most known cell-like structures were suggested by Oparin (1953, pp. 163–195) and Fox (1984). Already in these early theories, such “primitive cells” were supposed to be involved in evolutionary scenarios (see Sections 6.5.2 and 6.5.2.2). In contrast, the realization of the need for a protocell came late to gene-first proponents. Early-twentieth-century “geneticists” supported the notion of a “naked gene” (Troland 1914, 1917; Haldane 1967, p. 274). Dealing with early membranes posed a serious problem for gene-first scenarios that traditionally envisioned early cells as heterotrophic and thus considered membranes as possible barriers (see Orgel 2004, pp. 117–118). In distinction, many metabolism-first theorists embraced an autotrophic

conception (see, among many, Morowitz 1992; Morowitz et al. 2000). Continuing previous traditions, with the rise of the RNA-world concept, discussions first “neglected the cellular nature of life” (see, Pohorille and Wilson 1995; Szostak 2012b, pp. 1, 2).

Beginning in the 1970s, several pioneering groups conducted experiments designed to examine the prebiotic relevance of phospholipids and membranes (see Hargreaves et al. 1977; Morowitz et al. 1988). Further studies demonstrated that macromolecules can be encapsulated by vesicles under prebiotic conditions (Deamer and Barchfeld 1982; Oberholzer et al. 1995). During these years and later, the vital question of the origin of amphiphiles, membrane-forming long-chain molecules containing both polar and non-polar groups on the same molecule, was explored. In a seminal study, it was found that amphiphilic molecules are present in carbonaceous meteorites, for example, the Murchison meteorite, and can self-assemble into membrane structures (Deamer and Pashley 1989). The synthesis of amphiphiles, as well as other biogenic building blocks, is assumed to have also occurred by geochemical processes on Earth (see Damer and Deamer 2015, p. 875; Deamer 2017).

In the last few decades, the question of the origin of cellular life is raised by “geneticists” and “metabolists” alike (Ruiz-Mirazo et al. 2014). This question has become a major aspect of the emergence of life on Earth (Rasmussen et al. 2009) and, for some, especially metabolists, its defining aspect (Morowitz 1992, p. 9; see, Luisi 2015, p. 913). There is a consensus now among RNA-world researchers that RNA or pre-RNA macromolecules had to be isolated and confined by some sort of membrane (or other delimiting structures), “both to concentrate the ingredients of life and to promote a Darwinian process” (Monnard 2007, p. 389; Service 2013, p. 1034). It is realized that a population of RNA replicating molecules free in solution could not have evolved into more efficient or accurate replicators. “By keeping molecules that are closely related together, advantageous mutations can lead to preferential replication.” Within a compartment, better replicators will be able to replicate each other more efficiently and will have an advantage over other compartments (Szostak et al. 2001, p. 387; Service 2013, p. 1034).

6.5.5 A CASE STUDY: RNA-ORIENTED PROTOCELL RESEARCH GUIDED BY AN EVOLUTIONARY PERSPECTIVE

Work in progress reported in a series of papers by the Szostak laboratory during close to two decades explored mechanisms of encapsulation, growth, and division in experimental models of cellular compartments supposedly analogous to primitive protocells. These experiments were explicitly guided by the need to achieve a setting enabling Darwinian evolution in a protocell population. The work was originally led by a theory proposing that the origin of cellular life depended on the following elements: a membrane engulfing a protocell; a replicating genetic molecule within a protocell; the compatibility between these two elements; and their growing

interdependence (Szostak et al. 2001). Not ignoring the serious criticism addressed at this experimental study (see, Orgel 2003, pp. 213, 217) and the obstacles it faces, acknowledged by the Szostak group itself (see, Schrum et al. 2010, pp. 12–13), the theoretical and empirical aspects of these studies can serve as an instructive case demonstrating the heuristic value of the evolutionary perspective in the study of the emergence of life (see, e.g., Budin and Szostak 2011; Szostak 2011, p. 2895).

The work examined here was based on a heterotrophic conception, assuming the passage of organic building blocks from the prebiotic environment into the protocell. Permeability of vesicles to activated nucleotides is thus crucial for the compatibility of RNA and membrane required for an integrated, viable protocell. Relying on the ubiquity of phospholipids in biological membranes and their self-assembly in aqueous environment to form stable vesicles, phospholipids were considered “obvious candidates for prebiotic membrane components” (Hargreaves et al. 1977, p. 78). However, since phospholipid membranes are known to bar the entrance of polar and charged molecules, for example, activated nucleotides, the Szostak group tested the permeability of primitive membranes made of fatty acids (Mansy et al. 2008). They found that nucleotides that contained highly polar groups, for example, ATP, could not cross the fatty-acids membrane, but the less polar imidazole-activated nucleotides were permeable. If indeed this obstacle could have been overcome prebiotically, the authors contended that “extremely simple heterotrophic protocells could have emerged within a prebiotic environment rich in complex nutrients” (Mansy et al. 2008, p. 4).

Referring, in one of their first papers, to the catalytic function of montmorillonite clay in polymerizing activated ribonucleotides, the Szostak group reported that montmorillonite also accelerated vesicle assembly and growth when fatty acids were supplied as tiny lipid single-layered micelles to a mixture of fatty-acid vesicles (Hanczyc et al. 2003). Moreover, it was also found that RNA adsorbed to montmorillonite particles can be encapsulated within vesicles. These results pointed to the possibility of an assembly of protocell-like structures. However, a serious problem interfering with a plausible prebiotic fatty-acid vesicle in which RNA could have replicated is the incompatible effect of Mg^{+2} or other divalent cations on RNA on the one hand and on membranes on the other: RNA replication, both enzymatic and non-enzymatic, requires high concentrations of magnesium ions, which tend to destroy fatty-acid vesicles. Szostak and coworkers found, however, that while vesicles made of certain fatty acids were unstable in the presence of divalent cations, the addition of the glycerol ester of these acids stabilized the membrane (Chen et al. 2005). This combined composition also allowed the rapid diffusion of Mg^{+2} ions into the vesicle and their equilibration across the membrane. Furthermore, the presence of Mg^{+2} ions increased the permeability of the membrane to nucleotides, such as uridine monophosphate. This could have been advantageous to an encapsulated polymerizing RNA using the increased supply of nucleotides, while the polymeric product would be retained within the vesicle (Chen et al. 2005, pp. 13216, 13220). The downside of the glycerol ester-containing

stable membrane was the decrease of its ability to grow at the expense of both empty vesicles and added micelles, dynamic behaviors previously manifested by fatty-acid membranes (Chen and Szostak 2004).

A line of studies was devoted to processes of vesicle growth and division driven by various environmental physical and chemical processes. For example, some experiments explored the development of osmotic pressure on the inside of the membrane, exerted by encapsulated RNA (Chen and Szostak 2004). It was shown that internal osmotic pressure and the resulting extension of the membrane caused by sucrose, short oligonucleotides, and tRNA led to the uptake of additional membrane components from other vesicles in the near environment that were subjected to a lower osmotic pressure. This process was described by the authors as competition among vesicles for a limited resource (Chen and Szostak 2004, Supporting Online Text; see also, Budin and Szostak 2011, p. 5249). Szostak and colleagues pointed to the possibility that a simple physical mechanism, such as the exertion of osmotic pressure that led to competitive vesicle growth, could have mediated “a coordinated interaction between genome and compartment boundary” (Chen and Szostak 2004, p. 1474). Furthermore, a replicating RNA inside a vesicle and the resulting membrane growth due to increase of osmotic pressure could have *played an important role in the emergence of Darwinian evolution during the origin of cellular life*: “A faster replicase genotype would thus produce the higher-level phenotype of faster cellular growth” (Chen and Szostak 2004, p. 1746). It should be noted that, at this stage of the work, ribozyme replicase was still considered crucial for the evolution of protocells. Focus on non-enzymatic chemical replication of RNA (see [Section 6.5.3.1.4](#)) came later.

Difficulties arose when a plausible mechanism for the division of osmotically swollen vesicles was explored (Adamala and Szostak 2013, p. 495). A prebiotically feasible division process could not be demonstrated with the small unilamellar vesicles (around 100 nm in diameter) used in the osmotic pressure experiments. However, when experimenting with larger multilamellar vesicles (several microns in diameter), a division mechanism based on processes of growth and transformation into thread-like vesicles was demonstrated (Zhu and Szostak 2009; Szostak 2011, pp. 2896–2897). Applying mild shear forces by gently agitating the suspension of the transformed thread-like vesicles led to their division into multiple smaller spherical daughter vesicles. It is suggested that a prebiotic process that might have triggered such division could have been wind-driven waves on the surface of a pond (Szostak 2011, p. 2897). Cycles of growth and division were shown to repeat themselves (Zhu and Szostak 2009, pp. 5706–5709).

6.5.5.1 AN ALTERNATIVE EVOLUTIONARY PATHWAY: POSSIBLE ROLE FOR METABOLIC RIBOZYMES

When non-enzymatic RNA replication became the leading hypothesis in studying the origin of cellular life, an alternative evolutionary pathway to the osmotic-pressure-driven

process suggested itself. In this context, the first ribozyme to have evolved need not have improved replication but could have “carried out a metabolic function...that conferred an advantage on its host cell” (Szostak 2012b, p. 12). Attention was drawn, among other activities, to a metabolic ribozyme that could have catalyzed the synthesis of a possible membrane component, for example, phospholipids (2012b, p. 12). It was demonstrated that vesicles with mixed membranes of fatty acids and phospholipids grew faster, were transformed into thread-like vesicles, and thus favored division (Budin and Szostak 2011, p. 5250; Szostak 2011, p. 2898).

A hydrophobic dipeptide, AcPheLeuNH₂, synthesized inside a vesicle, was shown to exert a similar effect on membrane growth as did phospholipids (Adamala and Szostak 2013). This hydrophobic peptide was synthesized by the dipeptide ser-his, known to catalyze peptide bonds between amino acids (see, Wieczorek et al. 2013). The produced hydrophobic dipeptide then localized to the fatty-acid membrane and in a similar way to phospholipids drove vesicle growth at the expense of pure fatty-acid vesicles and micelles in its environment. Moreover, it was shown that such competitive growth also caused vesicles containing the hydrophobic dipeptide to be transformed to a filamentous form and to undergo division (Adamala and Szostak 2013, pp. 498, 499). The authors thus raised the possibility that metabolic ribozymes could have synthesized such hydrophobic peptides, leading to accelerated protocell growth and thereby conferring a strong selective advantage (Adamala and Szostak 2013, p. 500).

Realizing, however, that the synthesis of hydrophobic peptides by ribozymes might have been hampered by the polarity of nucleic acids, the Szostak group further suggested a way that might have circumvented this difficulty. A ribozyme could have catalyzed instead the synthesis of peptides such as ser-his, leading in this indirect way to the synthesis of a functional hydrophobic end product. “The synthesis of intermediate catalytic peptides [e.g. ser-his] could be an effective strategy for the synthesis of membrane-modifying products” (Adamala and Szostak 2013, p. 500).

6.5.5.2 PRIMORDIAL CHEMICAL RNA REPLICATION “TOO SLOW AND INEFFICIENT”?

Following their results, Szostak and colleagues claimed that a plausible prebiotic scenario for the evolution of primitive protocells capable of growth and division seems to suggest itself. However, nucleic acid replication within replicating vesicles is still elusive. On the one hand, based on the work discussed previously, non-enzymatic mode of replication might have led to the evolution of replicating RNA molecules and functional ribozymes. Yet, this possibility clashes with the realization that primordial chemical non-enzymatic RNA replication was probably too slow and inefficient to produce RNAs that were long enough to function as ribozymes. Relying on previous reports that shorter oligonucleotides can be assembled into non-covalent active complex, the Szostak laboratory studied the assembly of three model systems, one aptamer and two ribozymes, from their component oligonucleotides (Adamala

et al. 2015). It was found that subsets of short oligonucleotides first assembled into inactive complexes, forming a “primer-template” configuration. In the next step, these complexes were converted to fully functional, stable complexes by non-enzymatic template-directed primer extension (Adamala et al. 2015, pp. 484–487).

The authors also suggested that non-enzymatic primer extension may have allowed for the coexistence of short, unstructured oligonucleotides that could have functioned as templates and longer sequences that form functional complexes that could have been good catalysts (Adamala et al. 2015, pp. 487–488). Previous findings of the Szostak group on the random incorporation of 2'-5' linkages during non-enzymatic RNA copying (Engelhart et al. 2013) already alluded to the conflict between optimal templates that should be completely unfolded and good ribozymes that must have a stable folded structure. Since different copies of the same sequence will contain 2'-5' linkages in different locations, some copies would fold more readily and function as active ribozymes, whereas others would remain unfolded and serve as better templates for replication (Engelhart et al. 2013, p. 393). A question remains about possible synergism between the effects of 2'-5' linkages and those of non-enzymatic primer extension to produce distinct sets of template and catalytic oligonucleotides in primitive cells (Adamala et al. 2015, p. 488).

In summary, the list of remaining problems on the way to a possible gene-first evolutionary emergence of cellular life, enumerated and acknowledged by Szostak and coworkers, is daunting (see, e.g., Schrum et al. 2010, pp. 12–13; Szostak 2012b, pp. 12–13; Adamala et al. 2015, p. 483). It is nevertheless clear from the work examined here that the knowledge gained so far resulted from applying the evolutionary hypothesis of the origin of life to detailed mechanisms and processes. It appears that further possible progress will depend on an extension of the same program (e.g., Schrum et al. 2010, pp. 12–13).

6.5.6 A CASE STUDY: METABOLISM-FIRST AND THE POSSIBILITY OF EVOLUTION

Many of the evolutionary mechanisms suggested currently by “metabolists” continue the Oparin tradition. Oparin’s “metabolic” ideas in the 1920s and 1930s predated the rise of molecular biology. However, even later, he persisted in rejecting the genetic conception and instead of the “evolution of the molecule,” that is, DNA and RNA, he emphasized the “self-reproduction of the entire system” (Oparin 1965, p. 96). Based on data accumulated during the last decades on prebiotic chemistry and the hurdles faced by the prebiotic synthesis of RNA and RNA-like molecules, supporters of metabolism-first theories today contend that the gene-first conception is extremely implausible (De Duve 1991, pp. 112–113; Shapiro 2007; Peretó 2012, p. 5396; Luisi 2015, pp. 906, 917). Though relying on more sophisticated chemistry and computer simulation techniques, metabolism-first theories fundamentally share the Oparin principles based on the growth and inaccurate division of protocellular units, competition for resources

among these units, and selection of the metabolically more active and hence faster-growing assemblies (Fox 1984; Kauffman 1986, 1993; Segré et al. 2001).

In a paradigmatic paper delineating a theory of biochemical organization, metabolic pathways, and evolution, Harold Morowitz emphasized the “continuity between biogenesis and evolution” (Morowitz 1999, p. 39). He analyzed the emergence and evolution of metabolic cycles within membrane-enclosed vesicles in terms of natural selection and Darwinian competition, stressing that these processes did not necessarily require genetic macromolecules. According to the metabolic conception, information embodied in genetic polymers was a late development, a consequence rather than a prerequisite for prebiotic evolution (Morowitz 1992, p. 154). Most current metabolic scenarios assume the spontaneous emergence of autocatalytic metabolic cycles within a protocell (Morowitz 1992, 1999; Kauffman 1993, pp. 309, 323; Lancet and Shenhav 2009), within inorganic compartments in the vicinity of hydrothermal vents (Copley et al. 2007; Smith et al. 2009), or on the surface of nickel and iron sulfide minerals (Wächtershäuser 1988, 1992). Russell and Martin’s theory of the development of metabolic reaction chains in inorganic enclosures within hydrothermal pores (Martin and Russell 2007) will be discussed in [Section 6.5.7](#).

In distinction to “genetic” theories, “metabolic” models adopt an altogether different, “compositional” concept of information and inheritance (Segré et al. 2001, p. 137). Unlike the autocatalysis of a single genetic polymer, autocatalysis of a whole cycle is achieved by mutual catalysis of its chemical components when a certain level of chemical complexity of the system is reached (Morowitz 1992, pp. 153–154). A “reproduction” of the components of an autocatalytic cycle is suggested in the case of the reverse citric acid cycle, considered to be the most ancient metabolic network. The reduction of carbon provided by CO₂ and completed by the cycle leads to doubling of its constituents (Morowitz 1999, pp. 46–47). Chance differences arising in a group of such networks, if persisting through the process of “replication” and division, could have provided variant networks participating in a Darwinian-type competition for common energy and nutrients resources (Morowitz 1992, p. 153, 1999, p. 44).

A metabolic mode of reproduction and variation was also hypothesized by Günter Wächtershäuser in his theory of a “pyrite-pulled-chemo-autotrophic-origin.” Wächtershäuser’s autotrophic theory was among the first theories to locate the emergence of life in the vicinity of submarine hydrothermal vents. In few of his earlier works (Wächtershäuser 1988, 1990, 1992), Wächtershäuser suggested the emergence of the reverse citric acid cycle attached to and catalyzed by the mineral pyrite, FeS₂, in the environment of hydrothermal vents. This “surface metabolist,” comprising a core pyrite crystal and an attached layer of synthesized and interacting organic molecules, demonstrated growth-related division (Wächtershäuser 1992, pp. 104–107). Wächtershäuser proposed that variations could have resulted when rare products branched out of autocatalytic cycles and intervened catalytically in the working of the cycles and also in their own production (Wächtershäuser

1992, pp. 111–112). In more recent papers, Wächtershäuser no longer referred to the reverse citric acid cycle. He spoke about a “pioneer organism” in which “metabolic reproduction” resulted from an autocatalytic feedback mechanism (Wächtershäuser 2007). Metallo-catalysts synthesized small organic molecules, which in their turn enhanced the competence of metallo-catalysts to produce more organic molecules. When new organic molecules were produced in this way, not only reproduction but also metabolic innovation and growth in metabolic complexity were achieved (Huber et al. 2012).

A metabolic theory formulated by Kauffman (1986, 1993) postulated the emergence of self-reproducing metabolic systems consisting of interacting catalytic polymers, mainly peptides, within compartments. Based on mathematical analysis of a set of interacting catalytic peptides, Kauffman contended that when certain parameters, for example, length of polymers, number of possible polymers, and number of reactions within the set, are met, a stage is reached when all polymers catalyze the production of all the other polymers and the whole set becomes collectively autocatalytic (Kauffman 1993, pp. 309, 322). Kauffman also suggested several mechanisms that could account for selection among mutant sets, especially based on an Oparin-like division of the containing compartments (Kauffman 1993, pp. 331–332).

More recently, several authors, including Kauffman and Szathmáry, suggested a new version of the previous mathematical model of autocatalytic sets made of catalytic polymers (Vasas et al. 2012). The authors contended that under certain conditions of chemical evolution, rare reactions can lead to the rise of “viable autocatalytic cores” that allow the system to become evolvable. Unlike the original model, this version delineates a separation of the chemical system under scrutiny to “cores” and “periphery.” In a core, “all species catalyze the production of all other species including themselves,” and can thus be compared to a “genotype.” The periphery that consists of non-autocatalytic molecular species that are catalyzed by the core is described as analogous to a “phenotype” (Vasas et al. 2012, p. 2). It is further noted that while the mechanism suggested previously by Kauffman (1986, 1993) did not fulfill the conditions for evolution, molecular systems characterized by the newly suggested structure can become evolvable. In distinction to Kauffman’s previous model, which described a one-core system, “independent viable autocatalytic cores embedded in a large molecular network” allow for the possibility of competition and selection (Vasas et al. 2012, p. 5). Indeed, when many cores become enclosed in a compartment, competition between them ensues. Between-compartment competition can arise “due to the phenotypic effects of cores and their periphery at the compartment level.” This model thus presumes to explain how “a poor man’s natural selection could have operated prior to genetic templates” (Vasas et al. 2012, p. 1).

6.5.6.1 ARE METABOLIC CYCLES PLAUSIBLE?

As indicated in [Section 6.5.6](#), the main motivation to formulate metabolism-first theories is their authors’ conviction that the prebiotic emergence of a replicating genetic polymer was

extremely improbable. Critics of this assessment retort that the emergence of evolvable metabolic cycles is itself implausible (Anet 2004; Pross 2004; Eschenmoser 2007a, p. 12838; Peretó 2012, p. 5398). Metabolist scenarios face the double challenge of, first, establishing that an autocatalytic cycle can plausibly be organized under prebiotic conditions, and, second, of demonstrating evolvability of a group of such cycles. Whether these questions can be answered experimentally is questioned even by some metabolists (Lancet and Shenhav 2009, pp. 245–247; Pohorille 2009, p. 569). Quite a few researchers do not regard computer models and simulations, predominant in metabolic theories, as substitute to experimental results (Anet 2004, p. 656; Pross 2004, p. 312; Eschenmoser 2007a, p. 12838; Orgel 2008, pp. 10–11). Most metabolists, however, do consider such computer simulations as valid demonstrations (Smith et al. 2009, p. 445).

Genetically inclined researchers raised various points of criticism against metabolism-first models, focusing especially on the potential of metabolic autocatalytic systems, lacking a genetic template, to undergo Darwinian evolution (Eigen 1971, pp. 498–503; Maynard Smith and Szathmáry 1985, pp. 68, 71; Vasas et al. 2010). It is worthwhile to follow more closely Orgel’s analysis of the plausibility of metabolic cycles. A veteran gene-first proponent, Orgel’s position within the genetic camp was unique. Along with Crick and Woese, he independently suggested the RNA-world idea already in the 1960s (see [Section 6.5.2.2](#)). For years, he was a leading researcher of this theory and at the same time among its most severe critics (see [Section 6.5.3](#)). Being a convinced “geneticist,” he nevertheless knew firsthand that this conviction was “with good reason been challenged repeatedly” (Orgel 2000, p. 12503). Realizing the enormous challenge of solving the problem of the origin of life, he didn’t shy from considering the possibility that the genetic conception is not the right track after all. Referring to the theories of Kauffman (1986), Wächtershäuser (1988), and De Duve (1991), he wondered whether perhaps, “systems of high complexity can develop without any need for a genome in the usual sense” (Joyce and Orgel 2006, p. 21). Orgel acknowledged that demonstrating the existence of a complex, non-enzymatic metabolic cycle would be a major step toward solving the origin-of-life problem and demonstrating that a family of such cycles could evolve “would transform the subject” (Orgel 2008, p. 12).

Thus, in several of his papers (e.g., Orgel 2000), and especially in his last one, published posthumously (2008), Orgel carried out a thorough investigation of metabolic theories. As indicated earlier (in [Section 6.5.6](#)), the reverse (reductive) citric acid cycle was considered by Morowitz and colleagues and by Wächtershäuser in his earlier work (1988, 1990, 1992), as the core of early biochemistry and a possible metabolic infrastructure for evolution. Before considering the possibility of the evolvability of such an autocatalytic metabolic cycle, Orgel suggested that, first, the chemical plausibility of the prebiotic self-organization of such a cycle should be examined. Though several metabolic reactions that could have formed part of core metabolic chains were demonstrated (Cody et al. 2000; see also, Huber et al. 2003; Huber and Wächtershäuser 2006),

Orgel indicated that unlike genetic scenarios, based on a substantial body of experimental work, metabolic scenarios lack similar empirical basis and their evaluation has to rely on considerations of chemical plausibility (Orgel 2008, pp. 11–12; Peretó 2012, p. 5398). Orgel’s starting point was the fact that reactions involved in autocatalytic metabolic cycles in extant biochemistry depend on catalysis by specific enzymes. Orgel asked whether on the primordial Earth, prebiotic available catalysts such as mineral could have replaced enzymes.

Analyzing in detail the different reactions involved in the reverse citric acid cycle, the extent of specificity required by their catalysts, and the possible disruption of the cycle by side reactions, Orgel concluded that though a skilled chemist could have constructed such catalysts, it is questionable whether they could have been found on the ancient Earth. Whereas “it is not completely impossible” that specific catalysts for the various reactions could be found, “the chance of a full set of such catalysts occurring at single locality...in the absence of catalysts for disruptive side reactions seems remote in the extreme” (Orgel 2008, p. 8). This critique was addressed at the scenarios of both Wächtershäuser (1988) and Smith and Morowitz (2004).

Orgel also analyzed in detail Kauffman’s autocatalytic peptide-cycle model. The various pitfalls found by Orgel in this model will not be reviewed here (Orgel 2008, pp. 10–12; see, also, Lifson 1997; Anet 2004). Suffice it to say that indicating that Kauffman assigned to peptides properties that they do not have, Orgel concluded that Kauffman took for granted that it is possible to “write down on paper a closed peptide cycle and a set of catalyzed ligations leading from monomeric amino acids to the peptides of the cycles” and to expect “that [such] cycle would self-organize spontaneously and come to dominate the chemistry of a reaction system” (Orgel 2008, p. 10). (It should be added that Orgel, who died in 2007, could not have reviewed Kauffman’s new version of his model [Vasas et al. 2012]. For the response to Orgel’s 2008 critique of Kauffman’s original model, see, Vasas et al. 2012, p. 5). Orgel did mention the experimental demonstration by Ghadiri and colleagues of peptide cycles of the type suggested by Kauffman; and he did refer to the possibility of the self-replication of peptides (Lee et al. 1996; Ashkenasy et al. 2004). However, he pointed out that the “carefully designed peptides” used in these experiments were not relevant to the claims made by Kauffman of a spontaneous self-organization of polymerizing amino acids in a prebiotic setting (Orgel 2008, p. 11; see Luisi 2015, p. 915).

Based on his detailed analysis of various metabolic theories (Morowitz’s, Wächtershäuser’s, and Kauffman’s), Orgel concluded that the most serious challenge to these theories—the lack of specificity of non-enzymatic catalysts—casts a heavy doubt on the possibility of a prebiotic self-organization of non-enzymatic cycles (Orgel 2008, p. 12). According to Orgel, the lack of chemical plausibility is even more evident in claims for the evolvability of such cycles (*Ibid.*). Evolvability cannot arise unless a cycle can become more complex. Orgel mentioned a few ways by which this could have happened: a development of another autocatalytic cycle from a constituent

of the core cycle or the rise of a side reaction generating a catalyst for a reaction of the core cycle (Orgel 2008, p. 9). It should be noted that these mechanisms were indeed suggested by metabolists in their arguments for evolvability of metabolic cycles (Morowitz 1992, pp. 153–154; Wächtershäuser 1992, p. 89, 111–112, 2007, pp. 594–595; Shenhav et al. 2003, pp. 22–23; Pohorille 2009, p. 579; Smith et al. 2009, pp. 445–446). However, Orgel commented that such claims should be substantiated experimentally and not by faith alone. Generally speaking, he insisted that metabolic theories cannot be justified by the inadequacy of genetic theories and must be subjected to as severe a criticism, as has “rightly been applied to genetic theories” (Orgel 2008, p. 12). It should be restated that Orgel was a severe critic not only of metabolism-first theories. His last paper ended with a warning: “Solutions offered by supporters of geneticist or metabolist scenarios that are dependent on ‘if pigs could fly’ hypothetical chemistry are unlikely to help” (Orgel 2008, p. 12).

Yet, Orgel still pointed to the possible relevance of metabolic reactions to the evolutionary hypothesis not associated with the self-organization of complex metabolic cycles but as a source of organic molecules. He referred to a few simple cycles experimentally supported (Schwartz and Goverde 1982; Weber 2007) and considered the possibility that more simple cycles could be discovered (Orgel 2008, p. 12). He saw the relevance of these cycles and of various metabolic chain reactions to the origin of life in their potential to synthesize organic molecules needed to build a primitive genetic system (*Ibid.*). In this context, Orgel mentioned the successful active research on prebiotic syntheses catalyzed by metal sulfides under hydrothermal conditions (Cody et al. 2000; Wächtershäuser 2007). However, in considering the role of metabolism in preparing the way for a genetic system, Orgel pointed to the critical gap separating the chemistry of metabolism and that of replication: prebiotic syntheses tend to form complex mixtures of products, while polymer replication schemes require reasonably pure monomers. “No solution to the origin of life problem will be possible until [this] gap is closed...” (Orgel 2008, p. 12).

In light of Orgel’s crucial alert to this gap, it is worthwhile to call attention to the role of physico-chemical constraints in preparing the ground for the emergence of an evolvable infrastructure. An illustration of this role is provided by the work of the origin-of-life chemist Alan Schwartz, who pointed to several attempts to search for mechanisms of separation and selectivity, in order to get individual sugars, for example, ribose, out of mixtures of closely related products (Schwartz 2013, pp. 785–786). Schwartz noted, however, that the resulting products of such mechanisms were still mixtures, rather than individual sugars, and a process of complex separation was still missing (Schwartz 2013, p. 756). It is in this context that Schwartz discussed the possible role of physico-chemical processes in various geochemical sites on the ancient Earth that might have helped in attaining purer reactants out of heterogeneous products of prebiotic syntheses (Schwartz 2013, p. 787; see Schwartz and Henderson-Sellers 1983).

Schwartz called attention to the phenomenon called geo-chromatography that results in the selection and concentration

of potential reactants. This phenomenon was discovered in the early 1990s by Wing and Bada (1991), who studied the carbonaceous chondrite Ivuna. The researchers explained the specific repertoire of organic compounds on this meteorite as the result of “geochromatography,” a process driven by the flow of water on the parent body of the meteorite and the selective transport to the meteorite of some but not all organic components “of an originally more complex mixture of products” (Schwartz 2013, pp. 786–787). In distinction to chromatography carried in the laboratory, geochromatography occurring under natural conditions, on the parent bodies of meteorites and quite possibly on the primordial Earth, is more complex and multidimensional and thus might have involved highly selective processes. Schwartz suggested that such processes might have “contributed to the probability of the production of relatively homogenous samples of organic reactants” (Schwartz 2013, p. 787). He envisaged a number of separation and purification steps that would have made a self-assembly of a polymer or of a structure much more probable compared with a reaction out of an extremely complex mixture. (For a somewhat-different attitude to the question whether complex mixtures obtained in prebiotic reactions should be separated into pure and homogenous building blocks for the assembly of nucleotides, membranes, protocells, etc., see Szostak 2011).

6.5.6.2 A POSSIBLE ROLE FOR ORGANOCATALYSIS

The possible role of small organic molecules such as amino acids, short peptides, nucleotides, and cofactors in catalyzing synthetic prebiotic reactions has been suggested recently (Copley et al. 2007; Adamala et al. 2014). Smith et al. (2009) contended that such organic catalysts could have constituted an intermediate stage between catalysis by mineral surfaces and by macromolecules, that is, RNA and proteins, and could have functioned in chemical reaction networks (Smith et al. 2009, pp. 445, 444). These ideas were greatly inspired by the growing field of organocatalysis that focuses on catalytic asymmetric syntheses mediated by small organic molecules (Barbas 2008, p. 42). Experimental work is now widening the scope of organocatalysis beyond the study of the emergence of homochiral biological building blocks (Eschenmoser 2011, p. 12462) to a wider array of synthetic reactions that might have taken place during the emergence of life (Wieczorek et al. 2017). For example, the dipeptide ser-his was found to catalyze the condensation of amino acids (Luisi 2015, p. 911). This dipeptide also catalyzes the synthesis of RNA phosphodiester bond, forming short oligonucleotides in water-tectic phase (Wieczorek et al. 2013), and amino acids and oligopeptides were shown to catalyze the condensation of amino acids and nucleotides (Adamala et al. 2014). It is noteworthy that the amino acid proline was found to catalyze a wide variety of substrates, a generality highly unusual with enzymes (Movassaghi and Jacobsen 2002; Morowitz et al. 2005). Researchers in the organocatalysis field comment that, for a long time, chemists could not imagine that a small molecule like proline could match the reactivity of enzymes (Movassaghi and Jacobsen 2002, p. 1905; Barbas 2008, p. 43).

It was mentioned previously that Orgel's major criticism of the likelihood of prebiotic self-organization of autocatalytic cycles was based on the non-specificity of prebiotic molecules and mineral catalysts. Was Orgel's skepticism vis-à-vis metabolic autocatalytic cycles also a reflection of this attitude? Still, with no experimental demonstration, as yet, of the viability of prebiotic autocatalytic cycles, it is not clear whether the catalytic prowess of small organic molecules could have contributed not only to various prebiotic reactions but also to the self-organization of cycles.

6.5.6.3 ESCHENMOSER ON THE “GENETIC POTENTIAL” OF METABOLIC CYCLES

It is of interest to comment shortly on the position on metabolic cycles of the renowned origin-of-life chemist, Albert Eschenmoser. Similar to Orgel, he was doubtful as to the reality of such cycles because of “problems of the efficiency and selectivity of organocatalysts” (Eschenmoser 2007b, p. 570). Yet, unlike Orgel, he chose to refrain from a definitive judgment as to the plausibility of metabolic cycles, noting the “renaissance” brought about by the field of organocatalysis and the results and insights gained from this field (Eschenmoser 2011, pp. 12461–12462). Among Eschenmoser’s motivations in discussing metabolic scenarios was his wish to find a common ground between the metabolic and genetic viewpoints and to evaluate the “genetic,” that is, evolvable aspects of metabolic theories (Eschenmoser 2007a, 2007b). Eschenmoser (2011, p. 12461) called attention to the “genetic potential” in Wächtershäuser’s and Morowitz’s theories, both emphasizing the “replicator” aspect of their hypothetical autocatalytic cycle. However, even assuming the existence of such cycles and their reproduction as a whole, this would have been a necessary condition but not a sufficient one. For evolution, such autocatalytic cycles would have to be able to diversify in order to provide competing metabolic variations. Like Orgel (see, 6.5.6.1), it was on this point that Eschenmoser (2007a, p. 12828, 2011, p. 12461) found metabolic scenarios seriously lacking. He examined the possibility, raised by Wächtershäuser (e.g., Wächtershäuser 1992), of the contingent emergence of catalytic loops feeding into existing autocatalytic cycles and thus creating a new cycle (Eschenmoser 2007b, pp. 555–559). Nevertheless, he still reaffirmed the outstanding capabilities of informational polymers compared with metabolic cycles (see Peretó 2012, p. 5398; Vasas et al. 2010). Like Orgel, he thus emphasized the more probable role of such cycles in producing organic materials for the synthesis of genetic polymers (Eschenmoser 2007b, p. 559).

In summary, the question whether metabolism-first scenarios can suggest valid mechanisms for the evolutionary emergence of life is still open. According to eminent origin-of-life researchers, such as Orgel and Eschenmoser, who gave a serious consideration to these theories, such evolutionary mechanisms are highly doubtful. Nevertheless, it is clear that the search for plausible metabolic modes of reproduction, variation, and selection in theories across the metabolic

board (e.g., Kauffman and Szatmáry’s, Lancet’s, Morowitz’s, Wächtershäuser’s) played and still plays an important role in guiding metabolism-first research.

6.5.7 A CASE STUDY: PROTOMETABOLISM AS PREPARATION FOR RNA AND ITS EVOLUTION

6.5.7.1 ALKALINE HYDROTHERMAL VENTS AND THE ORIGIN OF LIFE

Following the discovery in the late 1970s of submarine vents and of flourishing extant organisms in and around the “Black-Smokers” chimneys in these sites (Corliss et al. 1979), Michael Russell and colleagues were among the first to raise the possibility of an autotrophic emergence of life in these sites (Baross and Hoffman 1985; Russell et al. 1988; Kaschke et al. 1994). Such an environment might have offered emerging life energy and nutrients, as well as numerous advantages, compared with the traditional soup scenario. Among those merits were independence from the primordial atmosphere, protection from extraterrestrial impacts, availability of inorganic catalysts and isolating compartment-like structures made of catalytic minerals comprising the chimneys and mounds, and the critical role of membrane-spanning electrochemical gradients (Russell and Hall 1997). From early on and up to Russell’s most recent works, his conception of life’s origin at hydrothermal vents was of a “drive to life,” based on the disequilibria between reducing agents (H_2 and CH_4) and electron acceptors (among others, CO_2 and Fe^{+3}) and between an acidic external ocean and alkaline hydrothermal fluid (Russell et al. 2014).

An early criticism of the submarine hypothesis was the claim that organic molecules could not have been synthesized and kept intact at the very high temperatures of these sites that might exceed 350°C (Miller and Bada 1988). However, hydrothermal vents with colder temperatures were discovered in 2000, farther from oceanic spreading centers (Kelly et al. 2001, 2005). Following the discovery of such a warm, alkaline system of vents, named the Lost City hydrothermal field (LCHF), bearing H_2 -rich water in the range of 40°C–90°C, and the hypothesis that such vents could have also existed billions of years ago (Martin and Russell 2007, pp. 1887–1888; Martin et al. 2008a, p. 812), such geochemical sites were suggested as optimal for the origin of biochemistry and the first living systems (Martin and Russell 2007; Russell et al. 2014, pp. 313–314). It was hypothesized that the microporous internal structure of the vents restrained reaction products from diffusing into the ocean. It was further suggested that such sufficient concentration of organic compounds might have led to the rise of an RNA world (Martin and Russell 2007, p. 1890).

The discovery of hydrothermal vents, and especially the Lost City off-ridge-vent system, led to intensive study of the geochemical process of serpentinization, a sequence of geochemical reactions that take place when sea water circulates through cracks in the oceanic crust. The term serpentinization derives from “serpentine,” one of a group of minerals, produced as a result of this process. The chemistry of the vents,

both of the hot, acidic, “black smokers” and of the cooler alkaline systems, such as Lost City, is dominated by these geochemical reactions. Sea water, rich in CO₂, upon interacting with the abundant Fe⁺² in the crust (especially in the form of the mineral olivine made of magnesium and iron silicate) generates vast amounts of H₂, while Fe⁺² is oxidized to Fe⁺³. The released H₂ reduces CO₂ to methane and other reduced carbon compounds (Martin et al. 2008a, p. 809). The processes of serpentinization are also responsible for the alkaline nature of the hydrothermal fluids that feed the mounds due to the dissolution of calcium, magnesium, and other metals by the circulating seawater in the crust that produces soluble hydroxides (Mielke et al. 2010, pp. 799–800).

Not only attesting to the enormous complexity of the study of the origin of life but also reflecting the complexity of the chemistry of hydrothermal vents, still vastly underexplored (Martin et al. 2014, p. 1093), the theory developed by Russell, Martin, and colleagues underwent many changes and represents a theory in progress (Russell et al. 2014; see Mazur 2014). The scenario suggested in the earlier papers (Russell et al. 1994; Russell and Hall 1997) and clearly formulated by Martin and Russell (2007) described the process of the emergence of life in compartment structures made of metal sulfides in an alkaline vent at a redox-pH-and-temperature gradient between sulfide-rich hydrothermal fluid and iron (II)-containing water at the primordial ocean floor. It was hypothesized that the fossilized chimneys and mounds at the ocean floor that contained FeS, NiS, and other metal sulfides and were formed by the process of serpentinization might have served as primordial catalytic inorganic enclosures (Martin and Russell 2007, p. 1890). This hypothesis was strengthened by breakthrough experiments by several groups demonstrating that FeS and NiS catalyze the synthesis of key organic compounds (see Heinen and Lowers 1996; Huber and Wächtershäuser 1997).

Russell originally supported Wächtershäuser’s early hypothesis of the reverse citric acid cycle as the metabolic cycle providing organic synthesis with energy and reduced carbon compounds (Russell and Hall 1997). Later, Russell and Martin came to consider a primitive form of the Wood-Ljungdahl pathway, a linear acetyl-CoA pathway of CO₂ fixation, to be a better candidate for the first biochemical pathway to arise within a hydrothermal mound (see, Russell and Martin 2004, p. 363). Whether the reverse citric acid cycle or the acetyl-CoA pathways are considered to be the most antique biochemical pathway of CO₂ reduction in early life, the idea common to many practitioners in the origin-of-life field is the continuity between primitive and extant life in terms of organic chemistry and biochemistry (e.g., Morowitz 1992, pp. 90–91; Orgel 2003, p. 213, 2004, p. 100; De Duve 2005a, pp. 17–21; Copley et al. 2007, p. 433; Martin and Russell 2007, p. 1922). In the acetyl-CoA linear pathway, operating in various eubacteria and archaeabacteria, CO₂ is the electron acceptor and H₂ is the donor. Thioester is the product, readily hydrolyzed to produce acetate. Importantly, this mechanism is exergonic, and the reactions in this pathway today are catalyzed by FeS and (Fe, Ni)S centers in proteins.

Exploring the physical and chemical dynamics of extant alkaline hydrothermal vents, for example, the temperature range in such systems, and especially the chemistry at such sites led to a reevaluation of the possible conditions in a Hadean hydrothermal system compared with those in extant sites. Most importantly, the mineral composition of today’s enclosed structures and the precipitate mounds at Lost City lack sulfides and are made mainly of carbonates (Mielke et al. 2010). This fact, as acknowledged by Russell and colleagues, “is a potential threat to the alkaline hydrothermal hypothesis” (Mielke et al. 2010, p. 801), clashing with a fundamental premise of the original theory that metal sulfides as catalytic constituents of inorganic membranes are central to the synthesis of organic compounds and the emergence of life. A possible answer to this challenge was the suggestion that the geochemical conditions at the vent-ocean interface were markedly different in the Hadean ocean compared with today’s oxic conditions. Back in the past, “the Hadean ocean was replete with Fe (II), and therefore FeS chimneys would have been abundant at that time” (Martin et al. 2008a, p. 809).

Trying to dispel at least some of the uncertainties and to reproduce the relevant conditions in the ancient ocean, a hydrothermal flow reactor, mimicking an assumed ancient natural reactor, was built at the Jet Propulsion Laboratory at the California Institute of Technology (Mielke et al. 2010, 2011). The first experimental test was aimed to investigate whether hydrogen sulfide and silica anions could have been dissolved from iron sulfides and basaltic rock wool in a representation of a Hadean ocean crust through the passage of the hydrothermal fluid (Mielke et al. 2010, p. 801, 2011, p. 934). Such anions were expected to precipitate as chimneys and catalytic compartments made of FeS, containing also nickel, cobalt, and other metals, through interaction with a Fe⁺²-containing solution representing the Hadean ocean (Mielke et al. 2010, p. 801). The authors reported that “the reactor operated to plan,” sulfide and silica were dissolved in the solution, which upon transfer to the ferrous “oceanic” solution produced chimneys and compartments dosed with iron sulfide (*Ibid.*). However, analyzing their results in detail (especially, following the rise and fall of peaks in sulfide concentrations released in the experiment), Russell and colleagues were led to reconsider the contention in their original model that the first compartments of life consisted purely of sulfides. They still contended that there would be enough sulfide to ensure a component of catalytic iron (and nickel-cobalt) sulfide within the walls of compartments, which will ensure “a growing network of reactions requisite for the onset of metabolism.” However, compartments would be mainly composed of carbonates, silicates, ferrous hydroxide, and other materials (Mielke et al. 2010, p. 808). Furthermore, they came to the conclusion that deposits of sulfides at alkaline vents at the Hadean era depended on processes in the oceanic crust beneath “and perhaps proximity to a 400°C hydrothermal spring discharging high concentration...of hydrogen sulfide” (Mielke et al. 2010, p. 801, 2011, p. 946). They emphasized, that “the generation of iron sulfide/hydroxy-rich chimneys would have been a rather rare, but inevitable, event” (Mielke et al. 2011, p. 946).

The Russell group is convinced that the emergence of biochemistry from geochemistry could not have taken place without “the potential across iron-sulfide bearing membranes.” It was electrochemical and thermal gradients, created across such membranes, that enabled the synthesis and storage of organic molecules and the development of proto-metabolism that led to the emergence of life (Mielke et al. 2011, p. 946). The rarity of iron sulfide membranes revealed in their experiments could have undermined this conviction. However, it is suggested that this threat could have been overcome by the dynamics of hydrothermal vents on the ancient Earth. Russell’s assumption of inevitability stemmed from the estimates that during the Hadean era, approximated at hundreds of millions of years “between the condensation of the first ocean and the Archean with its signs of life” (Mielke et al. 2011, p. 944), there were hundreds to thousands hydrothermal alkaline vents, each one producing billions of assorted compartments over their lifetimes of tens of thousands of years (Mielke et al. 2011, pp. 946, 944–945; see also Russell et al. 2014, p. 328).

The authors plan to use the reactor to attempt the synthesis of methane and other reduced carbon compound (Mielke et al. 2010, pp. 800, 808). Following a similar line of research, a more recent electrochemical reactor to simulate conditions in alkaline hydrothermal vents was built by Herschy et al. (2014). They tested simulated vent structures, containing catalytic Fe(Ni)S mineral, precipitated from a mixture of alkaline solution containing, among other components, Na₂S (representing vent fluid) with an acidic solution of FeCl₂, NiCl₂, and sodium bicarbonate (representing the acidic ocean). Low yields of formic acid and very low yields of formaldehyde, expected products of the reduction of CO₂, were detected in the experiments. The authors acknowledged that the formation of formaldehyde “is variable and inconsistent between runs and these methods are still being optimized.” Nevertheless, they considered the results a proof of principle (Herschy et al. 2014, p. 221) of the potential of alkaline vents to reduce CO₂ with H₂ (and to form simple organic molecules) “using natural proton gradients across thin, semi-conducting inorganic barriers (Herschy et al. 2014, p. 219).

6.5.7.2 THE EMERGENCE AND EVOLUTION OF THE RNA WORLD IN ALKALINE HYDROTHERMAL VENTS

Up to this point, our discussion of the theory of the emergence of life in alkaline hydrothermal vents revolved around the theory’s main guiding question: what was the source of the reduced organic compounds on which the origin of life depended (Martin et al. 2008a, p. 805)? Rejecting the alternatives of the organic soup and of Wächtershäuser’s surface metabolism, the theory of Russell, Martin, and colleagues focused on the spontaneous synthesis of organic compounds at the vents as an inevitable outcome of geochemical processes (Russell and Martin 2004, p. 362). Yet, the synthesis and concentration of organic compounds and the emergence of protometabolic reactions within the enclosed structures at the vents were conceived as just the first stage that might have led to the rise of a self-replicating system at the same site.

Russell, Martin, and colleagues considered the RNA world as an essential element in the origin of life that provided a basis for Darwinian selection and the evolutionary emergence of life (Martin and Russell 2007, p. 1893). However, they rejected the notion that the RNA world could have originated *de novo* on the ancient Earth, pointing not only to the need for prior protometabolism but also to the relics left by such protometabolism in extant biochemistry (Martin and Russell 2007, pp. 1901, 1918; Martin et al. 2008a, p. 811). Their model explored the possibility that a primitive form of the acetyl-CoA pathway of CO₂ fixation could have produced the reduced carbon and nitrogen constituents of purines and pyrimidines (Martin and Russell 2007, pp. 1893, 1908).

In several experiments, Russell and colleagues simulated an alkaline-hydrothermal-vent system in order to deal with the “intermediate stage,” once nucleotides existed, referring to “the transition from a solution of small organic molecules to a population of RNAs” (Koonin 2007, p. 9106). These experiments provided data relevant to the emergence of the RNA world (Baaske et al. 2007; Burcar et al. 2015). Baaske and colleagues have demonstrated in a simulated pore system the extreme accumulation of nucleotides and polynucleotides (e.g., DNA of up to 1000 base pairs) in plugged pores of various sizes. Such concentration and accumulation are driven solely by the strong thermal gradients present in hydrothermal vents simulated in the experiment and the structure of the pores. Resulting from an interaction between fluid shuttling along the pore by thermal convection and molecules drifting across the pore by thermodiffusion, “millimeter-sized pores accumulate even single nucleotides more than 10⁸-fold into micrometer-sized regions” (Baaske et al. 2007, p. 9346). In addition to providing a concentration mechanism for prebiotically produced small molecules and polymers, these results also raised the possibility that such compartments under the hydrothermal vents conditions “could be veritable ‘reactors’ for RNA synthesis” (Koonin 2007, p. 9105). High concentrations of nucleotides would push the equilibrium toward polymerization (Koonin 2007, p. 9105; see, Martin and Russell 2007, p. 1890). Another experiment demonstrated nucleotide oligomerization within synthetic hydrothermal iron-sulfide chimneys (Burcar et al. 2015). Notably, dimers of inactivated AMP and up to tetramers of activated AMP were synthesized. No oligomerization was detected with any other nucleotide. It was found that the addition of montmorillonite clay to the chimney-forming system improved oligomerization of inactivated AMP, an observation not reported before in aqueous solution (Burcar et al. 2015, pp. 517–519). Control experiments indicated the importance of the chimney structure itself to the process (Burcar et al. 2015, p. 515).

6.5.7.3 SELECTION AND EVOLUTION WITHIN AND AMONG COMPARTMENTS

Assuming that a population of self-replicating RNA molecules became available out of protometabolic processes, Martin and Russell noted “the dramatic transition in the nature of the chemistry at the vent...[when] natural selection

sets in" (Martin and Russell 2007, p. 1910). The stage in which populations of versatile RNA molecules in different compartments evolved independently (Koonin 2007, pp. 9105–9106) was speculated to have been ensued by processes involving a wider system of compartments. Porosity could have enabled movements of organic molecules of different sizes among compartments, and new compartments were continuously being formed by mineral deposits at the ocean interface (Koonin and Martin 2005, p. 649). These attributes of the vent system, evidenced in active current sites and assumed to exist in ancient vents, could have allowed for "organic molecules [invading] new territories, thereby generating discrete units on which selection could act" (*Ibid.*). Outlining further evolutionary stages, it was indicated "how Darwinian selection and evolution of genetic organization" culminated in the LUCA, still confined in an inorganic hydrothermal enclosure (Martin and Russell 2003; Koonin and Martin 2005).

6.5.7.4 PROTOMETABOLISM AND THE EVOLUTIONARY HYPOTHESIS OF THE EMERGENCE OF LIFE

An important difference between the Russell scenario and the scenarios examined here previously, genetic and metabolic alike, should be noted. These scenarios suggested that evolution through natural selection evolved gradually and that various primitive modes of selection took part in the emergence of a full-blown Darwinian system. The theory of Russell and colleagues, on the other hand, focuses on the earlier stages of the emergence of life as an inevitable outcome of deterministic geological and geochemical processes at alkaline hydrothermal vents (Russell et al. 2014, p. 308), postponing the introduction of selection and evolution to the rise of RNA.

6.5.7.4.1 De Duve's and Russell's Protometabolic Scenarios: A Comparison

In a similar fashion to Russell and colleagues, the eminent biochemist Christian de Duve regarded the RNA world as a crucial, though not the earliest, stage on the way to life. And in a similar fashion to the Russell theory, de Duve's protometabolic theory postpones the onset of natural selection to the rise of RNA. According to de Duve, nucleotides and their assembled sequences could have emerged only with the help of a previously growing protometabolism (de Duve 1991, pp. 133–143, 2005a, pp. 156–157, 2005b). A critical stage of de Duve's scenario was the prebiotic synthesis of peptide-like catalytic "multimers" with the help of thioester bond energy. De Duve suggested that thioesters were formed from the endergonic condensation of amino acids and other carboxylic acids with thiols (alcohol-type compounds containing sulfur), favored under acidic and hot conditions at hydrothermal vents (de Duve 1991, pp. 113–116). He thus supported such a volcanic setting on the ocean floor for the origin of life (de Duve 2005a, p. 64). De Duve argued that it was probable that among the synthesized multimers were a number of crude catalysts that could have catalyzed the synthesis of various organic compounds, including additional thioesters and multimers (de Duve 1991, pp. 113–116). Thus, like other metabolic

theories, de Duve's theory is based on an autocatalytic process that drove the growth of protometabolism.

It is crucial to note that de Duve insisted that, in the context of the origin of life, "random event or process" did not mean "statistically random" or chance-like but rather "not directed by genetic information" (de Duve 1991, p. 141). Unlike a chance-like or statistically random situation, in de Duve's scenario, not all possible multimer sequences were equally probable due to stringent physical and chemical constraints. Differences among the multimers in solubility, stability, or ability to fold affected their survival. Some of the physically and chemically selected multimers were further protected by being bound to substrates. This mechanism interactively selected both catalysts and substrates that constituted the emerging protometabolism (de Duve 1991, pp. 140–144). Due to physico-chemical selection channeling the synthesis and function of the catalytic multimers, de Duve claimed that only very rare peptides out of the theoretically possible ones could have been synthesized and only very rare peptides out of those produced could have survived. Thus, in this process, the end products were fully determined by the initial conditions (de Duve 1991, pp. 137–145, 213, 2005a, p. 24).

De Duve also sought to deal with the general problem of the multistage growth of complex biological molecules during the emergence of life. Without a "continuous renewal mechanism," such as replication, to encounter spontaneous decay phenomena (see Luisi 2015, p. 915), how could intermediates survive and reach effective concentrations (de Duve 1991, p. 141)? His proposed mechanism to overcome this problem was the selection and stabilization of multimeric crude catalysts by binding to substrates (de Duve 1991, pp. 143–145). He noted that this mechanism, unlike "regular" physical and chemical selection, "does not just rely on favorable coincidence. It is truly selective, in that it contains a built-in feedback loop that actually makes it save what is useful" (de Duve 1991, p. 143). At the same time, unlike natural selection, this mechanism "can operate with random chemistry of production," selecting by differential survival, in distinction to the complex machinery of replication, selecting by differential replication (*Ibid.*). In summary, de Duve contended that "chemical determinism had to suffice" in the protometabolic stage, during which the chemical infrastructure for natural selection was gradually being built. He also assumed that a continuous supply of catalysts could have been ensured as long as geochemical conditions remained stable (De Duve 2005a, pp. 23–24). Thus, in de Duve's scenario, the process of the emergence of life could be viewed as divided into two by the rise of RNA and the onset of natural selection. Prior to this stage, the emergence and growth of protometabolism depended on deterministic and reproducible chemical processes made possible by the stability of geochemical conditions.

A similar combination of de Duve's two elements, physico-chemical determinism and stability of conditions, was also crucial in the first stage of Russell and Martin scenario, as it ensured prolonged, developing metabolic activity leading to the RNA world (Martin and Russell 2007, p. 1901; see, Lane 2012, p. 36). With a strong deterministic commitment,

the Russell theory views life, “like other self-organizing systems in the universe, as an inevitable outcome of particular disequilibria” (Russell et al. 2014, p. 308). According to this theory, “metabolism was forced to emerge in such fine compartments” to resolve such disequilibria (Russell et al. 2014, p. 314). It was the “attempts” to reach equilibrium between the hydrothermal fluid and the Hadean ocean, “frustrated” by the spontaneous precipitation of the membrane between them, that provided the energy needed for chemical syntheses of organic compounds and for protometabolic reactions (Russell and Hall 1997, p. 378). As to the stability of conditions, hydrothermal reactors “sustainable over geological time-scales provided the continuity of conditions conducive to organic-chemical reactions” (Martin and Russell 2003, p. 65, 2007, p. 1901). The authors emphasized that the building blocks of biochemistry had to have “a continuous source of reduced carbon and energy and would have to remain concentrated at their site of sustained synthesis over extended times” (Russell and Martin 2004, p. 362). Addressing, like de Duve, the question of effective concentrations of intermediates in order to enable the growth of organic complexity, Martin and Russell referred first to the prevention of diffusion by the inorganic compartments. The possibility of a product nevertheless diffusing and thus discontinuing a reaction chain is countered by the argument of “an uninterrupted geochemical supply of the basic starting compounds” (Martin and Russell 2007, p. 1907). This could have led to the channeling of products into more complex organic compounds and possibly to the RNA world (Martin and Russell 2007, pp. 1890, 1907).

6.5.8 A CASE STUDY: COEVOLUTION OF GENES AND METABOLISM LEADING TO THE RNA WORLD

According to de Duve and Russell and colleagues, RNA and the RNA world could have emerged only with the help of a previously growing protometabolism. A proposal that replication and metabolism could have co-evolved in a hydrothermal-vent scenario and could have interactively led to the emergence of the RNA world was raised by Copley et al. (2007). The mechanism suggested by the authors was supposed to overcome the enormous challenge of the emergence of RNA from small molecules available on the primordial Earth. Their hypothesis entails a multi-stage process during which mutual catalysis among small molecules, such as amino acids and nucleotides, led to the rise of proto-metabolism, to the gradual synthesis of longer and more efficient catalysts, and to the emergence of RNA as the dominant macromolecule due to its unique combination of catalytic and template-replication capabilities (Copley et al. 2007, pp. 430–431). Copley and colleagues favored hydrothermal vents as the site for the origin of life, owing to the characteristics of these locations: compartmentalized structures lined with catalytic metal sulfides; small source molecules (e.g., CO₂, H₂, H₂S, and NH₃) vented into the porous structures; and, as attested by experiments (Cody et al. 2000), the possibility of catalyzed production of organic molecules, such as pyruvate, under high temperatures. They

further suggested that such synthesized molecules could have diffused through the walls of the porous structures to cooler regions of the vents, closer to the ocean water, allowing for the synthesis of more fragile molecules (Copley et al. 2007, p. 432).

The authors posited that to launch their multi-stage process toward the RNA world, the “core of the core” of necessary reactions must have included a pathway for the synthesis of organic compounds from CO₂ and H₂, such as the reverse citric acid cycle (Smith and Morowitz 2004) or the acetyl-CoA (Wood-Ljungdahl) pathway of CO₂ fixation (see Russell and Martin 2004; Martin and Russell 2007, p. 1887) and pathways for the synthesis of ribose, purines, pyrimidines, simple amino acids, and cofactors. Furthermore, it was contended by Copley and colleagues that the synthesis of nucleotides could have been achieved by “a surprisingly small” metabolic module that “was simpler than might be supposed.” All the components in this module can be synthesized from pyruvate (which, as said, can be made under hydrothermal conditions), with the addition of a few other compounds, such as NH₃ and CO₂ (Copley et al. 2007, p. 433).

The earliest *monomer stage* of the long process was suggested to include α-keto acids such as pyruvate, simple amino acids, NADH, ribose, purines, and pyrimidines. The synthesis of these compounds was assumed to have been catalyzed at the vents by mineral surfaces and available small molecules. Mineral surfaces could have helped to concentrate and retain reactants; to polarize functional groups that facilitated attacks by other charged groups; and to accelerate, even if modestly, rates of reactions (Copley et al. 2007, pp. 434–436). The significance to the emergence of life of the ability of small organic molecules to catalyze reactions, explored by the growing field of organocatalysis (see, 6.5.6.2), was noted by Eschenmoser and by Smith and colleagues (Smith et al. 2009; Eschenmoser 2011, pp. 12461–12462). Acknowledging the limited systematic knowledge of the catalytic capabilities of small molecules, Copley and colleagues nevertheless pointed to their possible role at establishing a monomer network (see Smith et al. 2009, pp. 444). They also suggested several chemical means that could have overcome the weak and non-specific binding interactions between small molecules, enhancing the probability of productive encounters. They mentioned, among these chemical means, the covalent attachment of substrates to catalytic molecules (Copley et al. 2007, p. 436) and predicted that the monomer stage led to increased concentrations of activated monomers (Copley et al. 2007, pp. 434–438).

The hypothesis guiding the proposal of the following stages was that mutual catalysis of molecules within the networks and selection of communities with increased concentrations of activated monomers led to ever-larger and more-effective catalysts. Such a selection led, first, to the formation of *multimers* made of amino acids, nucleotides, and cofactors (note difference from de Duve’s “multimers”) that combined randomly and also contained alternative sugars and bases and alternative backbone linkages. New options for catalysis at this stage became available, possibly catalysis of reactions by dinucleotides or dipeptides, such as ser-his, and

by the cofactor NADH (Copley et al. 2007, p. 438). At the next stage, a community of catalytic monomers and multimers containing a higher concentration of activated nucleotides allowed the synthesis of random, 3–10 nucleotide-long oligonucleotides, defined by the authors as *micro-RNAs*. These RNAs were more efficient catalysts owing to their increased size. Additionally, direct base pairing between complementary oligomers resulted in replication of catalytic components of the network. Notably, other non-replicable catalysts in the system, for example, amino acids, peptides, and cofactors, depended on the replication of RNA catalysts that promoted their synthesis (Copley et al. 2007, pp. 439–440). In such a way, the unique advantage of RNA within the community of catalysts and the interdependence between replication and catalysis were established.

The authors suggested that, at this stage, RNA replication proceeded by template-directed ligation. They considered as possible an early emergence of RNA replicase that catalyzed such ligation and thus overcame the slow rate of non-enzymatic ligation. However, in distinction to the common characterization of RNA replicase as “self-replicating,” Copley and colleagues emphasized the evolutionary logic underlying the emergence of this replicase, based on its ability to enhance the function of the entire system. Its selective advantage was the replication of “all the catalytic RNA molecules required to maintain the protometabolic network” (Copley et al. 2007, p. 440). Referring also to the possible selection for homochirality at this stage, the conclusion was that this phase of micro-RNAs “would have been the stage at which the die was cast, and emergence of RNA as the dominant macromolecule became inevitable” (*Ibid.*). The emergence of 11–40 nucleotides-long RNA molecules by the same selection process would have led to a *mini-RNA* stage. Forming secondary structures, these oligomers could function as ribozymes, such as those found to catalyze aminoacyl-RNA and peptidyl-RNA synthesis (see, Illangasekare and Yarus 1999). RNA replication by template-directed ligation was eventually replaced by a primer-extension mechanism. At the following *macro-RNA* stage, large RNA molecules could have formed tertiary structures such as the ribosome. At this stage, all the metabolic reactions sustaining the RNA world could have been catalyzed by ribozymes. However, RNA catalysts interacted with catalysts such as amino acids, metals, and organic cofactors (Copley et al. 2007, pp. 440–441).

Copley, Smith, and Morowitz asserted that metabolism and replication were intertwined “from the very beginning,” a conclusion obviating the famous chicken-and-egg problem. They again called attention to their claim that at all stages “replication was a function of a community of molecules that collectively generated monomers necessary to create larger molecules, rather than a property of a particular self-replicating RNA molecule” (Copley et al. 2007, pp. 441–442). This view of “replication,” contrary to the “genetic” focus on an information-carrying sequence, brings to mind conceptions of the collective self-replication of metabolic cycles described previously (Morowitz 1992, pp. 153–154; Segré et al. 2001, p. 137; Lancet and Shenhav 2009). However, in

distinction to traditional metabolic scenarios, Copley and colleagues’ model of “co-evolution” incorporated both metabolic and genetic conceptions, without, nevertheless, giving up their commitment to the primacy of metabolism.

Another hypothesis raised by Copley, Smith, and Morowitz crucial to their evolutionary view of the origin of life suggested that in addition to the obvious function of prebiotic catalysts in accelerating reaction rates, not less important was their role in channeling flux of materials through specific pathways, thus contributing to the emergence of sparse metabolic networks (Copley et al. 2007, pp. 432–433). They pointed out that though chemical diversity in a prebiotic environment seemed to be advantageous for the emergence of life, a sparse network of reactions in such an environment might have offered strong merits. “Given a limited amount of carbon, a sparse network allows the accumulation of individual components at higher concentrations than could be achieved if the carbon were distributed among an enormous number of compounds. The increased concentrations of specific compounds result in proportional increase in rates of second-order reactions... Further...there is less potential for unproductive side reactions” (Copley et al. 2010, pp. 3345–3346). It is significant that the hydrothermal-vent setting favored by the authors for the origin of life is highly compatible with the “sparseness advantage”: in distinction to ponds and lagoons that could have been supplied by an abundance of organic constituents from space but lacked abundance of catalysts, at hydrothermal vents, the opposite situation of “sparse set of inputs but an abundance of catalytic minerals” held (Copley et al. 2010, pp. 3347–3348).

More recently, Copley and Novikov attempted to explore experimentally the sparseness hypothesis by following the “catalytic landscape” of pyruvate under simulated hydrothermal-vent conditions. The study focused on the products that could form from pyruvate in cooler regions of the vent that were “more conductive to biogenic molecules” (Novikov and Copley 2013, pp. 13283–13284). They developed a novel pressurized reactor that could simulate vent chemistry, while exploring changing parameters and various catalytic minerals (Novikov and Copley 2013). Copley and Novikov identified in their experiments several products formed of pyruvate in a simplified system containing a varied range of transition metal sulfides, CO₂, H₂, H₂S, and, in some cases, NH₄Cl, at 25°C or 110°C, within the pressurized reactor. A particular interest of the investigators, the carboxylation of pyruvate to oxaloacetate, an intermediate in the tricarboxylic acid cycle, was not detected in the experiments. On the other hand, the reduction of pyruvate to lactate by minerals, not demonstrated previously under hydrothermal conditions, was achieved. Thiolated products were easily formed, and the reductive amination of pyruvate to alanine was also observed with different minerals, with the addition of NH₄Cl, at strikingly different levels (Novikov and Copley 2013, pp. 13284–13287). In control experiments with no minerals, the majority of pyruvate was recovered intact. The products depended not only on the presence or absence of additional substrates, for example, ammonia, but also on the nature of the catalytic minerals and the temperature (Novikov and Copley 2013,

pp. 13284–13285). Most importantly, the researchers found that several reaction pathways in which specific metal sulfides and small molecules catalyzed the synthesis of products from pyruvate were preferentially favored, “allowing accumulation of higher concentrations of few components rather than low concentrations of many components” (Novikov and Copley 2013, p. 13283). Thus, dependent on the availability of mineral catalysts and the interaction between catalysts and co-reactants, a reaction network favoring non-random specific pathways was beginning to be shaped (Copley et al. 2007, p. 432; Novikov and Copley 2013, p. 13288).

6.5.8.1 WHAT KIND OF EVOLUTION?

The description of the model by Copley, Smith, and Morowitz is replete with terms usually applied in the context of a Darwinian process: co-evolution, evolutionary logic, selection, favored communities, etc. Yet, this model does not propose a prebiotic buildup of either a genetic or a metabolic infrastructure capable of engaging in a primitive mode of replication/reproduction/division, mutation, and selection. Rather, the many-staged process claimed to have gradually led to the emergence of the RNA world was based in each of its stages on physical and chemical constraints that channeled the products toward a certain direction. These channeling effects were achieved via the catalytic abilities of minerals and the catalysis of reactions by, among others, amino acids, nucleotides; and growingly by di-amino acids, di-nucleotides, peptides, and short RNA sequences. All these catalyzed reactions depended on the physical and chemical properties of these organic catalysts and their interactions with their substrates. The availability of inorganic and organic catalysts and specific reactants at the vent site, together with environmental conditions such as temperature and pH, contributed collectively to a process of evolution governed by physico-chemical selection that favored communities with better chances of sustaining their constituents. Such selected communities were able to synthesize more effective catalysts, including replicating RNAs. The channeled process toward the RNA world, according to the proposed mechanism, was not a chance-like process (Copley et al. 2007, pp. 431–432). As the mutual catalysis in protometabolic reaction networks led to more effective catalysts, the “emergence of RNA as the dominant macromolecule became inevitable” (Copley et al. 2007, p. 440).

6.5.9 A CASE STUDY: “SYSTEM-FIRST” EVOLUTIONARY SCENARIO IN A “HYDROTHERMAL FIELD” SETTING

An origin-of-life scenario that explicitly focuses on processes of physical and chemical selection in molecular systems was suggested by researchers David Deamer and Bruce Damer (Damer and Deamer 2015). Considering the properties of hydrothermal sites as conducive to the emergence of life, the authors favor “hydrothermal fields,” associated with small ponds on volcanic land masses emerging from the ocean, rather than submarine hydrothermal vents, as a more suitable

environmental candidate. Deamer and colleagues believe that for cellular life to begin, a fluid-phase membrane made of amphiphilic compounds was more advantageous than a mineral-made compartment. Most importantly, the fluctuating environment of hydration/dehydration cycles characterizing hydrothermal fields is the basis for their scenario. (For a more detailed comparison between alkaline hydrothermal vents and hydrothermal fields, see Deamer and Georgiou 2015, p. 1093).

Their scenario takes place in a hydrothermal field on a volcanic island rising out of the Earth’s first ocean, resembling sites like Kamchatka, Hawaii, Iceland, and Yellowstone today (Damer 2016). Extant hydrothermal fields are characterized by cycles of hydration and dehydration in clay-lined freshwater pools undergoing evaporation and replenishment by hot springs and rainfall (Damer and Deamer 2015, pp. 873–874). According to Damer and Deamer, it is highly likely that various organic molecules such as amino acids, nucleobases, and membrane-forming amphiphiles have been synthesized by geochemical processes associated with volcanism, or delivered to Earth by comets and meteorites and were available at such sites (Martin et al. 2008b, pp. 135–136; Damer and Deamer 2015, p. 875; Deamer 2017). As a guide to possible synthetic reactions on the ancient Earth, Damer and Deamer rely on organic compounds synthesized by non-biological processes in carbonaceous meteorites in the early solar system (see Pizzarello et al. 2013). Such organic compounds, from either endogenic or exogenic source, are considered to have been dissolved by precipitation and accumulated in hydrothermal pools.

The authors, first, suggest how hydration-dehydration cycles drove the assembly of vesicles with encapsulated polymers. During the dry phase, dehydrated amphiphiles self-assembled into multilamellar structures on mineral surfaces at the pool edges and functioned as scaffolding that captured and concentrated organic monomers between amphiphilic layers (Deamer 2012; Toppozini et al. 2013). Condensation reactions between the monomers then led to the creation of polymers that resembled peptides, oligonucleotides, and possible complexes of the two (Damer and Deamer 2015, p. 881). Numerous laboratory simulations have demonstrated the polymerization of monomers, for example, mononucleotides, under dehydration-phase conditions (Rajamani et al. 2008; Deamer 2012). The mechanism of condensation involves the concentration of monomers up to the point when water activity becomes sufficiently low. “Water molecules become leaving groups and ester bonds are synthesized. Activation energy is provided by the elevated temperatures of the hydrothermal site” (Damer and Deamer 2015, p. 876). The polymerization of amino acids into oligopeptides under similar conditions was also reported (Forsythe et al. 2015).

At the hydrated phase of the scenario, lipid vesicles were produced when water interacted with the amphiphilic multilamellar matrix and polymers synthesized at the dry phase were captured in the vesicles (see Deamer and Barchfeld 1982). Damer and Deamer have calculated that trillions of vesicles of a diameter of typical bacteria could have been produced

from a few milligrams of amphiphiles. The produced vesicles or “protocells,” some empty and some containing polymers, were each unique in its composition, both in respect to their membranes and to their contained polymers. With each vesicle representing an “experiment,” this resulted in “a natural version of combinatorial chemistry in which a few vesicles survive while most are dispersed” (Deamer 2014, p. 637; Damer and Deamer 2015, p. 876). Selection of the vesicles that began at the hydrated phase was first determined by membrane stability, effected, for example, by the random presence of a polymer that stabilized the membrane. Specific polymers could have interacted with specific amphiphiles by electrostatic forces, hydrogen bonding, and hydrophobic interactions. In the next dehydration phase, the surviving protocells fused again with the multilamellar matrix and the stabilizing polymers were distributed to the next generation of protocells. The authors also noted that vesicles composed of strongly associated amphiphiles and polymers would have persisted even during the dehydration and fusion phase (Damer and Deamer 2015, p. 878).

The most important element in the hydrothermal-field scenario is what Damer and Deamer describe as “coupling” of the contents of the protocells between the hydrated and dehydrated phases, which repeat themselves indefinitely. “The system is continuously experimenting, tending toward combinations of polymers that are more stable than other combinations” (Damer and Deamer 2015, pp. 879–880). Furthermore, it is hypothesized that, in addition to such processes of physical selection, given a continuous “coupled phase cycles” over extended time span, rare combinations of functional polymers will emerge. Among them, polymers, using their own sequences as templates, will catalyze growth by polymerization. The rare protocells encapsulating such polymers will take over in a process of chemical selection between molecular systems. This evolutionary process will give rise to molecular systems that “...could plausibly possess the necessary structures and functions for the transition to cellular life” (Damer and Deamer 2015, pp. 872–873, 881).

6.5.9.1 FUNCTIONAL PROPERTIES OF PROPOSED POLYMERS

Damer and Deamer acknowledged that the hypothesis of the emergence of functioning systems is so far speculative, in distinction to the physical selection parts of the scenario based on multiple observations and experiments (noted previously). However, they suggested predictions that could be tested to check the validity of their overall model. First, they proposed a list of the functional properties of polymers that could have emerged gradually, participating in the continuous evolution of protocells toward living systems (Damer and Deamer 2015, pp. 881–882).

1. S-polymers—bind to and stabilize a membrane-bound protocell.
2. P-polymers—form pores in the bilayer membrane that will allow access of potential nutrients to the protocell.

3. M-polymers—catalyze reactions of a primitive metabolism among molecules that entered the protocell, providing energy and products for polymerization reactions.
4. R-polymers—undergo a primitive version of replication, using their own sequence as a template. C-polymers, a subset of this group, catalyze their own replication.
5. F-polymers—provide feedback control for various processes.
6. D-polymers—initiate and control the division of a protocell, following the duplication of its contents. The authors note that this function requires the joint action of all the other functional polymers. Most importantly, when protocells can divide in solution, the scaffolding of the dehydrated phase will not be needed. At this point, “the transition to life would occur” (Damer and Deamer 2015, p. 882).

It is predicted that when various functional polymers accumulate in a protocell, it is possible that interactions between polymers may produce novel emergent functions. For example, interactions between oligopeptides and oligonucleotides could produce a primitive version of coding that guides catalyzed polymerization and replication (*Ibid.*).

6.5.9.2 FROM PHYSICAL AND CHEMICAL SELECTION TO NATURAL SELECTION

The Deamer and Damer scenario described here aims to account for the gradual emergence of complex functional protocellular systems from organic compounds on the ancient Earth, without relying, for most of the process, on the Darwinian mechanism of replication, division, and natural selection. Damer and Deamer suggest that it was the capturing and concentrating of organic monomers and their condensation into polymers by the mineral-amphiphilic scaffolding during the anhydrous phase that obviated the need for “the complex and high-risk process of replication and division in the bulk phase” (Damer and Deamer 2015, pp. 879, 882). Only when the long, continuous process of repeating cycles and coupled phases culminated in the emergence of functioning molecular systems supporting both metabolism and replication, controlled protocell division in solution took over (2015, p. 882). At this stage, natural selection proper could have taken center stage, instead of the previously exclusive physico-chemical selection processes. It should be emphasized that Damer’s and Deamer’s focus all along is on the emergence and evolution of molecular systems. Their theory is thus a “system first” rather than “gene-first” or “metabolism-first” theory (Deamer 2014, p. 637; Damer and Deamer 2015, pp. 873, 881).

From an evolutionary perspective, it is noteworthy that features commonly associated with the Darwinian mechanism, such as the emergence of novel adaptive properties in response to selective hurdles, are hypothesized to arise as a result of physico-chemical processes and to be physically

and chemically selected. Thus, for example, membrane-stabilizing polymers and polymers forming pores in the membrane are synthesized by chance in the dry phase and are encapsulated by vesicles in the hydrated phase. However, these polymer types are selected as adaptations to imposed hurdles of vesicle survival and of the need for transport of nutrients across membrane barrier. Not only polymers ensuring stability and porosity of protocells but also combinations of more complex polymers featuring intricate functions, such as catalysis of template replication, are hypothesized to participate in an evolutionary process, in which physical and chemical selection plays a major role (Damer and Deamer 2015, pp. 879–880).

6.5.10 CONCLUSION

This chapter was aimed to demonstrate that origin-of-life researchers commonly evaluate the emergence of life as an evolutionary process. It was also intended, through the discussion of a few representative case studies, to show what could have been the characteristics of a prebiotic evolutionary process. No consensual theory is yet available to account for the origin of life on Earth, nor is there an experimental confirmation of such theory. However, the various scenarios discussed here demonstrate the crucial role played by the evolutionary hypothesis of the origin of life in pursuit of a solution. As a reminder, what I suggest to call “the evolutionary hypothesis of the origin of life” maintains that the transition from a lifeless environment to the first living systems involved a long series of stages growing in complexity. Prebiotic evolution constituted in highly constrained and channeled physical and chemical processes that led to the emergence of infrastructural entities capable of gradually engaging in Darwinian evolution.

The notion that the emergence of RNA and an RNA world was a necessary stage at one point or another on the way to life is supported by the scenarios considered in this chapter. The many challenges involved in the prebiotic synthesis of RNA led to the formulation of metabolism-first and proto-metabolism models as alternatives to the gene-first conception. Yet, the “great explanatory power the [RNA world] hypothesis provides for understanding how Darwinian evolution might have begun” is acknowledged across the board (Schwartz 2013, p. 784). Similarly, the idea that compartmentalization was necessary for the evolutionary emergence of life is accepted by “geneticists” and “metabolists” alike (Szostak et al. 2001, p. 387; Monnard 2007, pp. 387–390, 389; Luisi 2015, pp. 906–918, 913). On the other hand, the question of the prebiotic geochemical setting in which life could have emerged and the various implications of such a setting (e.g., nature of compartments and source of organic molecules) is still a bone of contention (e.g., Copley et al. 2010; Damer and Deamer 2015).

This CONCLUSION, however, should first and foremost comment on the evolutionary aspects of the scenarios discussed in this chapter, noting their differences and especially their unifying framework. *Gene-first and metabolism-first*

models, despite their fundamental divisions, hypothesize that evolution through natural selection emerged gradually and that primitive modes of natural selection took part in the emergence of a full-blown Darwinian system. Experiments performed by the Szostak group on lipid vesicles containing a genetic polymer showed primitive forms of division, competition, and selection of such vesicles. Data from other laboratories on the role of physical and chemical factors, for example, involvement of mineral and organic catalysis in the prebiotic synthesis of an RNA polymer and an engulfing vesicle (e.g., Deamer and Barchfeld 1982; Miyawaka and Ferris 2003; Huang and Ferris 2006; Monnard 2007, p. 389; Joshi et al. 2009; Brack 2017), were extended through Szostak’s experiments also to the behavior of growing and dividing vesicles (Hanczyc et al. 2003). These processes were determined by, among others, the chemical nature of the membrane, affecting its physical behavior; internal osmotic pressure within the vesicle and the resulting extension of the membrane; exertion of mild shear forces, for example, wind-driven waves; and, notably, catalysis by clay minerals and small organic molecules, such as ser-his (Chen and Szostak 2004; Szostak 2011). Experiments by this group also established the possibility of a non-enzymatic, chemical replication of RNA, and revealed that RNA copies produced by such chemical replication showed catalytic activities (Szostak 2011; Adamala and Szostak 2013; Engelhart et al. 2013). This experimental work substantiated Szostak’s conviction that “*Darwinian evolution itself emerged in a series of stages, step by step*” (Szostak 2012a).

Hypotheses concerning primitive forms of reproduction, division, and selection already in early stages of the emergence of life are also promoted by several *metabolism-first models* (Morowitz 1992; Segré et al. 2001; Vasas et al. 2012). However, in distinction to Szostak’s gene-first scenario, “metabolic” models discussed here adopt an altogether different, “compositional” concept of information and inheritance (Segré et al. 2001, p. 137) and apply the gradual emergence of the Darwinian framework to autocatalytic metabolic cycles within a protocell (Morowitz 1992, 1999; Kauffman 1993, pp. 309, 323; Lancet and Shenhav 2009), within inorganic compartments in the vicinity of hydrothermal vents (Smith et al. 2009), or on the surface of nickel and iron sulfide minerals (Wächtershäuser 1988, 1992). Metabolism-first scenarios allot a major role to physico-chemical constraints and physico-chemical selection. Wächtershäuser’s “surface-metabolist” scenario provides a clear example in his hypothesis of chemical selection processes on a pyrite surface that were due to the differential propensity for detachment of the various organic molecules formed on the pyrite surface (Wächtershäuser 1992, p. 96). In a later version of his scenario, Wächtershäuser spoke about a “pioneer organism,” in which “metabolic reproduction” resulted from an autocatalytic feedback mechanism (Wächtershäuser 2007). Metallo-catalysts synthesized small organic molecules, which in their turn enhanced the competence of metallo-catalysts to produce more organic molecules (Huber et al. 2012). Interestingly, Wächtershäuser referred to the “conversion

from an early, direct, chemically deterministic mechanism of evolution by ligand feedback to...a genetic mechanism of evolution by sequence variation [as] truly an evolution of the mechanism of evolution. It surely must have occurred in multiple phases..." (Wächtershäuser 2007, p. 597).

The approach to the involvement of natural selection in the emergence of life is different in the *proto-metabolism case studies* of Russell and de Duve, which postpone the onset of natural selection to the emergence of RNA. Both scenarios emphasize the necessary preparatory role of metabolic synthetic reactions in producing organic molecules, including the building blocks of RNA, and in setting the stage for natural selection (De Duve 1991, pp. 133–143, 2005a, pp. 156–157, 2005b; Martin and Russell 2007, pp. 1890, 1893, 1910). De Duve contends that during the stage in which the chemical infrastructure for natural selection was gradually being built, protometabolic reactions growing in complexity depended on deterministic chemical processes, whose continuity was made possible by the stability of geochemical conditions (de Duve 2005a, p. 23–24). Importantly, he called attention to the fact that the products of protometabolic reactions were not statistically random, owing to stringent physical and chemical constraints. (De Duve 1991, pp. 137–145, 213; 2005a, p. 24). Thus, in de Duve's protometabolic scenario, the onset of natural selection depended on a prior evolutionary process involving physical and chemical selection (1991, pp. 143–145).

According to the Russell and Martin scenario, metabolism grew out of the geochemistry at alkaline hydrothermal vents, and a necessary condition for this emergence was the electrochemical and thermal gradients across membranes in the porous structures containing iron sulfides (Russell et al. 2011, p. 946, 2014, p. 308). Theoretical and experimental work (Baaske et al. 2007; Burcar et al. 2015) also raised the possibility that compartments under the hydrothermal vents conditions "could be veritable 'reactors' for RNA synthesis" (Koonin 2007, p. 9105). Thus, this proto-metabolic model involves an early phase, referred to by Russell and colleagues as "the kind of thermodynamically driven evolutionary process" (Russell et al. 2014, p. 326), in which the highly constrained geochemical conditions at the vent determined the emergence and growth of metabolism, and a later stage, in which natural selection within and among compartments took over. The overall process is described by the researchers as "an evolutionary transition from geochemical to biochemical processes" (Martin et al. 2008a, p. 805).

The role of physical and chemical selection is notable in the scenario of *Copley and colleagues*, in which genes and metabolism are suggested to have *co-evolved toward an RNA world*. The emergence of protometabolic reaction networks, described by the researchers, is based predominantly on the catalytic abilities of minerals and small organic molecules (Copley et al. 2007). Mutual catalysis of molecules within the networks and selection of communities with increased concentrations of activated monomers are suggested to have led to ever-larger and more-effective catalysts. A crucial element of the co-evolution model is the hypothesis that nucleotides could have been synthesized in the vents by "a surprisingly small"

metabolic module (Copley et al. 2007, p. 433) and could have been part of the emergence of protometabolism from the very start. Each of the many stages depicted by the authors depended on physico-chemical constraints that channeled the products in a non-random direction, as demonstrated by their experiments on the "catalytic landscape" of pyruvate in hydrothermal vents (Novikov and Copley 2013, p. 13283). It is important to note that the overall evolutionary process detailed by the investigators is governed by physico-chemical selection that favored communities with better chances of increasing the levels of monomeric building blocks (Copley et al. 2007, p. 431). Such selected communities were able to synthesize longer and more effective catalysts, including replicating RNAs, thus resulting gradually in a transition to evolution through natural selection.

From the above concluding comments, it is apparent that the case studies examined in this chapter share the hypothesis that the emergence of Darwinian evolution depended to a large extent on physico-chemical constraints, especially on catalysis by minerals and small organic molecules and on physico-chemical selection processes. This unifying theme is brought to its most explicit expression in the "*system-first scenario in a hydrothermal-field setting*," proposed by Damer and Deamer. These investigators focus specifically on processes of physical selection of more stable polymers and on chemical selection of rare combinations of functional polymers, taking place in the fluctuating environment of hydration/dehydration cycles characterizing hydrothermal-field sites.

It is important to note that the evolutionary hypothesis of the origin of life provides a decisive rebuttal to the argument against the possibility of prebiotic evolution, as formulated by the prominent evolutionary biologist Richard Dawkins. In his argument, discussed in Chapter 3.1 of this volume, Dawkins contends that the first living system, that is, a replicating apparatus at the root of the evolutionary tree, had to emerge by a highly improbable, single-step chance event (Dawkins 1986, p. 140). According to Dawkins, physical and chemical selection events, lacking the element of heredity or "memory," are transient and cannot, in principle, lead to an accumulation of selected small advantages necessary for an evolutionary process (Dawkins 1986, pp. 43–74). The scenarios described in this chapter "beg to differ." Based on theoretical considerations and empirical data, they raise the possibility of stepwise processes that offer an alternative to the notion that the origin of life was the result of a single improbable chance event. The hypothesis raised by Damer and Deamer is particularly illuminating as an answer to Dawkins's contention. According to their scenario, in the "coupling" of the contents of protocells between the hydrated and dehydrated phases, which repeat themselves indefinitely, "reactions do not occur just once and then approach equilibrium, but instead reaction products accumulate and can undergo increasingly complex interactions" (Deamer and Georgiou 2015, p. 1092). Not less important, their scenario is based on the statistics of large numbers. Near-infinite number of combinations of randomly synthesized polymers encapsulated in protocells, each constituting an "experiment," can arise in the physico-chemical setting

of a hydrothermal pool and, being physically and chemically selected, may gradually lead to the onset of natural selection.

We still don't know whether any of the scenarios examined here will eventually be able to provide an answer to the question of the emergence of life on Earth. It seems clear, however, that the evolutionary hypothesis of the origin of life is a fruitful hypothesis, leading researchers toward new avenues in the search for a solution.

6.6.1 INTRODUCTION

Alice laughed: “There’s no use trying,” she said; “one can’t believe impossible things”

(Carroll 1999)

So enigmatic are the complexities of living states of matter that we tilt at windmills to gain an understanding: we arm ourselves with quixotic ideas, hopeful of winning the battle. In this review, I lay out a *physicochemical* line of attack: it constrains speculations; it clarifies assumptions; and it brings into focus the molecular mystery of “becoming alive and evolving.” It delineates complex yet realistic processes of life’s origins—a “jigsaw puzzle” yet to be fully worked out (Spitzer 2017).

I organize this review as follows. In [Section 6.6.2](#), I re-consider traditional predicaments of origins research—the questions of life’s natural “designers,” Schrödinger’s unknown biophysical laws, and the questions related to “defining life.” These re-appraisals suggest that life’s emergence can be viewed as a “jigsaw puzzle” based on existing physicochemical laws and cyclic prebiotic processes driven by diurnal and tidal energies. The updated version of the puzzle is summarized in [Section 6.6.3](#). Then I take a top-down view in [Section 6.6.4](#), and discuss the physicochemical complexity of today’s bacterial cells (Spitzer 2011) in order to exploit the assumption that first Archaean organisms were similar to today’s bacterial cells. Next, in [Section 6.6.5](#), I discuss experimental ideas based on bottom-up (chemical) and top-down (biochemical) processes energized by cyclic

temperature and water activity gradients (Spitzer 2013b, 2014); their cyclic character caused proto-nucleic acids to evolve as unwinding and rewinding double helices—replayed today in polymerase chain reactions (PCRs). In [Section 6.6.6](#), I suggest that the same cyclic energies brought about repeated fusions of first cells with environmental nucleic acids and with each other—a natural mechanism of cellular evolution analogous to genetic engineering.

I conclude that Earth’s diurnal and tidal cycles drove phase-separations and prebiotic chemical reactions towards cellular life in the microspaces (compartments) of consolidating geochemical matrices (Spitzer and Poolman 2009). The “compartments first” paradigm (Morowitz 1992) is *unconditionally* required to constrain diffusional decay to disorder mandated by the second law of thermodynamics. Orgel (2004) expressed this requirement intuitively as “molecules that stay together, evolve together.” Further, the cyclic “triple” chemical coevolution of proto-proteins and proto-nucleic acids *with and within* the micro-compartments must proceed under high macromolecular crowding at relatively high ionic strengths. Under these conditions, the excluded volume effect of biomacromolecular crowding becomes commensurate with hydration and screened electrostatic forces at a distance of about one nano-meter. Only at such close distances can cyclic chemical evolution progress to today’s molecular recognition (e.g., substrate-enzyme binding), to the complementarity of hydrogen bonding of nucleobases (genetics), to protein folding and the assembly of biomacromolecular “machines” (bio-catalysis), and to the repeatable rebuilding of cellular “architecture” of dividing cells (Harold 2005).

6.6.2 CELLULAR COMPLEXITY CREATES PREDICAMENTS

Origins research has been a very broad and complex effort involving many scientific disciplines, as evidenced in this handbook and in many books and compendia (e.g., Deamer and Fleischaker 1994; Lahav 1999; Brack 2000; Bedau and Cleland 2010). Such wide transdisciplinary research has inevitably engendered many diverging viewpoints, including those addressing “complexity.”

I use the term “complexity” in an informal meaning of “being very complicated” (Spitzer 2013a; Whitesides and Ismagilov 1999). In the physicochemical sense, the complexity refers to concentrated (crowded) mixtures of many kinds of interacting molecules undergoing cyclic phase separations and chemical reactions in permeable containers. “Molecules” are taken broadly, including ions, macromolecules, and polyelectrolytes; “phase separation” has the normal physicochemical meaning of the appearance of liquid and solid phases. However, in the presence of macromolecules and surfactant (amphiphilic) molecules, phase separations of “semi-solid” phases at low water activities become tantalizingly complicated; complex materials then appear with diverse morphologies of submicron domains—crystalline, amorphous, and liquid, including interpenetrating networks (Spitzer 2011).

In the cytological sense, the complexity refers to the processes of the cell cycle. I borrow the *eukaryotic* term “cell cycle” (which has well-defined stages) to describe also the growth and division of prokaryotic cells as representatives of the “first” life. In this case, the cell cycle is a complex physicochemical process of the nucleoid being replicated while attached to the growing cell envelope, with subsequent nucleoid segregation and cell envelope re-organization into two cells.

Because physicochemical complexities of life’s emergence have not been explored in much detail, it is constructive to re-appraise some traditional views about the nature and origins of life.

6.6.2.1 THE “BLIND WATCHMAKERS”

How Darwinian evolution fits into molecular mechanisms of life’s emergence has not yet been adequately explained. That Darwinian evolution is “blind,” even at the microbial level, is uncontroversial: genetic variations occur *before* natural selection—before the “blind watchmaker” can act on them (Dawkins 1987)—cf. [Section 8](#) of this handbook. That genetic variations arise from errors in replications of nucleic acids (nucleoids and chromosomes) is also uncontroversial, cf. [Section 6.6.6](#).

But how does planetary prebiotic *chemical evolution* operate? How does the “clutter” or “gunk” of prebiotic molecular inventory chemically react, phase-separate, and evolve into “proto-cells” and then into single-cell ancient organisms? After all, the major product of Stanley Miller experiments is “goo” of many kinds of chemical compounds; after all, organic synthetic reactions often produce complex (“intractable”) mixtures of chemicals (Miller 1953; Shapiro 1986, 2007; Schwartz 2007; Robertson and Joyce 2012; Scherer et al. 2016). Because Stanley Miller experiments generate a multitude of carbon compounds in less than a week, the chemical complexification of Earth was a *very fast* evolutionary process, with many parallel chemical reactions in different geochemical locales ([Figure 6.6.1](#)).

Experimental evidence thus suggests that prebiotic Earth was a complex dynamic reservoir of molecules: heterogeneous, phase-separating mixtures in molecularly homogeneous multicomponent electrolyte solutions, undergoing chemical reactions driven by diurnal and tidal energies (Earth-Moon rotations). From astrochemical observations, we also know that complex mixtures of many kinds of molecules are being created and occur throughout the cosmos, cf. [Section 4](#).

Regardless of the chemical details of prebiotic molecular inventory, physical chemistry and planetary sciences do provide a plausible “principle” of life’s emergence: living states of matter arose through (natural) planetary energies acting *repeatedly* on prebiotic chemical matter (Spitzer and Poolman 2009; Spitzer et al. 2015; Spitzer 2017). Such cyclic—stoking—energies create non-random dynamic “patterns,” the first necessity for a life to arise (Whitesides and Boncheva 2002; Hazen 2005). Cyclic energies can drive phase separations, that is, submicron colloidal nucleations

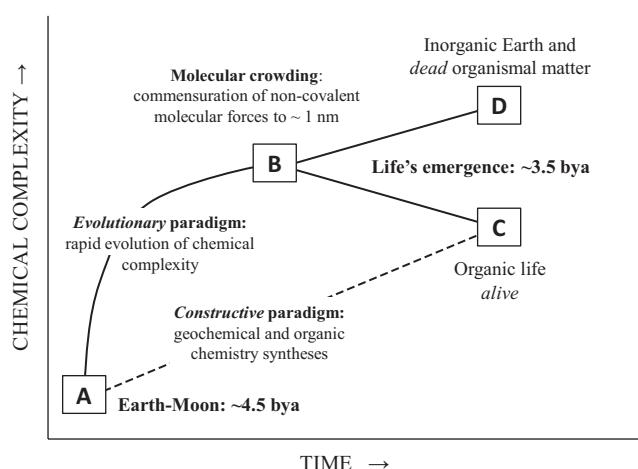

FIGURE 6.6.1 Evolution of Earth's physicochemical complexity and the emergence of life. After the formation of the Earth-Moon planetary system [A] the physicochemical complexity of prebiotic processes grew very fast, until a “self-purifying” process (phase-separating in localized micro-spaces) [B] began to evolve toward cellular life, currently simplified to only five nucleobases, two derivatives of ribose, phosphates, 20 amino acids, two-tail hydrophobic surfactants, and multi-ionic aqueous electrolyte of relatively high ionic strength. After the appearance of life [C], the chemical complexity of Earth [C + D] grew fast also through dead organismal matter [D].

toward micro-scale agglomerations and crystallizations; they can drive the reverse phenomena of re-dispersions and dissolutions; they can drive chemical reactions back and forth, for example, condensation/hydrolysis reactions; and today, cyclic temperatures drive amplifications of DNA segments in cell-free PCR protocols.

Thus, in general, cycling temperatures and the gradients of water activity and chemical and electrochemical potentials play an essential part in the emergence of life. As a corollary, life is extremely unlikely to emerge *spontaneously* (in the sense of chemical thermodynamics and kinetics) from a “prebiotic soup” of molecules, representing a one-of-a-kind, highly improbable event of kinetically arrested accumulation of high free energy in localized molecules of just the right kind, which self-reacted and self-organized, creating first “molecular replicators” or first “simple proto-cells.” Though statistically imaginable and described as a “near miracle,” this view has now been abandoned. It is noteworthy that it was entertained by influential scientists, such as Monod and Crick (Fry 2000).

6.6.2.2 SCHRÖDINGER'S LAWS OF LIFE

The above clarification that cellular life emerged in a “blind” cycling process through chemical reactions and phase separations is closely related to cellular metabolism—the energies that cells require for reproduction. This is one issue that Schrödinger addressed in his book “What is life?,” originally published in 1944 (Schrödinger 2012); the other topic was the physicochemical nature of the gene.

On metabolism, Schrödinger (incorrectly) suggested that an organism “feeds on negative entropy” and that it extracts “order” from the environment. He assumed (writing for a general audience) that it was not worthwhile to make a rigorous distinction between free energy, the combination of the first and second laws of chemical thermodynamics, and entropy, the second law (Perutz 1991), being focused on the statistical nature of the second law and of quantum mechanics. Since then, however (e.g., Hinshelwood 1946), it has been uncontroversial that biological cells do obey the first and the second laws of thermodynamics, albeit through mechanistically complex couplings of thermodynamically spontaneous reactions with non-spontaneous reactions, summarized and arranged in biochemical metabolic cycles. Many such cycles (glycolytic, tricarboxylic, biosynthetic pathways, etc.) are described in textbooks (Zubay 1998; Schaechter et al. 2005; Kim and Gadd 2008; Alberts et al. 2010), including the creation and dissipation of free energy stored in the membrane potential (Mitchell 1979; Harold 1986; Nicholls and Ferguson 2002). Fundamentally then, biological cells operate as *open thermodynamic systems*; the cells exchange molecules and energies with the environment—they cannot exist without it; they are not autonomous—they are dynamically *united with the environment* from which they emerged; and their genome must fit the environment—or they die.

On the question of the gene, Schrödinger brought forth the idea of molecularly coded genetic information. He described a gene imaginatively as a large and extremely stable, isomeric molecule, the isomers of which create aperiodic crystals of the “hereditary substance” (chromosomal DNA) that can be mutated by quanta of radiation. Though such a model explains radiation-induced mutations, it does not explain how the “hereditary substance” gets replicated; Schrödinger therefore suggested that other physical laws (yet-to-be-discovered) are required.

Schrödinger’s prediction of new laws of biophysics, not directly related to biochemistry, has been pursued through abstract physical and philosophical concepts, for example, processes of self-assembly arising from energy flows far from equilibrium, criticality phenomena, autopoiesis, teleonomy, dynamic kinetic stability, and theories of metabolic autocatalytic cycles and of hyper-cycles of replicating molecular quasi-species (Eigen and Schuster 1979; Kauffman 1993; Bak and Paczuski 1995; Solé and Goodwin 2000; Luisi 2003; Pross 2005; Morowitz and Smith 2007; Pascal and Pross 2015). These theoretical concepts have remained remote from the replicating and segregating nucleoids in growing and dividing cells.

It is noteworthy that Pasteur’s “microbiological law”—all life only from life—is valid also in thermodynamic and quantum mechanical sense: a single bacterial cell may not self-assemble spontaneously from the “dead” (complex) mixture of its natural biomolecules and “start living.” As Crick observed already in 1966, it might be more important to find out how to re-assemble a living bacterial cell from its natural components than to deploy organic chemistry to synthesize all its biomacromolecules (Crick 1966). Or, in Harold’s language, the question is how to bring about the dynamical molecular “architecture that distinguishes a living cell from

a soup of the chemicals of which it is composed” (Harold 2005). Remarkably, the Crick-Harold challenge remains open.

6.6.2.3 DEFINING LIFE

The conceptual issues with life’s “blind designers” and Schrödinger’s unknown biophysical laws are enmeshed in efforts to define life—in the question “what is life?” This topic is reviewed in [Section 2](#) of this handbook; the jigsaw puzzle in the next section gives a physicochemical view. The puzzle makes the meanings of biological terms, for example, “being alive and evolving,” relatively clear and positioned for further elucidations. Thus, the jigsaw puzzle can be viewed as a “theory that provides meaning” (Benner 2010) or at least as a “theory that is beginning to provide meaning.”

More generally, however, *physicochemical* properties of molecules and related laws (Atkins 1978, 2003, 2007, 2011) provide the footing—a firm foundation, from which to consider any definition of life, even though the value of such definitions is uncertain (Luisi 1998; Cleland and Chyba 2002; Lazcano 2008; Benner 2010; Cleaves 2010; Szostak 2012; Trifonov 2012). Depending on the temperature range, molecules exhibit a wide range of molecular motions (a prerequisite for chemical reactions), including translational diffusion, without which life cannot exist. Molecular diffusion was discovered qualitatively already in the early nineteenth century by Robert Brown; much later, Einstein and Perrin quantified Brownian motion, cementing the view that all molecules are real, albeit very small objects (Newburgh et al. 2006). As such, they are subject *only* to physicochemical laws, principally chemical thermodynamics and quantum chemistry. Therefore, definitions of life that impute *biological* characteristics, for example, Darwinian evolution, to chemical systems become tautological. Neither bacterial cells *in vivo*, nor the molecules comprising them have any inherent capability for Darwinian evolution—cells *cannot help but* exhibit Darwinian evolution because of molecular (and supra-macromolecular) errors in the transmission of genetic information, cf. [Section 6.6.6](#). Similarly, no physicochemical properties of molecules indicate that molecules can *spontaneously* self-organize in “cycles” and self-replicate (Orgel 2000). They can do so only in reproducing cells or in designed cell-free systems, which eventually reach equilibrium, cf. Shapiro’s golfer’s analogy in [Section 6.6.3.1](#).

6.6.3 THE PHYSICOCHEMICAL JIGSAW PUZZLE OF LIFE’S ORIGINS

The metaphor of a “jigsaw puzzle” (Brack 2000; Higgs and Lehman 2015), in a physicochemical adaptation, has proved useful in tying together wide-ranging themes of origins research (Spitzer 2017). Such themes are the prebiotic Earth environments, prebiotic chemistry, self-assembly processes, energetics, and bio-informational polymers (Deamer and Fleischaker 1994). The “roadmaps” of NASA and of the European Space Agency suggest similar topics as discussed in [Section 1](#) of this handbook. Since “life’s origins” is a very broad research area (Smith and Szathmáry 1999; Knoll 2003; Lane 2003; Mesler and Cleaves 2016), the physicochemical jigsaw puzzle

is intentionally limited and focused only on the question of how Hadean chemistry evolved into Archaean microbiology.

6.6.3.1 THE EVOLUTIONARY NATURE OF THE PUZZLE

A physicochemical jigsaw puzzle avoids any particular reaction schemes, such as those of organic synthetic chemistry, geochemistry, or atmospheric photochemistry. Any such reaction schemes must include a natural mechanism of how the desired components get separated from the overall chemical inventory of the prebiotic Earth. The three-phase “line” boundary of atmosphere, hydrosphere, and lithosphere seems the most natural geochemical location for a life to emerge: at these “beach and rocky shores,” prebiotic molecules of wide-ranging water solubility can accumulate, chemically react, and phase-separate (“self-purify”) under the reactive conditions of cyclic solar energies and hydration-dehydration cycles of tidal seawater. That cyclic (rhythmic) or fluctuating environments played a role in life’s origins has been suggested before, though the concept has not been developed from a physicochemical standpoint (Lahav 1999; Deamer 2011). Thus, Earth acts as a huge chemical reactor, both on chemical engineering “geo-scales” and on molecular scales of cyclic chemical reactions and phase separations (Spitzer and Poolman 2009; Stüeken et al. 2013).

It remains an experimental fact that organic syntheses involving bonding of carbon atoms, including Stanley Miller-type experiments, yield many organic compounds, often in complex “tarry” mixtures, depending on the initial mix of starting materials and the chosen reaction conditions (Shapiro 1986). In this sense, multi-step syntheses of organic chemistry (of natural products) cannot mimic unconstrained processes of prebiotic environments. Shapiro described the issue this way: “*The analogy that comes to mind is that of a golfer, who having played a golf ball through an 18-hole course, then assumed that the ball could also play itself around the course in his absence*” (Shapiro 2007). Though synthetic organic chemistry has demonstrated a number of plausible prebiotic reaction schemes, this approach has now run its course. It has been described as the “end of the beginning” of origins research (Sutherland 2017). The reason is, as Shapiro implies, that synthetic strategies of organic chemistry discount the diffusional effects of the second law—they require “Maxwell’s demons” on prebiotic Earth to separate (purify) molecules for pre-conceived chemical reactions. However, Shapiro’s golfer’s analogy concerns equally any other *constructive* (non-evolutionary) paradigms ([Figure 6.6.1](#)), such as the designs and constructions of artificial life or of simple or minimal proto-cells. Their primary goal is to “design, synthesize and engineer life,” rather than to illuminate life’s complex organismal nature and its *natural* evolutionary emergence from abiotic chemistry (Woese and Goldenfeld 2009).

The physicochemical jigsaw puzzle of life’s emergence is updated and expanded here into two parts, shown in [Figure 6.6.2a](#) and [6.6.2b](#).

These figures split the original puzzle into the bottom-up chemical part and the top-down microbiological part. The Earth-Moon rotations provide two cyclic driving energies: solar radiation and seawater tides, designated as [A] in [Figures 6.6.1](#)

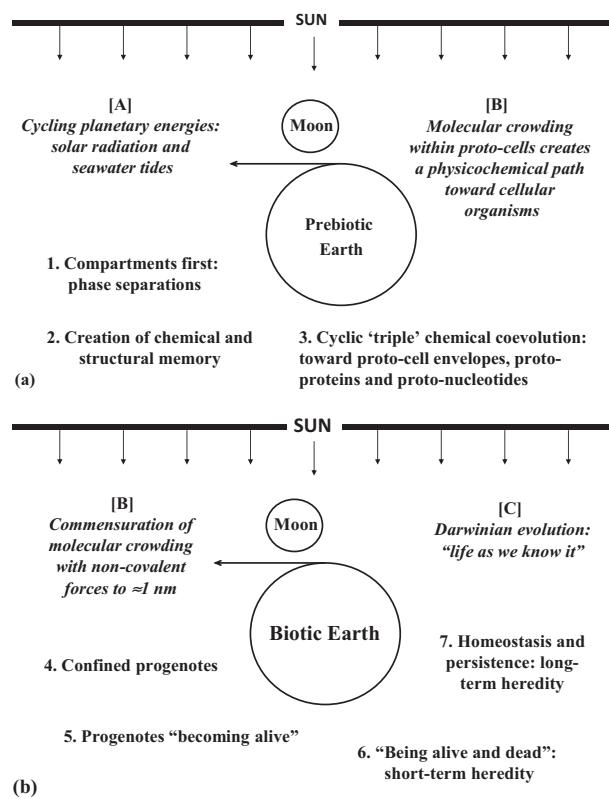

FIGURE 6.6.2 (a) The bottom-up chemical part of the jigsaw puzzle.

[A] Cyclic planetary energies are the “creators” of life. Jigsaw puzzle pieces #1: Life originated in a “compartments first” paradigm, required by the nature a biological cell as an open thermodynamic system. Such compartments came about through phase separations and consolidations of geochemical sediments. #2: The lagging responses of the compartments to the driving planetary energies create chemical and structural memory, a prerequisite for a cellular emergence of life. #3: The chemistries of proto-nucleic acids, proto-proteins, and proto-cell envelopes coevolved. [B] Molecular crowding in proto-cells signifies the possibility of a physicochemically defined path toward cellular life.

(b) The top-down microbiological part of the jigsaw puzzle.

Molecular crowding in proto-cells [B] signifies the evolution of interacting proto-macromolecular surfaces at about 1 nm separations. Jigsaw puzzle piece #4: *Confined progenotes* represent “triple” coevolution of proto-metabolism, proto-genetics, and proto-cell envelopes toward today’s biochemistry; onset of the evolution of homo-chirality and of the cytoplasmic excess of potassium; Woese’s concept of progenotes (Woese 1998; Koonin 2014) is extended by specifying permeable confinements to satisfy the requirement of an open thermodynamic system. #5: “*Progenotes becoming alive*”; proto-metabolism, proto-transcription, and proto-translation have begun to get stabilized under cyclic gradients. #6: “*Being alive and dead*”; proto-metabolism, proto-transcription, proto-translation, and proto-replication begin to show short-term heredity over a few generations under cycling gradients in still evolving unstable proto-cell-envelopes; onset of heterotrophy; the age of LUCAs with fixed genetic code; the rooting of the Tree of Life (Doolittle 1999). #7: *Homeostasis and persistence*; proto-ribosomes, proto-nucleoid, and proto-cell envelope functionally unify and stabilize and partly decouple from environmental cyclic energies; establishment of persistent cell cycles less dependent on cyclic environmental gradients, that is, energized also by chemical free energy of nutrients. [C] “*Prokaryotic life as we know it*.” Cellular Darwinian evolution via molecular errors in template replications of DNA and via fusions of cells with environmental nucleic acids and with themselves (natural genetic engineering); prokaryotic evolution with plasmids and viruses, and the start of evolution of proto-eukaryotic cellular structures with multiple membranes and nucleoids, relentlessly driven by cyclic environmental conditions.

and 6.6.2a. The prebiotic part is largely unchanged from the first version of the puzzle (Spitzer 2017), but it does emphasize the fundamental *physicochemical* condition for a life to emerge [B]: *only* when macromolecular crowding becomes commensurate with hydrogen bonding and screened electrostatic forces at about 1 nm, the prebiotic chemical evolution can proceed toward confined progenotes and first cellular organisms (Figures 6.6.1 and 6.6.2).

The microbiological part (Figure 6.6.2b) is substantially expanded to describe the emergence of cellular life. This part of the puzzle is quite tentative, dealing with biological issues such as “becoming alive” and “being persistent”; the suggested

experiments in Section 6.6.5.2 will throw more light on these very complicated supra-macromolecular issues. The end point [C] signifies the emergence of single-cell organisms, or “life as we know it”; the creation of genetic variations; and their natural selection via interactions with the environment (Darwinian evolution).

6.6.3.2 PROVISIONAL OBSERVATIONS AND CONCLUSIONS

The phenomena and conditions described in the updated puzzle in Figure 6.6.2 show that life’s emergence was a highly complex planetary process. Nevertheless, even at this early

stage of assembling and solving the puzzle, we can make some provisional conclusions about the processes, physicochemical conditions, and principles through which first prokaryotic-like organisms came about:

1. The emergence of life is a *cyclic evolutionary process of reacting and phase-separating molecules*, the results of which are contingent on Earth-like prebiotic chemical compositions and cyclic energies (solar radiation and seawater tides).
2. Cycling planetary energies are the “blind designers” of prebiotic chemical evolution, while natural selection is the “blind watchmaker” of organismal Darwinian evolution.
3. Chemical prebiotic evolution is continuous with Darwinian evolution through *supra-macromolecular cellular* evolution.
4. Biological cells operate as open thermodynamic systems and thus can “defeat” the second law of thermodynamics. Fundamentally, they can do it *only locally and temporarily*, with expenditures of external energies and evolution of heat. Hence, there is no “Schrödinger-like unease” between chemical thermodynamics and the living states of matter.
5. Cellular life can emerge and evolve only when *macromolecular crowding* becomes commensurate with screened electrostatic forces and with hydrogen bonding (including hydration and the related hydrophobic effect), over a distance of at about 1 nm.
6. Cell envelopes, metabolism, and genetics evolved *together with* the environment, as a complex cycling open thermodynamic system.
7. The statistical nature of the second law and of quantum mechanics, combined with the contingencies of cyclic environments, creates errors in the transmission of genetic information (molecular and supra-macromolecular errors in nucleoids and chromosomes), and thus, the progeny are not exact copies. This makes cellular *Darwinian evolution inevitable*—a fact or a law of nature.
8. The first persistent life came about when the nucleoid and the cell envelope unified in a *homeostatic* open thermodynamic chemical system, with increased dependence on chemical free energies of environmental nutrients. “Homeostatic” means the maintenance of repeatable spatiotemporal “architecture” during each cell cycle, as the cell responds to variable environmental conditions.
9. Prokaryotic “life” is a *cyclic state of matter* of being alive and having progeny. Viruses are not alive, because they do not operate as open thermodynamic systems.

These provisional observations appear more or less plausible. The physicochemical jigsaw puzzle shifts attention from particular prebiotic chemical reactions to supra-macromolecular pattern-forming processes driven by external cycling energies; it also shifts attention from the catalytic

surfaces of specific minerals to the supra-macromolecular geochemistry of consolidating sediments that create “liquid” micro-spaces and “solid” permeable confinements. Some cyclic experiments are described in [Section 6.6.5](#) from both bottom-up (chemical) and top-down (microbiological) standpoints. First, however, it is helpful to take a top-down view of today’s prokaryotic cells *in vivo*, because we cannot avoid the assumption that “first” Archaean cells already had a similar degree of complexity 3.5 billion years ago.

6.6.4 WHY DO BACTERIAL CELLS APPEAR SO COMPLEX?

In the last 20 years, there has been a dramatic progress in understanding the structuring of prokaryotic cells during their cell cycle (Kyne and Crowley 2016); it involves spatiotemporal replication, localization, and segregation of the nucleoid, together with cytoplasmic proteins—a complex process “orchestrated” with the growth and division of the cell envelope. These advances have come from many directions, the most important being the following:

1. Fluorescence spectroscopic studies of diffusion using genetic fusions of the green fluorescent protein (GFP) with target proteins and nucleic acids. The “surprising” result has been the characterization of the cytoplasm as a crowded but “watery” medium, indicating fast diffusion of *small* metabolites, proteins, and nucleic acids (Verkman 2002); under osmotic stress, the diffusion patterns become significantly altered, particularly for larger biomacromolecules (Konopka et al. 2009; Mika and Poolman 2011).
2. The greater acceptance of (complex) effects of biomacromolecular crowding *in vivo* on the folding, stability, and association of biomacromolecules vs. conventional “dilute” biochemical protocols *in vitro* (Zimmerman and Minton 1993; Ellis 2001; Zhou et al. 2008; Sarkar et al. 2013; Boersma et al. 2015).
3. The discovery of “cytoskeleton” (eukaryotic-like) proteins in bacteria and their role in bacterial division processes (Lutkenhaus 2003; Michie and Löwe 2006).
4. The visualization of cellular ultrastructure by three-dimensional (3-D) cryotomography (Baumeister 2005; Nickell et al. 2006; Oikonomou and Jensen 2017) and by computer (and “artistic”) modeling of bacterial cytoplasm (Elcock 2010; Goodsell 2010; Cossins et al. 2011; Yu et al. 2016).

These recent developments transformed our view of a prokaryotic cell from a “bag of enzymes” (Mathews 1993) to a highly crowded, yet well-regulated “architecture” of cytoplasmic biomacromolecules confined in a multilayered cell envelope that includes the bilayer plasma membrane (Baumeister 2005; Harold 2005; Silhavy et al. 2010).

This change of perspective has implications for directions in origins research. When the simplest life had been perceived

as “...*a packet of proteins and nucleic acids, cofactors and so on...*” (Orgel 2004), it then seemed reasonable to concentrate on synthesizing the bag’s components. However, bacterial cells are now known to be dynamically *nano-structured* in an energy-consuming spatiotemporal “architecture,” which is substantially repeated during each cell cycle. Thus, it cannot be considered that bacterial cells are a mixture of molecules that can somehow “self-assemble” or that a simpler prebiotic mixture of similar molecules could have self-assembled and started a cell cycle on prebiotic Earth. Rather, life’s emergence, point [B] in Figure 6.6.1, began with *dynamical phase-separation* of one or more localized and self-purifying processes from the totality of complex non-living cycling processes on prebiotic Earth.

In general, the spatiotemporal complexity of today’s prokaryotic cells can be described as follows:

1. *Multicomponent*, containing many kinds of small molecules, ionic salts, surfactant-like molecules, macromolecules, polyelectrolytes, and water.
2. *Phase-separated* from nutrient environments, that is, bounded by membranous layers, and phase-separated within, as a dynamic non-equilibrium sol-gel system.
3. *Crowded*, with a high total volume fraction of biomacromolecules that create super-crowded microgels with vectorial electrolytic nano-channels that guide the diffusion of ions and low-molecular-weight metabolites.
4. *In disequilibrium*, both in chemical sense and in physical sense, that is, catalytically reacting (growing) with inflows of water, ions, and nutrients from the environment and vice versa.
5. *In a re-emergent process*—an energy-consuming, thermodynamically open, “chemical engineering” process of imprecise cyclic replications and segregations of the nucleoid into daughter cells.

The first four characteristics define any complex *non-living* chemical mixtures that occur naturally in planetary environments. Examples of prebiotic molecular complexity include the great variety of carbon compounds that have been identified so far in our solar system and observed in the distant universe (McDonald et al. 1991; Chyba and Sagan 1992; Dworkin et al. 2001; Bernstein 2006; Pizzarello 2006; Rhee et al. 2007; Carrasco et al. 2009; Ehrenfreund and Cami 2010) and the readily formed “tars” in non-enzymatic organic syntheses of prebiotic biomolecules and biopolymers (Miller 1953; Shapiro 1986; Schwartz 2007; Scherer et al. 2016). Another example of non-living complex matter is “dead organismal matter” in the process of reaching physicochemical equilibrium (Atkins 2011).

The fifth property—re-emergence—differentiates *complex living states* from complex chemical states, as described previously. This property is quintessentially biological, as re-emergence requires the maintenance of cellular identity during the cell cycle, that is, the chemical maintenance and

continuation of the genome (nucleoid) and the physical maintenance and continuation of the phenotype (the cell envelope).

Complex chemical mixtures, considered as non-equilibrium reactive open thermodynamic systems (e.g., permeable colloidal micro-spaces, chemical reactors, and biological cells), can either be approaching an equilibrium or be kinetically arrested away from equilibrium; or they can be in a steady state, chemically reacting but not evolving, their properties being independent of time; or they can be in a non-steady state, chemically reacting and evolving in a random, irreproducible fashion, contingent on the kinds and ranges of external inputs, that is, on the environment. Only when non-equilibrium complex molecular mixtures are continuously phase-separating and chemically reacting under *cyclic non-steady state conditions*, that is, repeatedly stoked with energy, their chemical evolution into living states becomes conceivable. These general points are next elaborated in greater detail, using textbook sources (Schaechter et al. 2005; Kim and Gadd 2008; Phillips et al. 2009) and the emerging advances in the understanding of dynamic cellular ultrastructure of bacterial cells.

6.6.4.1 MULTICOMPONENT AND IONIC COMPOSITION

Bacterial cells are composed of many kinds of chemical compounds—ionic and hydrophobic in a wide range of molecular sizes, from nanometers to micrometers. The latter represents very long nucleic acids and cell wall biopolymers (Zimmerman and Murphy 2001). A great deal of biochemistry has been concerned with their isolation and purification and with determinations of their chemical compositions, 3-D chemical structures, *in vitro* biochemical reactivity and reassembly, and their cellular localizations and physiological functions *in vivo*.

In a bacterial cell, there are over 1000–2000 kinds of proteins, many kinds of RNAs, a single DNA polymer, and three to six kinds of phospholipids. There are also inorganic chemicals of non-biological origin that are important reactants or catalysts (widely available from the environment), chief being water and carbon dioxide and inorganic ions, for example, K^+ , Na^+ , Mg^{+2} , Ca^{+2} , $[HCO_3]^{-1}$, $[H_2PO_4]^{-1}$, $[HPO_4]^{2-}$, $[SO_4]^{2-}$, and Cl^{-1} . Physicochemical interactions between bacterial biomolecules and biomacromolecules are mediated by water and simple inorganic ions, and thus, cellular life depends critically on a buffered aqueous (multicomponent) electrolyte of relatively high ionic strength. The bacterial membrane is also ionic—it contains anionic lipids (Yeung et al. 2008), including highly charged cardiolipin (Romantsov et al. 2008). There are relatively few strictly uncharged biomolecules (and few, if any, biomacromolecules), except for “special cases” of proteins at their isoelectric points or zwitterionic lipids and similar compounds derived from choline. Uncharged “food” molecules, such as sugars, are transported via membrane proteins and then converted by kinases to anionic organic phosphates, in order to become available to cell’s biochemistry. Finally, as viewed from the nutrient medium, the bacterial cell *in toto* is charged, as evidenced by

cells' electrophoretic motion in an external electric field (van Loosdrecht et al. 1987; de Kerchove and Elimelech 2005).

6.6.4.2 MULTIPHASE SEPARATIONS

Phase separations of any kind imply classical physicochemical concepts of "high concentrations" of molecules, when their molecular size and shape and non-covalent molecular forces come into play, cf. the difference between the ideal gas law and van der Waals equation for real gases. The attractive forces responsible for the existence of liquid and solid phases, in general, are van der Waals forces and ion-dipole and similar Debye-type polar forces between small neutral molecules, as well as screened electrostatic forces between ions in solution, described by the Debye-Hückel theory.

However, the case of the multicomponent and ionic cytoplasm is much more complicated on account of the presence of biopolymers and their high "biomacromolecular crowding" *in vivo* (Ovadi and Srere 1991; Ellis 2001; Zhou et al. 2008). The designation "biomacromolecular crowding" reflects the high overall concentration of all biomacromolecular components. On a nanometer scale and microsecond (and longer) timescales, biomacromolecular surfaces can be considered as "smoothed-out," or averaged out, into four kinds of molecular "patches" that interact through attractive and repulsive non-covalent forces. These patches are hydrophilic (capable of hydrogen bonding), hydrophobic, and positively or negatively charged (Spitzer 2011; Wang et al. 2011; Laue 2012).

The two most important "cytological" attractive non-covalent forces are as follows:

1. Hydrogen bonding of water molecules with each other and with polar "patches" (ionic and hydrophilic) at folded biomacromolecular surfaces (Pauling et al. 1951; Eisenberg, 2003). The hydrogen-bonded network of water molecules brings about the hydrophobic effect—the "expulsion" of hydrophobic molecular surfaces from the network of hydrogen-bonded water molecules (Tanford 1980; Southall et al. 2002).
2. Screened and direct electrostatic attractions between cationic and anionic molecular "patches" of biomacromolecular surfaces (Schreiber and Fersht 1996; Halford 2009). The coulombic interactions are reflected in bimodal distributions of isoelectric points of many proteomes, with peaks in the alkaline pH region (negatively charged proteins) and in the acidic region (positively charged proteins), suggesting that electrostatically induced clustering (gelation) is common inside many cells (Kiraga et al. 2007; Spitzer and Poolman 2009). Similar electrostatic interactions account for interactions ("packaging") of the nucleoid with cationic proteins or polyamines inside a bacterial cell (Friedrich et al. 1988; Zimmerman 2006; Lee et al. 2015).

The effects of attractive forces are countered by repulsive non-covalent forces, notably by the excluded volume effect

of biomacromolecular crowding (Zhou et al. 2008; Foffi et al. 2013) and by screened electrostatic repulsions between anionic molecular surfaces. At close separations below 1 nm, these screened repulsions can be very large (Spitzer 1984; Spitzer 2003), ensuring that the crowded cytoplasm does not collapse into an agglomerated, non-functional gel.

6.6.4.3 CELLULAR CROWDED COMPLEXITY

Generic textbook pictures of bacterial cells show four physicochemical phases (each being also multicomponent):

1. The hydrophobic cell envelope of a particular geometrical shape (coccoid, rod, etc.), the key functional part being a lipid bilayer studded with a high number of many kinds of hydrophobic membrane proteins. Nevertheless, other parts of cell envelopes may also be critical for survival (Silhavy et al. 2010). For example, the L-forms of bacteria, lacking a cell wall, would not generally thrive in planetary unconstrained environments; they require specialized environments for survival (Niemark 1986; Errington 2013).
2. The phase-separated nucleoid (Valkenburg and Woldringh 1984; Woldringh and Nanninga, 2006) portrayed like a bundle of "spaghetti," representing anionic DNA helices tied up by cationic proteins and amines into denser conformations.
3. The ribosomes, large phase-separated clusters of proteins and nucleic acids, are shown as tiny spheres scattered throughout the cytosol (Alberts et al. 2002) or attached to mRNA strands (polyribosomes) that are connected to DNA through RNA polymerase (Schaechter et al. 2005)
4. The "unstructured" cytoplasm—a "bag of enzymes."

At greater spatiotemporal resolutions, nucleoid double helices and proteins and their hetero-dimers and trimers (biomacromolecular complexes and "nano-machines") can be shown "randomly crowded," representing ~25% of the volume of the cytoplasm (Zimmerman and Trach 1991; Elcock 2010; Goodsell 2010). Simple physical models of such high crowding show that cytoplasmic biomacromolecules are essentially "touching" *in vivo* (Phillips et al. 2009; Spitzer 2011; Spitzer and Poolman 2013). They thus interact via repulsive and attractive non-covalent forces over short distance of about 1 nm, significantly reducing rotational diffusion (Wang et al. 2011), thereby ensuring functional dynamics of folding and association of biomacromolecular surfaces, as they are being synthesized.

Dynamic clustering of biomacromolecules *in vivo* has also been described from a top-down biochemical perspective as "quinary" structure (McConkey 1982; Monteith et al. 2015), as "metabolons," where reactants and products are shuttled between the catalytic sites within biomacromolecular clusters, without bulk diffusion in the cytoplasmic sol (Srere 1985; Ovadi and Srere 1991; Mathews 1993). Another view of the cytoplasm is that it is composed of functional modular

“hyperstructures” (Hartwell et al. 1999; Norris et al. 2007) or various “omes” of system biology. For example, the FtsZ divisome (Rowlett and Margolin 2015) is synthesized and assembled before cell division takes place in *Escherichia coli*. The bacterial cytoplasm has been also described as a “sieve-like meshwork” of bacterial cytoskeleton and of other proteins (Mika et al. 2010), and as a glassy material liquefied by metabolism (Parry et al. 2014).

The bacterial crowding *in vivo* can significantly increase, up to ~50% volume fraction, in hyperosmotic media, when the cell loses water. The protein sensors and transporters within the cell envelope then become activated and import osmolytes (e.g., potassium ions and glycine betaine) that reduce the osmotic outflow of water and thus render plasmolysis less severe (Poolman et al. 2004; van den Bogaart et al. 2007; Wood 2011). Astonishingly, *E. coli* cells can re-adjust and resume growing, under such extreme “super-crowded” conditions, provided that the increase of crowding is performed in a stepwise sequential manner (Konopka et al. 2009). The stepwise process allows biomacromolecules enough time to re-structure their spatio-temporal architecture—to adapt to higher crowding conditions (Cayley et al. 1991). However, not all cells survive such severe mechanical stresses of viscoelastic “shrinking” brought about by a hyperosmotic shock.

Thus, under “normal” osmotic (environmental) conditions, non-covalent molecular forces organize a robust, amazingly well-orchestrated “ballet” of cytoplasmic molecular motions, which, remarkably, avoids any catastrophic (fatal) agglomerations of biomacromolecules. Nevertheless, when environmental conditions change over large ranges of variables, for example, of temperatures, the “orchestrated ballet” can partly (or altogether) collapse into irreversible folding (misfolding) and aggregations of proteins and nucleic acids (Ellis and Minton 2006; Boquist and Gröbner 2007; Pastore and Temussi 2011).

6.6.4.4 ELECTROLYTIC NATURE OF CELLULAR REGULATION

The earlier description of the physicochemical complexity of a bacterial cell—ionic and multicomponent, multiphase, and crowded and super-crowded—is made much more complicated by the fact that, during the cell cycle, there are about 1000–2000 concurrent and sequential biochemical reactions within the cell and between the cell and the environment. These biochemical reactions are well-synchronized and regulated to yield many physiological processes, such as the import of nutrients into the cell by the cell envelope and the replication and segregation of the nucleoid during the cell cycle, as well as many physiological responses to environmental stresses (Storz and Hengge 2011).

In order for such a complex cellular system to work reasonably reproducibly during the cell cycle (as it does), biochemical reactions have to be localized within the cell and within the cell envelope. Thus, biomacromolecules are localized as two-dimensional (2-D) “rafts” within the plasma membrane and cell envelope (López and Kolter 2010) and in “super-crowded” 3-D gels within the cytoplasm, as

hypothesized by the sol-gel model (Spitzer 2011; Spitzer and Poolman 2013). In the sol-gel model, the “super-crowded” biomacromolecular clusters (agglomerated micro-gels) are associated with (i) the cytoplasmic side of the cell envelope (which inter alia increases its mechanical stability), and (ii) the nucleoid in the middle, which extends all the way into the cell envelope. Similar model was used previously to explain very fast diffusion in mitochondria (Partikian et al. 1998). The functioning of this complex chemical system rests in the regulating nature of non-covalent molecular forces, brought into action by biochemical signaling reactions. Gel formation (biomacromolecular super-crowding) and the reverse processes of gel liquefaction are controlled by an increase or decrease of hydrophobic and screened electrostatic interactions. For example, methylations and de-phosphorylations increase non-covalent attractions (leading to gel formation), and the reverse reactions increase repulsions (leading to gel liquefaction).

In the super-crowded gelled regions, biomacromolecules are separated by narrow channels filled with percolating multi-ionic electrolyte solution that hydrates (stabilizes) biomacromolecular surfaces and thus maintains their biochemical functions. Such channels are theorized to have semi-conducting electrolytic properties, based on solutions of a system of differential Poisson-Boltzmann equations (Spitzer 1984; Spitzer 2003; Spitzer and Poolman 2005). The channels sort out and direct both inorganic ions and biochemical ions into different parts of the crowded cell according to their overall charge, for example, ATP^{-3} , ADP^{-2} , AMP^{-1} , $[\text{H}_2\text{PO}_4]^{-1}$, and $[\text{HPO}_4]^{-2}$. These channels can be considered as transient “microfluidic electrolytic integrated circuits,” ultimately “programmed” by the nucleoid (genome) but contingently re-adjusting in response to environmental signals during the cell cycle—an aspect of cellular homeostasis, cf. jigsaw puzzle #7 ([Figure 6.6.2b](#)). There are many other signaling reactions, such as adenylations and acetylations, which, in addition to simple charge effects, modify the channel morphologies on the crucial 1-nm scale.

Biochemistry and phylogenetics suggest that the genetic code became “immutable” in the last universal common ancestors (LUCAs’ populations. Because confinement is mandatory for a life to emerge, we assume that LUCAs also had semi-permeable “surfactant” bilayer, or layers, functionally similar to that of today’s prokaryotes, that is, able to stabilize hydrophobic membrane proteins and the excrescences of the nucleoid and prevent uncontrolled diffusional access of environmental ions into the cytoplasm. The chief characteristic of cellular phospholipids, both bacterial and archaeal (Albers and Meyer 2011), is their two-chain hydrophobic tail that is known to favor flexible “flat” nano-phases of bilayers suitable to form micron-sized vesicles, whereas single-chain surfactants give rise to spherical micelles and, at high concentrations, to cylindrical nano-phases. It is noteworthy that polar tri-cyclic hydrocarbon fused rings and similar carbon compounds derived from polycyclic hydrocarbons could have been involved in the initial hydrophobic evolution of proto-cellular envelopes and hydrophobic membrane proteins, cf. [Section 6.6.5](#).

In conclusion, today's bacteria exhibit an unprecedented physicochemical sophistication, which has enabled them to evolve in very different environments and exploit very different environmental energies. Remarkably, this sophistication is based on only a few “building blocks” of life: five nucleobases, phosphate esters based on two versions of ribose, 20 amino acids, and some phospholipids with two-tail hydrophobic chains. The ancient proto-prokaryotic cells exhibited such physicochemical sophistication already ~3.5 billion years ago, point [C] in [Figures 6.6.1](#) and [6.6.2](#), when they began to emerge via crowded, confined, and self-purifying (cyclic) chemical processes represented by point [B] in [Figures 6.6.1](#) and [6.6.2](#). These complex chemical processes eventually “*crystallized and annealed*”; Woese's *metaphorical* phrase of crystallization and annealing (Woese 1998) thus turns out to echo actual but complex physicochemical processes, which involved submicron “self-purification” (repeated *crystallizations*) within permeable microspaces under cyclic mechanical stress relaxations (*annealing*). The physicochemical nature of “becoming alive” thus becomes somewhat clearer.

6.6.5 EXPERIMENTAL PARADIGMS OF CYCLIC EVOLUTIONARY PROCESSES

The physicochemical jigsaw puzzle suggests an experimental paradigm, based on cyclic external energies that drive cyclic chemical processes within evolving compartments. Historical questions, such as whether the emergence of life was a rather sudden phenomenon, or whether it required long gradual processes or specialized geochemical locations, cannot be rigorously answered. It is thus unlikely that the chemical “bottom-up” part of the puzzle of life's emergence ([Figure 6.6.2a](#)) can be quantified and experimentally investigated to yield definitive conclusions; yet, some experiments are worth doing, to better understand the evolutionary potential of *non-living* cyclic chemical processes.

6.6.5.1 BOTTOM-UP CYCLIC CHEMISTRY

An underappreciated aspect of Stanley Miller approach (Miller 1953) is its open-ended character—a “see-what-happens” approach—to find out if any building blocks of life can be detected from electrical discharges in prebiotic atmospheres. The results were positive, showing the presence of amino acids, and they led to many variations of such experiments, including the re-analyses of old samples with new analytical methods (Bada and Lazcano 2003; Johnson et al. 2008). However, the *unconstrained* nature of Stanley Miller experiments has been subsequently relaxed in search for synthetic pathways toward all “building blocks” (amino acids, nucleobases, sugars, phosphate esters, etc.), transforming plausible natural processes of volcanic electrical discharges to less plausible multi-step strategies of synthetic organic chemistry (Shapiro 1986, 2007; Orgel 2004; Eschenmoser 2007; McCollom 2013; Patel et al. 2015).

6.6.5.1.1 Chemical Engineering Simulators of “Model Earths”

The original rationale of Stanley Miller experimentation can be re-established in designed chemical engineering simulators of “prebiotic Earths” (Deamer 2011), operating under cycling planetary conditions (Spitzer 2013b). By varying the initial compositional conditions, different process outcomes will materialize after a given period of operation, for example, after a week, a month, or a year, while implementing a specific observational and sampling protocols to characterize the overall process. This “take-the-bull-by-the-horns” approach could thus uncover the rates of chemical complexification of prebiotic habitable planets vs. initial compositions, that is, the prebiotic chemical evolution between [A] and [B] in [Figure 6.6.1](#), where low initial chemical complexity is assumed (a higher chemical complexity of initial compositions, e.g., with polycyclic hydrocarbons, is also a plausible alternative). The results would illuminate the evolutionary potential of reactive dynamic pattern formation in *non-living*, phase-separating chemical systems, driven by cyclic external energies. As an aside, since 1953, chemical engineering processes underwent unprecedented computerization of hardware, such as load cells, pumps, and new sensors, which makes the design of chemical processes on “model Earths” much more feasible, though not simple.

6.6.5.1.2 Bottom-Up “Proof-of-Concept” Experiments

Before building an all-encompassing pilot plant simulator of a model prebiotic Earth (or any habitable planet), some preliminary “proof-of-concept” data could be obtained with simple experiments. The following questions and ideas may be useful in considering such preliminary experiments.

1. Did prebiotic Earth have only simple low-molecular-weight molecules at any point in its formation during the emergence of our solar planetary system? What would be the effects of adding polycyclic hydrocarbons?
2. How will planetary sciences select model initial compositions of the atmosphere, hydrosphere, and lithosphere and the specifics of cycling electromagnetic irradiation and seawater tides?
3. What surface-active compounds are likely to arise from the selected initial compositions? How will they create “micro-spaces,” or sedimentary matrices?
4. What will be the role of poly-phosphates in stabilizing and dispersing inorganic and organic precipitates (in tidal sediments) in the nano- to micro-ranges of sizes? How will they evolve under cycling environmental conditions?
5. Did biochemical chirality (Ault 2004; Weissbuch and Lahav 2011) and the cytoplasmic excess of potassium (Mulkidjianian et al. 2012) become coupled in the cyclic chemical evolution of geochemical tidal sediments under crowding molecular conditions?

Based on these questions, at least two simple, “proof-of-concept” experiments can be designed, even though they are not directly related to the issues of life’s origins (Spitzer 2013b).

The first one can address the question of the origin of homo-chirality and potassium ions in confined *non-living* cyclic chemical states. Because K⁺ salts are generally less soluble than Na⁺ salts and may crystallize first in chirally distinct crystals, as observed by Pasteur (Flack 2009), their cyclic dissolutions and crystallizations could enrich any micro-spaces with K⁺ and create an enantiomeric excess of chiral organic anions at the same time. Thus, a mixture of potassium and sodium salts of racemic organic ions (e.g., glutamate) can be subjected to cyclic crystallizations and dissolutions in the presence of “micro-spaces,” for example, pumice or artificial “sedimentary phases,” while monitoring the concentration of K⁺ and Na⁺ ions and of the organic ions in both the “micro-space” phase and the supernatant solution. Could the surfaces of micro-spaces act as templates to enable or stimulate the creation of enantiomeric excess (Weissbuch and Lahav 2011)?

Second, the “goo” of tarry compounds from Stanley Miller experimentation could be cyclically fractionated and the fractions analyzed and evaluated for surface and interfacial activity and thus for the ability to form hydrophobic permeable micro-spaces or vesicles. These compounds may not represent classical surfactant structures of one or two long hydrophobic tails with polar heads but could be derived from polycyclic aromatic hydrocarbons, with some methyl and polar groups attached to fused carbon rings (Bernstein et al. 1999, 2002; Sandford et al. 2013). Such polycyclic molecular structures are similar to derivatives of rosin acids, some of which are efficient surfactants for emulsion polymerization (Blackley 1975). Paradoxically, rosin acids, such as abietic acid, are of biotic (plant) origin, though this is irrelevant from a functional cellular standpoint (discounting the possibility that polycyclic hydrocarbons could be bio-signatures of “cosmic plant life”). Thus, ancient proto-cell envelopes may not have had the traditional bilayer of today’s cells but may have had a less “precise” multilayer morphology of hydrophobic nano-phases derived from polar polycyclic hydrocarbons.

6.6.5.2 TOP-DOWN CYCLIC MICROBIOLOGY

The top-down “microbiological” paradigm (Figure 6.6.2b) assumes that ancient Archaean organisms had cellular biochemistry and molecular biology similar to today’s prokaryotes, including the physicochemical complexity of confining cell envelopes. This paradigm is likely to yield more compelling results, compared with the “bottom-up” chemical approaches that have much deeper historical roots, which can be approached only indirectly, cf. the points [A]-[B]-[C, D] in Figure 6.6.1.

The top-down microbiological paradigm is based on Crick’s suggestion to assemble living bacteria from their natural (separated) components (Crick 1966). Specifically, it is based on the question of whether bacterial *biotic soups* can be brought into a living state through temperature and hydration/dehydration cycles. Thus, the goal is to make sure that the

spatiotemporal architecture of a living physicochemical state is broken down and then recovered through cyclic evolutionary processes (Harold 2005; Davey 2011; Spitzer 2014). The first stage of this experimentation is the creation “dead biotic soups” (which, incidentally, could also illuminate the important medical issues of killing pathogenic bacteria).

6.6.5.2.1 Making “Biotic Soup”

Any bacterial population can be lysed, yielding a lysate for further characterization and experimentation. Importantly, the lysate has all the biomolecules in the right proportions, from which a “living state” ought to arise. The following questions could help with experimental designs:

1. *Growth conditions before killing.* Which dead bacterial populations are the likeliest to be “stoked” by temperature and hydration/dehydration cycles back into living states? Which nutritional medium to select or design?
2. *Methods of killing.* Which physical means of killing to choose? Starvation, a mild hypo-osmotic shock, various degrees of sonication, different rates of freezing at different water activities? Different rates of heating and boiling? And the combinations of such killing processes?
3. *Timing of killing.* At which point in the growth curve to “kill?” Mid-point exponential, early on in the population growth, with sufficient “food” leftover, or in the stationary stage, or some particular state of nutritional or environmental stress?
4. *How to characterize the biotic soup?* There will be ribosomes, plasmids, and nucleoids, all partly broken, with partly attached “broken” cell envelopes (Tremblay et al. 1969; Firschein 1989; Zimmerman and Murphy 2001); their kinds and concentrations will depend on particular selection 1., 2. and 3. above.
5. *Is the biotic soup really dead?* Important but not an easy experimental question (Davey 2011). When the cytoplasmic spatiotemporal architecture is only “partially” broken down, semi-living states of bacteria such as “being injured, sick, comatose” may arise and be amenable to recovery.

6.6.5.2.2 “Putting Humpty-Dumpty Together Again”

According to the notion that Earth’s diurnal cycles and tidal hydration/dehydration cycles were the “designers” of living systems, such cycles may also perform “repeat” experiments with biotic soups in continuous evolutionary attempts to reconstruct a living system—“Putting Humpty-Dumpty together again” (Giersch and Gershenson 2009). Both temperature and hydration-dehydration cycles *shape* supra-macromolecular colloidal structures needed for “life” through non-covalent attractive and repulsive interactions inherent in biomacromolecular crowding and *drive* some biochemical reactions more than others. Perhaps, the externally energized biotic soup “lives” when the temperature goes up and becomes dormant or dead when the temperature goes down, thus simulating the confined progenetic stages #4 and #5 of the jigsaw puzzle (Figure 6.6.2b).

Some questions to consider, regarding the dynamic cyclic reconstruction of living states, are as follows:

1. Could chemostat equipment and processes and PCR protocols be modified and adapted for recovering living states of bacterial soups? How could the “feeding” regimes of nutrients be synchronized with cooling/heating cycles?
2. Could experimental equipment in studying biofilms at high “crowding” be adapted for recovering living states?
3. What would be the starting volume fraction of all biomolecules and biomacromolecules?
4. What effects could be observed by increasing the ATP/ADP ratio?
5. How to determine biochemical conversions (the “growth of the biotic soup”) and “define” operationally different kinds of living states? What would be the criteria to distinguish between the living and the dead; the comatose; the sick or injured; the dormant; the viable but non-culturable?

Any emergent living state may not readily materialize in the classical prokaryotic physical forms (coccoid, rod, etc.), because the formation of a *closed cell envelope with a lipid bilayer membrane* is expected to be the most challenging phenomenon to bring about and manipulate by cycling physicochemical gradients. The cycling experiments may have to be done in the “super-crowded” regime (Spitzer 2011; Spitzer and Poolman 2013), when “super-cells,” with imperfect internal compartments and multiple proto-nucleoids, in effect “proto-biofilms,” will initially start assembling and disassembling. Such unstable pre-Darwinian “barely living states” may evolve into LUCAs, that is, with fixed genetic code but not well-established heredity mediated by horizontal gene transfer (HGT) and maintained by cyclic energies.

Additional biotic soup experimentation can include the following: (i) Using the cycling biotic soup as a supporting medium for the replication of phages and of other viruses (*inter alia* demonstrating the “semi-living” status of a growing and cycling biotic soup). (ii) The mixing of different bacterial species in the initial biotic soup to genetically increase the chances and speed of emergence of living states and also to create “new” LUCAs, viruses, and bacterial species by “recombination” of existing genomes or their fragments. (iii) The development of characterization methods, for example, centrifugal fractionation (Schuster and Laue 1994; Harding and Rowe 2010; Rowe 2011).

6.6.6 BACTERIAL CELLS AS EVOLVING CHEMICAL MICRO-REACTORS

As the jigsaw puzzle suggests, prebiotic chemical evolution and organismal Darwinian evolution are continuous through *cellular evolution*; thus, molecular and supra-macromolecular aspects of cellular evolution are critical for understanding life’s nature and its origins (Woese 1998; Koonin 2014).

Since both biological cells and chemical reactors are open thermodynamic systems, their operation and regulation can be usefully contrasted. Admittedly, a bacterial cell differs from an industrial reactor by obvious realities: (i) the walls of a reactor are fixed and are not part of chemical production as compared with the cell envelope; however, they are “permeable,” as raw materials go in and the product gets out, and (ii) the solid-state computer with an appropriate software program that regulates and controls the reactor resides outside and is not part of the production either, as compared with the “viscoelastic nucleoid program” that is inside the cell and gets re-manufactured. In both cases, there are many sensors and regulators that monitor and control the process inside and outside. However, trying to understand bacterial cells as chemical reactors, or as computers (Bray 2009; Danchin 2010), can be taken only so far. Nevertheless, such analogies do illuminate the workings of a cell as a self-programmed chemical engineering process, which, as any such process, is prone to *stochastic and contingent errors*, malfunction, and even catastrophic upsets.

6.6.6.1 THE PROCESS ERRORS OF THE CELL CYCLE

The process errors of the bacterial cell cycle, when they occur during the replication and segregation of the nucleoid, account for Darwinian evolution; without errors, Darwinian evolution cannot operate. The errors arise during the template synthesis of complementary strands of DNA (molecular errors, such as point mutations); but they can also arise through *supra-macromolecular* mechanisms, when living cells fuse with environmental nucleic acids or with each other; such “colloidal errors” account for HGT. Regardless of the causes of the errors, they can be lethal and non-lethal and anything in between (Davey 2011). The lethal errors release biomolecules into the environment for potential re-use by other living cells (heterotrophy), and the non-lethal errors create Darwinian genetic variations on which natural selection can act (Barrick and Lenski 2013).

When the process errors in the cell cycle are *negligibly small*, one cellular micro-reactor will give rise to two copies with vanishingly small differences—only *ideal biological* cells are then produced, and Darwinian evolution cannot be observed. (In chemical engineering language, the production is within the product’s specifications). Larger process errors (but non-fatal) make the difference between the two copies quite apparent—the bacterial cell will have evolved in the original Darwinian sense, yielding one or both new cells noticeably different but similar to the original cell. This means that the cellular DNA has changed, producing different phenotypic strains. (In chemical engineering language, the product is out of specification—it is a “different” product.) Very large errors bring about failures—the death of bacterial cells. Such errors come from large and sudden changes in the environment, when the process-control computer’s capability becomes compromised—or in Darwinian language, the genome’s computer-like performance has not yet reached the required evolutionary stage to ensure its own survival. (In chemical engineering language, the manufacturing process software has failed, as it was not designed to cope with such unexpected inputs.)

6.6.6.2 Is CELLULAR EVOLUTION “SALTATIONAL”?

It is not inconceivable that large, normally fatal cellular errors may, though extraordinarily rarely, bring about very different but still functioning (perhaps poorly) cellular micro-reactors that can dynamically re-stabilize under cyclic environmental conditions and evolve into new kinds of cells, *for example*, by fusions of simple cells, incorporating internal lipid surfaces and multiple nucleoids. Eukaryotic cells did likely arise this way (Sagan 1967; Martin et al. 2015). We can thus distinguish three kinds of cellular Darwinian evolution, plus an ideal prokaryotic cell cycle that can serve as a reference process, which does not evolve.

1. *Non-evolving ideal cell cycle* is characterized by: a) its operation and regulation (growth and division) are without errors, and b) the ideal cells are “infinitely” apart from each other, ensuring that they reproduce in a constant nutrient environment, with no interactions between the cells.
2. *Molecular micro-evolution* arises from errors in the template replication of DNA within any one cell cycle, when no nucleic acids pass through the cell envelope. This molecular mechanism corresponds approximately to the “gradualism” of Darwin’s original conception, though even single-point mutations can have noticeable phenotypic effects.
3. *Molecular meso-evolution* arises from dehydrating-hydrating fusions between living cells and “dead” environmental DNA and RNA, including viruses, which evolved into natural bacterial transformation, transduction, and “sexual” mating. These supramacromolecular mechanisms account for large changes in the genome, such as lateral or horizontal gene transfer (HGT).
4. *Molecular macro-evolution* arises from direct cell-to-cell fusions *in vivo*, for example, in biofilms, when at least one cell is alive and survives the fusion process. Such fusions give rise to complex proto-eukaryotic cells, involving multiple DNA nucleoids, different kinds of protein-RNA complexes (“ribosomes” and other cellular machinery), and new membranes.

The latter two kinds of cellular Darwinian evolutions are not related to errors in DNA template synthesis; they involve large-scale breaking, re-sealing, and re-organizations of cell envelopes, with concurrent melting, hybridization, and recombination of nucleic acids, driven by cycling temperature, water activity, and other gradients. Such large “errors” can be caused by physicochemical stresses (e.g., temperature and water activity) that microbial populations are exposed to in cycling and fluctuating environments. When such fusions survive and re-stabilize, they could be viewed as “saltational,” as they come about by quite different mechanisms that generate new cellular structures, compared with molecular errors in the template syntheses of nucleic acids. Indeed, similar environmental fusions (breaking and sealing of cell envelopes in large biofilm formations) probably gave rise

to first simple multicellular organisms and thus accounted for some of the major transitions in evolution (Smith and Szathmáry 1999).

The above-mentioned terms, such as “macro-evolution,” are similar to those used in classical (non-molecular) evolutionary theories (Sapp 2003); however, in this review, they have specific physicochemical meanings, related to a recently coined term “natural genetic engineering” (Shapiro 2011). The jigsaw puzzle thus reflects processes that are analogous to the methods of genetic engineering and the protocols of PCRs.

6.6.7 CONCLUSIONS AND PERSPECTIVES

A number of publications have recently promulgated a degree of disquiet about the refractory nature of origins research; they have begun to question its assumptions and its goals. A few examples illustrate these concerns:

1. “*The natural path from simple cosmic molecules to cells, from chemistry to biology, remains undiscovered.*” (Harold 2014).
2. ...no convincing models explain how living cells formed from abiotic constituents... (Stüeken et al. 2013).
3. “*Most chemists believe, as do I, that life emerged spontaneously from mixtures of molecules in the prebiotic Earth. How? I have no idea.*” “*The cell is a bag with a Jell-O of reacting chemicals...a network of reactions, organized in space and time in ways we do not grasp*” (Whitesides 2007).
4. “...questions concerning the biogenesis...have never been asked or addressed in a proper way” (Luisi 2014).
5. ...we are not yet even at the beginning of the end of our quest... (Sutherland 2017).

As the above opinions imply, origins research is undergoing a wide-ranging re-appraisal, indicating that some of the traditional assumptions may need a significant revision, even a revolution. The main advance in the origin-of-life research has been the rejection of an idea that complex molecules such as a protein or an RNA got synthesized by chance on prebiotic Earth (a near miracle). It is now recognized that some *evolutionary sequences* of events or milestones with plausible continuity between them ended up in life’s emergence (Deamer and Fleischaker 1994; Lahav 1999; Fry 2000; Spitzer and Poolman 2009; Hud et al. 2013; Sutherland 2017; Spitzer 2017).

The physicochemical jigsaw puzzle represents evolutionary processes inherently continuous through daily “blind experiments” performed by cycling diurnal and tidal energies. The jigsaw puzzle identifies physicochemical requirements that have to be met for a life to emerge, in particular the unconditional requirements for compartmentalization and a large degree of macromolecular crowding (point [B] in Figure 6.6.1). The (numbered) jigsaw puzzle pieces, however,

are only tentative evolutionary milestones to be worked out in greater detail. The very first early proto-life after the point [B] was chemically complex (diverse), with lower fidelity of DNA replication, while evolving toward today's "simplified" biochemistry of a few building blocks common to all life, the point [C]. The very first early life after the point [B] had a high "genetic temperature" (Woese 1998), or fast proto-species evolution and extinctions, when replication, transcription, and translation machineries evolved and stabilized (crystallized and annealed), together with the cell envelope, creating a homeostatic capability. However, the total chemical complexity on Earth started to increase very fast, represented by the sum of the cycling organismal matter *in vivo*, point [C], and dead organismal and inorganic matter, point [D], in [Figure 6.6.1](#). This evolutionary chemical paradigm is different from the *constructive* (complexification only) paradigm, cf. [Figure 6.6.1](#); the latter is an engineering paradigm, based on designs of orderly progression from simple molecules, which react to yield building blocks of today's biomacromolecules, which then polymerize and self-assemble into proto-cells that evolve into cellular life (e.g., Jortner 2006).

The bottom-up chemical part of the jigsaw puzzle, in the evolutionary path from [A] to [B] in [Figure 6.6.1](#), can be studied via chemical simulators of prebiotic Earths and with some simple non-living cyclic systems to illustrate the evolutionary potential of chemical processes driven by cyclic energies. The microbiological top-down part of the jigsaw puzzle from [B] to [C, D] can be studied under the assumption that Archaean first organisms and today's bacteria were substantially similar. The jigsaw puzzle has thus been expanded to better describe the evolution of "becoming alive" all the way to "being alive and having progeny" in [Figure 6.6.2b](#). These cellular phenomena can be investigated through microbiological experimentation with "biotic soups," using cyclic processes analogous to PCR and genetic engineering protocols, for example, cyclically fusing "environmental" DNA through the membrane into a prokaryotic cell, and similar fusion experiments with living cells.

As a caveat, it may turn out that the assumption of physicochemical, metabolic, and genetic similarity between today's bacteria and the first archaean organisms may not be a good one. The ancient organisms originated with the help of cyclic planetary energies, which, in effect, acted as a "scaffold" for a life to emerge, cf. the history of "chemical scaffolds" in the origin-of-life research (Fry 2000). Undoubtedly, cyclic environmental temperatures and changes in ionic strength aided the natural evolution of replication, hybridization, and recombinations of nucleic acids, as well as the natural "genetic engineering" of fusions of cells with each other and with environmental nucleic acids. When the nucleoid and the cell envelope jointly stabilized to create a *homeostatic* cell, the "scaffold" of cyclic environmental energies was partly replaced with nutrients' chemical free energies, ensuring life's persistence, with evolving metabolic and genetic cycles that could exploit many different "food" sources (geochemical sites). Which, if any, bacterial species can be taken as a 3.5-billion-year-old

living fossil, still significantly dependent on the "scaffold" of cyclic environmental gradients?

Lastly, the fundamental physics question raised by Schrödinger in 1944 can still be contemplated: "Does the statistical nature of the 2nd law and of quantum mechanics play any (major) role in the occurrence of cell cycle errors?" If so, such true random errors need be distinguished from other sources of replication errors, such as errors arising from cycling and variable environments. Experimentation with an ideal bacterial cell cycle could throw some light on this fundamental question.

Regardless of these historical concerns, the questions of life's emergence can be tackled experimentally in an evolutionary paradigm of continuous *cyclic chemical processes*, particularly in the "microbiological" part of the puzzle. Such processes have an inherent evolutionary nature, but their chemical nano-phase complexity and dependence on the "arrow of time" make their investigations challenging.

DEDICATION

This article is dedicated to the late Prof. Robert Shapiro. I met him only once in 2008; his observations on the predicaments of origins research were compelling.

7.1.1 INTRODUCTION: A BRIEF OVERVIEW OF OPARIN'S COACERVATES

In Chapter 1.1 of this handbook, a brief introduction to the importance of Oparin's work for astrobiology was provided. Most significantly, in 1924, he proposed a major hypothesis about the origin of life on Earth, which is now accepted as a key foundation of astrobiology (Oparin 1924, 1938, 1966). Oparin's hypothesis stated that the origin of life on Earth can be understood in terms of the laws of chemistry and physics, and thus, it does not need any explanations that involve supernatural causes. Oparin further proposed that life arose in the Earth's distant past by chemical reactions and physical processes under the specific conditions on the early Earth and over a long period of time. The significance of Oparin's work is covered throughout this handbook. This chapter focuses on Oparin's work on coacervates, which he proposed as a model for the primordial protocells.

Since his original proposal of coacervates, Oparin made experimental progress in preparing coacervates and studying their properties (Oparin 1938, 1966). He found out that coacervates are feasible as prebiotic compartmentalized systems and can serve as sites for the primitive metabolism. In addition, coacervates can undergo a primitive self-replication by splitting into the smaller units.

The coacervate model is that of a membraneless protocell, which, however, allows for the separation of the protocell content from the aqueous environment. Coacervates are formed in water and comprise either droplets or layers, in

which the coacervate exists as a separate aqueous phase, which has a clear boundary from the rest of the aqueous medium. Such coacervates, according to Oparin, are capable of absorbing organic molecules from the aqueous environment. The absorbed molecules may react inside the coacervate to produce new chemicals. If coacervates absorb the appropriate catalysts from the environment, chemical reactions inside coacervates will be facilitated. As coacervates grow, due to the absorption of more chemicals from the environment, they become thermodynamically unstable and then split into the daughter cells. This process provides a primitive self-replication, which is driven by the well-understood physical forces, such as a thermodynamic instability of the system or its breakage upon a mechanical impact. In addition, the daughter cells acquire chemicals from the original cell, and thus, the chemical composition is preserved. Such a replicating system is not as reliable as a genetic system, which evolved later, but it represents a good prebiotic beginning. A faster growth of coacervates would result in a faster replication. Such coacervates would be selected. However, at some point, there will be a shortage of chemical food in the environment. Oparin proposed that coacervates would compete for the food. Coacervates that are able to develop chemical pathways to make their own food would be selected. Such coacervates would have a primitive metabolism. Thus, the Oparin's coacervate model involves natural selection at the chemical level and provides a feasible way for the chemical evolution to occur, in the absence of a more reliable genetic system.

7.1.2 THE OPARIN'S PROTOCELLS: DETAILS OF THE DEVELOPMENT OF HIS EXPERIMENTAL MODEL

Oparin's development of the coacervate model for protocells went through two stages. He first developed a general idea based on the science of the colloidal gels, and later, he introduced coacervates. This is described in the following two subsections, 7.1.2.1 and 7.1.2.2.

7.1.2.1 THE INITIAL IDEA: COLLOIDS AND GELS

In conceiving his protocell model, Oparin started with the knowledge that at that time was a “comparatively young science of colloid chemistry,” in his own words (Oparin 1924). Oparin started from Graham’s description of colloids from 1861 and developed it further. Graham’s colloids are substances that usually give cloudy solutions and cannot pass through the vegetable or animal membranes. The examples that Graham gave include starch, proteins, gums, and mucus. Oparin linked these properties to the protoplasm, which, he stated, is mostly made up of “very large and complicated particles and therefore must give colloidal solutions” (Oparin 1924). Oparin then addressed precipitates of colloidal substances, which form as “clots or lumps of mucus or jelly” (Oparin 1924). Coagulates of gels have some structural features that resemble protoplasm. Oparin connected feeding of the living organisms to the ability of the colloidal coagula to extract various substances from the solution and absorb them. One example includes dyes. The absorbed substances penetrate the coagula, and some of them enter into the chemical reactions with them. Thus, the process in which various chemicals are absorbed into the coagula and react inside is analogous to the first stage of metabolism, namely the feeding.

Since starch and proteins tend to make colloidal solutions in water, Oparin thought that such substances would be good candidates for the primordial colloids. He proposed that carbohydrates and proteins were available on the early Earth. As it will be shown later, in Section 7.1.4, modern advances in prebiotic chemistry challenge this assumption, especially in regard to carbohydrates. Oparin stated that these colloidal solutions are not stable and that dissolved organic substances would have come out of the solution in the form of precipitates, coagula, or gels. He stated that when such separation occurred, the resulting organic body would become an “individual.”

Oparin believed that the first piece of organic slime that was formed on the early Earth had many of the features that we now consider characteristic of life. Even if such slime could not metabolize fully, it could still nourish itself, by absorbing and assimilating substances from its environment, since such behavior is characteristic of organic gels (Oparin 1924).

Oparin introduced the concept of competition for nutrients between the bits of gel and the selection that resulted therefrom. He visualized bits of gel floating in a mixture of nutrients and absorbing them. Each bit of gel grew at the expense of the nutrients, but since the bits of gel were not identical in their chemical composition, they assimilated the material from the

environment at different rates. The bits of gel that absorbed faster also grew faster, and their surface became larger. The larger pieces of gel were more likely to break up, owing to the mechanical reasons or surface tension. Such a breakage of the gel pieces gave new pieces that inherited the original gel structure. This was the basis of self-reproduction. As the cycle of growth and break up continued, changes that were acquired by the new gels were transmitted to their offspring. Oparin believed that this cycle provided a basis for selection of the gels with an improved absorption and assimilation of the nutrients.

As the nutrients became increasingly depleted, a battle for the nutrients took place. The bits of gel had the options of using the old ways of nutrition by acquiring organic substances from the medium or by “eating” (assimilating) other bits of gel, or they could develop a way of synthesizing organic nutrients from the inorganic precursors. Such synthetic ability would give them an edge in competition and would lead toward a more developed metabolism. Eventually, the original primitive gel bit forms were not competitive anymore and were wiped out by being eaten by the more advanced gel bit forms (Oparin 1924).

7.1.2.2 THE DEVELOPMENT OF THE IDEA: THE INTRODUCTION OF COACERVATES

In his later work, Oparin became much more specific in his model of the primordial protocells, and his gel bits became replaced by coacervates (Oparin 1938, 1966).

In his 1938 book, Oparin described work by de Jong from 1931 and 1932 on the coacervation phenomenon (Oparin 1938). In the aqueous solution of hydrophilic organic colloids, besides coagulation, another process occurs, which is termed coacervation. It includes separation into two layers, a fluid sediment, rich in the colloidal substance, termed the coacervate, and another liquid layer that is in equilibrium with it, termed the equilibrium liquid. Oparin described how, in many instances, the coacervate does not settle out immediately as a continuous fluid layer but, instead, remains in the form of microscopic droplets that are floating in the equilibrium liquid. These droplets may later fuse with each other to form a layer. Oparin contrasted the coacervates, which represent a fluid mass, with the coagulates, which do not. Most importantly, although in both the coacervate and the equilibrium liquid, the solvent is water, coacervates are sharply demarcated from the surrounding medium by a clearly discernible surface. This description of coacervates is still valid (e.g., Menger and Sykes 1998). Oparin clearly recognized the potential of coacervates to serve as compartmentalized primordial protocell systems.

In his 1938 book, Oparin described preparation of coacervates, in which he followed work by de Jong. Oparin gave a detailed preparation of complex coacervates from two or more colloidal solutions, which have opposite charges. The classical preparation is by mixing dilute solutions of gelatin and gum arabic and then adjusting the pH until coacervation occurs. This occurs at a pH below the isoelectric point of gelatin (pH 4.82). At such pH, gelatin will become positive, while the gum arabic will still be negatively charged. Coacervation is induced by

such a change in pH, and droplets will separate from previously homogeneous solution. Oparin gave more examples of coacervates, such as those formed from gelatin and egg lecithin and from gelatin and protamine. Since coacervates have an inherent ability to absorb substances from the environment, such substances could react with the coacervate constituents. According to the experiments by de Jong, this would result in an increase in size and weight of the original coacervates. Oparin also described the influence of electrolytes, salts, temperature, and the pH on the formation of coacervates.

In his 1966 book, Oparin gave numerous other examples of complex coacervates that were made in his laboratory. These were prepared from complex biomolecules, and the pH was adjusted until a coacervation occurred (Oparin 1966). These will be discussed in [Section 7.1.4](#).

7.1.3 OPARIN'S EXPERIMENTS: CHEMICAL REACTIONS INSIDE COACERVATES

Oparin went further in his studies of coacervates than just preparing them and observing their physical properties. In his more advanced work, he explored chemical reactions within the coacervates (Oparin 1966). This work was particularly well-summarized by Hanczyc and Fenchel (Fenchel 2002; Hanczyc 2009).

In an important experiment, a coacervate was prepared from gelatin and gum arabic so as to contain the phosphorylase enzyme. This was accomplished by exploiting the tendency of dissolved enzymes to become trapped inside coacervates. The phosphorylase enzyme catalyzes polymerization of glucose-1-phosphate into starch. When glucose-1-phosphate was added to the external medium of coacervate, it was first adsorbed and then incorporated into the coacervate. When this happened, the starch production occurred inside the coacervate. Phosphate, which is a by-product, diffused out of the coacervate. This important experiment demonstrated that a biologically relevant reaction can occur inside the coacervate. Further, while the enzyme phosphorylase and the starch molecule that was formed were trapped inside the coacervate, glucose-1-phosphate and phosphate could pass through the coacervate boundary, thus mimicking the cell membrane (Fenchel 2002; Hanczyc 2009).

In another experiment, a coacervate was prepared so as to contain two enzymes, phosphorylase and β -amylase. Then, glucose-1-phosphate was added. As in the previously described experiment, starch formed inside the coacervate. However, since β -amylase was present, it catalyzed the reaction of starch, in which maltose was released. Maltose diffused out of the coacervate into the external medium. This experiment modeled a two-step enzymatic pathway inside the coacervate (Hanczyc 2009).

Additional experiments were performed by Oparin to illustrate the ability of coacervates to act as chemical reactors for biologically important reactions and to mimic protocells (Oparin 1966, 1971). Such experiments include polyadenine synthesis, Nicotinamide Adenine Dinucleotide (NAD) redox reactions, and ascorbic acid oxidation (Hanczyc 2009). In one such experiment, the enzyme NADH (Nicotinamide Adenine

Dinucleotide H; the reduced form of NAD⁺) dehydrogenase was trapped inside the coacervate. Then, the redox dye methyl red and NADH were added to the external medium. When these substances diffused inside the coacervate, the NADH dehydrogenase catalyzed the reduction of methyl red, coupled to the oxidation of NADH to NAD. This experiment simulated a simple electron-transfer system (Fenchel 2002).

7.1.4 TYPES OF COMPONENTS OF OPARIN'S COACERVATES AND THEIR PREBIOTIC FAVORABILITY

First, details about the types of components of Oparin's coacervates are presented in [Section 7.1.4.1](#). Then, prebiotic feasibility and favorability of these components are evaluated in [Section 7.1.4.2](#).

7.1.4.1 CHEMICAL FEATURES OF THE COMPONENTS OF OPARIN'S COACERVATES

Most often, Oparin used the gelatin-gum arabic coacervate, but he also prepared numerous other types of coacervates in his laboratory (Oparin 1966). These are listed in [Table 7.1.1](#).

In most of his experiments, Oparin followed a straightforward formula for the formation of complex coacervates, in which two biological macromolecules with a potential of

having opposite charges were mixed, and the pH was adjusted until the opposite charges were established.

Details about the types of Oparin's coacervates from [Table 7.1.1](#) are given in the following paragraphs.

Gelatin-gum arabic coacervate consists of the protein and carbohydrate parts. Gelatin is a protein mixture formed by a partial hydrolysis of collagen extracted from animal skin, bones, cartilage, and ligaments (Hanczyc 2009). Gum arabic is an extract from the Acacia trees. It consists of a complex and variable mixture of arabinogalactan oligosaccharides, polysaccharides, and glycoproteins (Hanczyc 2009). Oparin also used serum albumin as another protein. In addition, he used histones, protamine, and clupein as biological proteins. These contain basic amino acids. Other constituents of his coacervates included nucleic acids RNA and DNA and the lipid component consisting of oleic acid.

7.1.4.2 PREBIOTIC FEASIBILITY AND FAVORABILITY OF THE COMPONENTS OF OPARIN'S COACERVATES

What is in common to all Oparin's coacervates is that they are composed of complex biological macromolecules, which also have, in most instances, variable structures. Such complex structures were not feasible on the prebiotic Earth. This is the case with the oligo- and polysaccharides and other sugar-containing macromolecular structures, such as glycoproteins, RNA, and DNA. Complex carbohydrates that Oparin used cannot be considered as prebiotic materials, since there are no known simple polysaccharide syntheses under the simulated prebiotic conditions (Kolb et al. 2012; Kolb 2015, 2016). For the protein components that Oparin used, one may consider their simpler, prebiotically feasible versions. For example, instead of a protein, one could imagine a prebiotic proteinoid, which could be formed by condensation of prebiotic amino acids. Prebiotically feasible syntheses of such proteinoids have been described (Fox and Harada 1958; Fox 1964). However, capability of such proteinoids for making coacervates has not been evaluated. Oparin also used proteins containing basic amino acids. Such amino acids do not appear to be prebiotically favored, based on the report by McDonald and Storrie-Lombardi (2010). These authors concluded that lysine and arginine would not have been abundant on the prebiotic Earth, since most attempts to synthesize these amino acids under various prebiotic conditions were not successful, and they were not identified in the carbonaceous meteorites. The authors assumed that histidine, which is also classified as a basic amino acid since its imidazole side chain can act as a base, would behave mostly as neutral within proto-peptides under the plausible pHs of the prebiotic environments. Thus, the proteinoids, which would be based on the basic amino acids, do not appear to be prebiotically favored.

Most options from [Table 7.1.1](#) include complex biomolecules whose prebiotic synthesis is not feasible or is not favored, because of the presence of carbohydrates or basic amino acids, respectively. Only one case, that of protein-lipid (Simoneit et al. 2007), could be potentially prebiotic in principle; however, the prebiotic versions of these components have not been tested for their coacervate-forming ability.

Considering this analysis, questions arise if coacervates can be made of molecules that are simpler than those that were chosen by Oparin and if such molecules could conceivably be synthesized under the simulated prebiotic conditions. A single compound, dioctyl sodium sulfosuccinate (AOT), an amphiphile, has been found to fulfill these requirements (Kolb et al. 2012; Kolb 2015, 2016), but there may be many others. For example, zwitterionic geminis, which are also single organic compounds, have been shown to make coacervates readily (Peresypkin and Menger 1999). However, their prebiotic feasibility has not been studied.

The AOT case is discussed in [Section 7.1.5](#).

7.1.5 AN AOT-BASED PREBIOTICALLY FEASIBLE COACERVATE THAT CAN SERVE AS A CHEMICAL REACTOR

AOT, which is chemically dioctyl sodium sulfosuccinate, can make coacervates and was used in the study of the coacervate structure and properties (Menger and Sykes 1998). The chemical structure of AOT is shown in [Figure 7.1.1](#).

Chemical features of AOT molecule comprise the branched alkyl chains, ester of succinic acid, and a sulfonate group. All these functional groups and their combinations have been found in various organic compounds on carbonaceous meteorites (Peltzer et al. 1984; Cronin and Pizzarello 1990; Cooper et al. 1992; Cronin and Chang 1993; Cronin et al. 1995; Cooper and Chang 1995; Cooper et al. 2001; Pizzarello and Huang 2002; Sephton 2002, 2005; Fuller and Huang 2003; Task Group 2007; Schmitt-Kopplin et al. 2010). Specifically, carboxylic acids are the most abundant free compounds in Murchison meteorite (Sephton 2005). Succinic acid is common on meteorites such as Murchison (Peltzer et al. 1984) and Tagish Lake (Pizzarello and Huang 2002). Organic sulfonates have been extracted from Murchison (Cooper and Chang 1995). Branched alkyl chains, in general, are more prevalent than the straight chains (Cronin and Pizzarello 1990). Organic alcohols are also found (Task Group 2007). Esters can be readily made by the solid-state processes on asteroids, which are the parent bodies of meteorites (Kolb 2012). Thus, AOT is a potentially prebiotic molecule (Kolb et al. 2012; Kolb 2015, 2016), although it has yet to be prepared in the laboratory under the simulated prebiotic conditions.

Preparation of an AOT coacervate in a form of two layers, the coacervate and the equilibrium liquid, was performed (Kolb et al. 2012). [Figure 7.1.2](#) shows the appearance of such a coacervate.

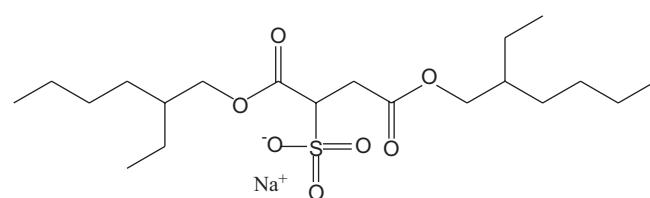

FIGURE 7.1.1 Chemical structure of AOT.

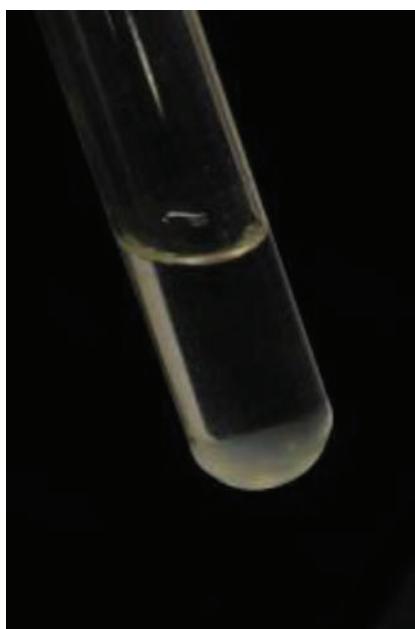

FIGURE 7.1.2 A photograph of the AOT coacervate showing the coacervate layer on the bottom and the equilibrium layer on the top.

Next, a chemical reaction was performed in the coacervate to mimic Oparin's experiments inside the coacervates. The reaction was chosen to fulfill the criteria of being prebiotically feasible, to be easy to perform, and to allow for an easy observation of the product. The Passerini reaction (Hooper and DeBoef 2009) was chosen (Kolb et al. 2012; Kolb 2015, 2016). Chemical equations for a typical Passerini reaction are shown in [Figure 7.1.3](#).

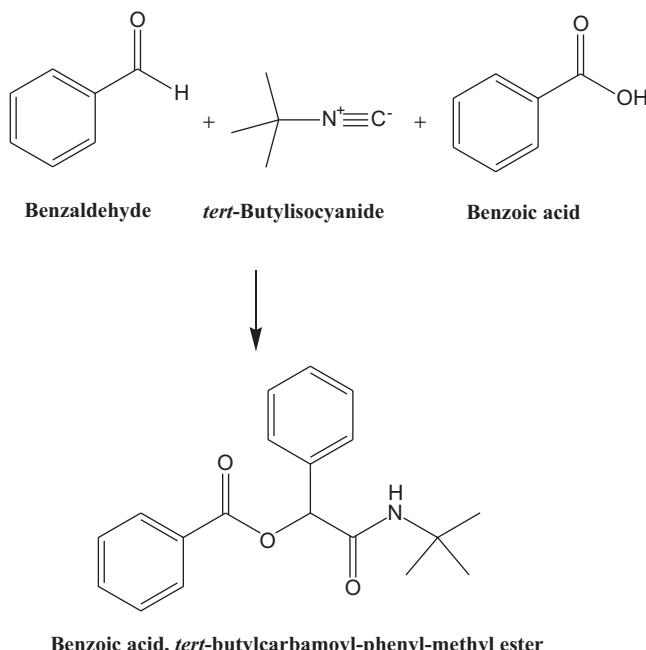

FIGURE 7.1.3 Chemical equations for the Passerini reaction.

The Passerini reaction is a multicomponent reaction in which water-insoluble starting materials react quickly and quantitatively in water to give a single product, which is also water-insoluble. The reaction is facilitated by the hydrophobic effects, in which the organic starting materials are driven toward each other to escape water. This brings them closer, which results in a fast and selective reaction. This represents one of many cases of the so-called “on-water” reactions (Lubineau et al. 1994; Pirrung and Sarma 2004; Narayan et al. 2005; Pirrung et al. 2008). Such reactions have only recently been studied for their prebiotic potential. (They are further covered in [Section V](#) of this handbook.) Starting materials for the Passerini reaction are all prebiotically feasible, based on the occurrence of such types of compounds in the meteorites. In addition, the product has a good potential to react further and contribute to the prebiotic chemical diversity. The Passerini reaction is quite fast and can be followed visually by observing the formation of a white solid product. When the mixture of the starting materials is introduced into the coacervate, a white product forms almost instantly. This is shown in [Figure 7.1.4](#).

The Passerini reaction product was removed from the coacervate and identified as the correct product by its melting point and the Infra Red (IR) spectrum. The Passerini reaction was also run and observed and the product identified in the same way as in the Oparin's gelatin-gum arabic coacervate. This showed that the reaction is not dependent on the coacervate structure, at least not for these two examples.

In the conclusion of this section, the experiments done with AOT demonstrate that a prebiotically feasible coacervate can be found and that a prebiotically feasible reaction can be run in it (Kolb et al. 2012; Kolb 2015, 2016).

FIGURE 7.1.4 A photograph of the AOT coacervate with the white solid product of the Passerini reaction in it.

7.1.6 OPARIN'S COACERVATE MODEL FOR PROTOCELLS: FROM THE ACCEPTANCE TO THE REJECTION AND BACK TO THE ACCEPTANCE

During the period in which Oparin proposed his coacervates and had done the experimental work with them, coacervates were considered a prebiotically plausible way to form protocells. This notion was supported by different types of experiments by Oparin and his co-workers and later by his followers (Oparin 1938, 1966, 1971; Evreinova et al. 1973, 1974, 1975, 1977; Gladilin et al. 1978; Oparin and Gladilin 1980). The types of such experiments were described in [Section 7.1.3](#).

The proposal of coacervates as prebiotic protocells was revisited several times, notably by Walde et al. (1994). These authors briefly addressed Oparin's coacervates and then proposed that micelles and vesicles were better suited for self-reproduction than coacervates, since the former are, ostensibly, more stable. Walde et al. doubt the prebiotic importance of Oparin's coacervates:

“Oparin's reactions with coacervates represent an important reference in the field of the chemistry of life, but somehow their importance seems to be more historical than scientific. This is due to the fact that coacervates are generally regarded as dubious structures; in fact, they are devoid of thermodynamic stability (they generally precipitate in a short time and build a water-free layer...) and as such they are difficult to synthesize in terms of structure or of physicochemical properties” (Walde et al. 1994).

This claim that lack of the “water-free” layer of coacervates is not consistent with the accepted understanding of coacervates, by which a coacervate is in fact an aqueous layer. Further, coacervates are not devoid of thermodynamic stability. Still, the grim picture of “dubious” coacervates, as presented by Walde et al., as well as these authors' emphasis on micelles, may have inhibited further research on the prebiotic role of coacervates. It also appears that prebiotic chemists might have been unaware of the vigorous research on coacervates unrelated to the prebiotic objectives. Such research resulted in voluminous literature on coacervates in the fields of study such as colloids, polymers, physical chemistry, and pharmaceuticals (e.g., Singh and Burgess 1989; Burgess 1990; Burgess et al. 1991; Burgess and Singh 1993; Rabiskova et al. 1994; Menger and Sykes 1998; Menger et al. 2000; Menger 2011; Devi et al. 2017). Modern work on coacervates repeatedly demonstrated, by a variety of characterization methods, including the instrumental techniques, that coacervates are by no means “dubious” structures but are real and measurable, as shown in a recent review (Devi et al. 2017), among other sources. Also, coacervates can be quite stable. A statement that micelles are more stable than coacervates should not be generalized. In fact, molecules depart and reenter micelles at the microsecond timescale, and a mere dilution can destroy micelles instantly.

In a fascinating reversal of the micelles' fortunes, various authors have shown that the micelles can transform into

coacervates under some conditions (Stuart et al. 1998; Wang et al. 1999, 2000; Dubin et al. 2008). For example, when simple salts are added to certain micelles above their critical micelle concentration, coacervates form in a stepwise process. At the beginning, micelles aggregate to form submicroscopic clusters, which then coalesce first into droplets and then into two separate layers, thus producing a coacervate. Therefore, to focus only on micelles (e.g., Walde et al. 1994; Luisi 1996), while disregarding coacervates, was becoming increasingly difficult to justify.

Recent work on coacervates as models for protocells has remedied this problem. Examples include work by Szostak and his co-workers (Jia et al. 2014) and Mann and his research group (Mann 2012; Li et al. 2014; Kumar et al. 2016; Martin et al. 2016; Qiao et al. 2017; Rodriguez-Arco et al. 2017). These recent works have shown that coacervates are excellent models for protocells and complex cell-like behavior. Coacervates have also been studied recently as models of membraneless organelles by Keating and her co-workers (Aumiller Jr. et al. 2016). Their work has also been quite fruitful. However, this modern work is focused on coacervates' ability to model protocells and membraneless organelles, without examining prebiotic feasibility of the coacervate components. Hopefully, the latter examination will be realized in the future.

7.1.7 SUMMARY

Oparin proposed coacervates as models for the primordial protocells. Coacervates absorb nutrients from the environment, a process that causes their growth. At some point, due to their thermodynamic instability or mechanical breakage, coacervates split into the daughter cells. This represents a primitive self-replication. Coacervates were initially selected based on the speed of their growth and self-replication. When food in the environment became scarce, coacervates that had the ability to synthesize their own food were selected. This provided a pathway to a primitive metabolism. Chemical features of the constituents of Oparin's coacervates were examined for their prebiotic feasibility and favorability. Modern developments in prebiotic chemistry do not lend much support to the latter for most constituents of Oparin's coacervates. Examples include complex carbohydrates and proteins that have basic amino acids. However, a simple amphiphile, AOT, which makes coacervates readily, is prebiotically feasible and has been proposed as a prebiotic substitute for the original components of the Oparin's coacervates. Further, the Passerini multicomponent reaction, a prebiotically feasible reaction, has been shown to occur inside the AOT coacervate, as well as in the Oparin's gelatin-gum arabic coacervate. This supports the Oparin's proposal that coacervates can act as primordial chemical reactors. Oparin's model of coacervates as protocells has gone in and out of favor over a period of time but has recently been revived by vigorous research demonstrating that coacervates are excellent models for protocells and also for the membraneless organelles. However, in these recent studies, chemical constituents of the coacervates are not prebiotically feasible.

DEDICATION

This chapter is dedicated to the memory of A. I. Oparin, whom I never met, but whose 1924 pamphlet on the origin of life influenced me to become a chemist when I was only 13 years old and an astrobiologist later in life. I felt inspired by the power of scientific explanations ever since I read his precious book, a small tattered paperback, which is now lost somewhere or perhaps was found by another interested 13-year-old.

7.2.1 INTRODUCTION

The quest to understand the origins and evolution of life has led scientists to attempt the bottom-up assembly of an enclosed synthetic entity capable of performing both metabolism and self-replication functions (Figure 7.2.1).

The common features of all forms of life include a membrane enclosing the individual cell, self-replication, metabolism, and the use of homochiral molecules. The origin of the homochiral nature of life is a vast subject in its own right, so, in the present paper, we will focus on the emergence of the

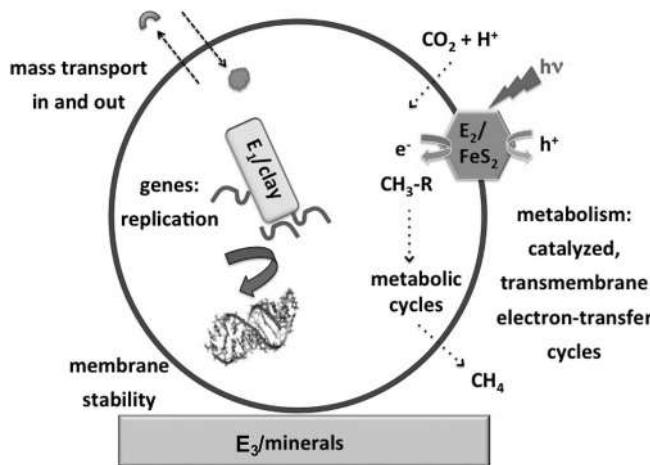

FIGURE 7.2.1 Schematic of model protocell with semi-permeable membrane and molecular machinery for replication and metabolism (Sahai et al. 2016). The protocell is shown at the mineral-water interface. Minerals (e.g., montmorillonite clay, photocatalytic iron sulfide, and TiO₂) may have played the roles of prebiotic enzymes (E₁–E₃) in several functions. The role of minerals as reactants and catalysts in the OoL has been reviewed recently (Cleaves et al. 2012). Reproduced with permission from Consortium of Scientific Societies.

membrane, self-replication, and metabolism. The operative definition of life in the origins of life (OoL) field accepts the cell as the basic unit of life and the RNA, proteins, and membrane-forming molecules as the fundamental molecular building blocks of life (Kee and Monnard 2016). Simple enclosed bilayer membranes or vesicles composed of single-chain amphiphiles (SCAs) without encapsulated reactants were originally referred to as model protocells in the literature (Segré et al. 2001). Subsequently, the term was extended to include vesicle-peptide or vesicle-RNA intermediate states. In the present paper, the term “protocells” will be used to refer to simple lipid vesicles, to intermediate states, and to more complex entities. Indeed, Kee and Monnard (2016) have stated eloquently that, “one cannot speak of a protocell type, but rather a lineage of protocell systems that slowly evolved from simple self-assembled molecular systems towards pre-cellular entities capable of self-sustenance and self-replication.”

In one school of thought in the OoL community, protocells are believed to have possessed membranes composed of SCAs rather than the phospholipids (PLs) typical of modern cells (Figure 7.2.2) (Deamer and Oró 1980; Oró et al. 1990; Monnard and Deamer 2002; Mansy et al. 2008; Albertsen et al. 2014; Dalai et al. 2016b; Fiore et al. 2017).

The prebiotic synthesis of PLs has been considered too complex (Hargreaves et al. 1977), whereas SCAs may have been present on early Earth because complex mixtures of organic compounds, including fatty acids (FAs), fatty alcohols, and polycyclic aromatic hydrocarbons (PAHs), have been discovered in carbonaceous chondrites that can form membrane like structures (Yuen and Kvenvolden 1973; Deamer and Pashley 1989) (Figure 7.2.3).

Single-chain amphiphiles have also been synthesized by Fischer-Tropsch type (FTT) reactions under simulated hydrothermal vent conditions (Nooner and Oró 1979; McCollom et al. 1999; Rushdi and Simoneit 2001; Foussoukos 2004;

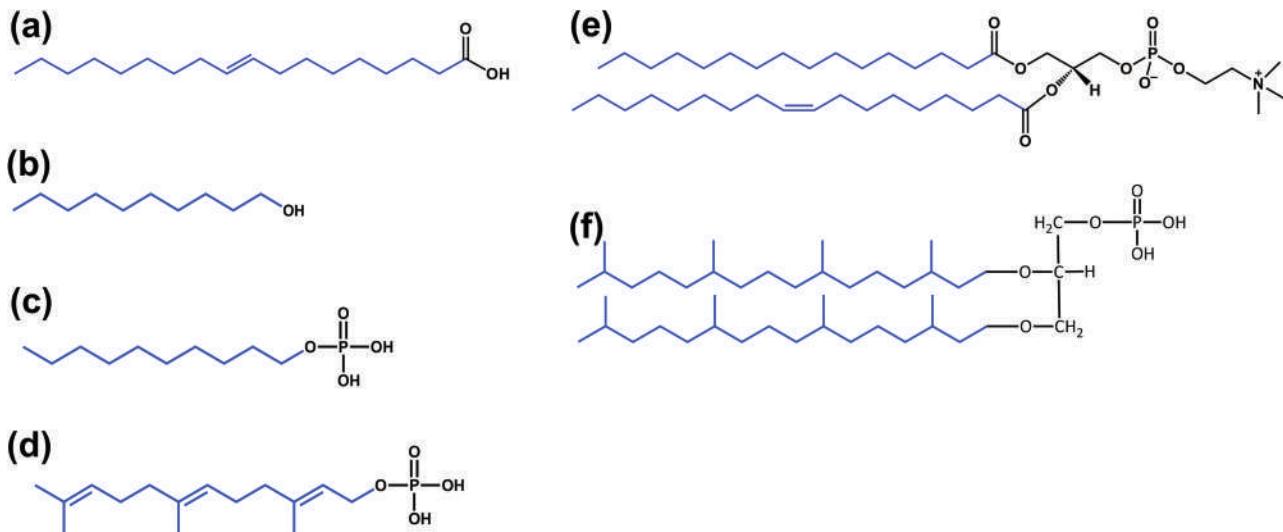

FIGURE 7.2.2 Structure of membrane-forming amphiphiles and co-surfactants. Complexity of the membrane increases with evolution for better adaptability and functionality. FIGURE 7.2.3 Cryo-transmission electron microscopy (TEM) image of synthetic FA vesicles resembling cell membranes in aqueous solution.

McCollom 2013). Although the abiotic synthesis of PLs has been considered a major challenge in the OoL community, several studies have recently reported non-enzymatic synthesis of PLs and closely related compounds (Rao et al. 1982; Maheen et al. 2010; Patel et al. 2015; Devaraj 2017). The PL membranes into which self-reproducing catalysts are embedded are capable of further PL synthesis (Hardy et al. 2015). Thus, PLs and related compounds may have been present prebiotically, at least in trace amounts. Protocell membranes composed of amphiphilic peptides have also been proposed in the literature (Fox and Harada 1960; Fox 1980).

The survival, growth, and division of a protocell would have required mass and energy transfer across the membrane, presumably leading eventually to the emergence of advanced transmembrane transport machineries, metabolism, and self-replication. One may envisage several steps in this evolution of protocells (Figure 7.2.4).

First, SCAs produced on the early Earth by abiotic synthesis and/or exogenous delivery would have self-assembled into enclosed lipid-bound compartments (Figure 7.2.3). These vesicles or earliest protocells could encapsulate solute and colloids (molecules and mineral nanoparticles) from the environment. The solutes and colloids would be distributed both in the aqueous vesicle interior and in the hydrophobic space provided by the hydrocarbon tails of the membrane bilayer, depending on the relative hydrophilicity of the molecules. Subsequently, synergistic interactions between the encapsulated entities, membrane components, and extra-vesicular environment would eventually lead to the development of selective solute transport; autocatalytic networks (proteins and protoenzymes), resulting in energy transduction (proto-metabolism); and a rudimentary machinery (RNA and ribosomes) for self-replication. These processes would have been influenced by various environmental factors such as atmospheric and aqueous composition, temperature, and pressure.

In general, a requirement of any geochemical environment for the OoL is a disequilibrium system with sustained fluxes of mass and energy at least compared to the rates of organic

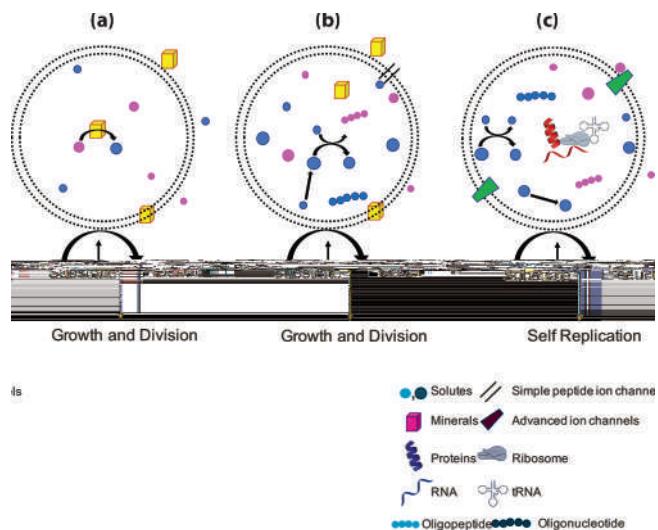

FIGURE 7.2.4 Schematic representation of model protocells of increasing complexity. (a) Simplified protocell that can only undergo metabolism; (b) protocell that can undergo metabolism and store genetic information; and (c) fully autonomous protocell with metabolism and replication.

molecule synthesis and degradation. Many prebiotic syntheses require ultraviolet (UV) radiation, ${}^{\bullet}\text{OH}$ free radicals or H_2O_2 , lightning and wetting-drying cycles associated with solar energy, geothermal heat, and tidal action, which implies a sub-aerial or shallow sub-aqueous geochemical environment on Earth's surface. The prebiotic simple precursor compounds are envisioned to have been used by the protocell to build more complex polymers, eventually resulting in metabolism and self-replication machineries. Thus, a heterotrophic metabolism is suggested, often with the implicit assumption that the emergence of RNA and lipid membranes preceded metabolism, because some RNAs (e.g., ribozymes) can serve both genetic and catalytic roles. This is known as the “RNA world hypothesis” (Gilbert 1986; Joyce 2002; Bernhardt 2012). Others have argued against the RNA world and proposed that metabolism, which may be described as self-organizing autocatalytic biochemical cycles, emerged first. This is known as the “metabolism-first” or “protein world” hypothesis and generally implies a chemoautotrophic metabolism for protocells. Some compelling geochemical environments for a chemoautotrophic OoL include low-temperature, alkaline hydrothermal vents, also known as “white smokers,” and high-temperature, acidic hydrothermal vents, also known as “black smokers” (Wächtershäuser 1988, 2000; Amend and Shock 2001). The large temperature, pH, and other chemical gradients between the hydrothermal vent fluid and ambient ocean water are proposed to provide the chemical and thermal energy for prebiotic organic molecule synthesis in the chemoautotrophic scenario. Despite tantalizing descriptions of the proposed steps involving mineral walls as the earliest “membranes” in the evolution of chemoautotrophic organisms at hydrothermal vents, few experimental studies exist, taking a bottom-up self-assembly approach to test these ideas; these

studies provide rich opportunities for future investigations. In comparison, most experimental studies on protocell synthesis in the OoL field have focused on lipid-bound membranes in the heterotrophy perspective. In this chapter, therefore, we will focus primarily on a review of studies where organic molecules are believed to have formed protocell membranes.

We will first describe the thermodynamic requirements for the self-assembly of SCAs into aggregates with various morphologies (phases), including vesicles, followed by the effects of lipid chemistry and structure as well as environmental conditions such as solution composition (pH and dissolved ions or “salts”), temperature, and pressure on the stability of SCA vesicles as model protocells. We will then summarize studies of protocell growth and division and competition between different populations of protocells in the development of predator-prey relationships in a “protoecology.” Examples of synergistic interactions between lipid membranes, solutes (inorganic ions, monomers, and short oligomers of nucleotides or amino acids), and mineral nanoparticles resulting in polymerization to longer oligomers, with the facility for folding and, hence, simple functions (*e.g.*, selective membrane transport and catalysis) will be presented. Finally, it will be proposed that increasing complexity leads to the co-emergence of ribosomes, transmembrane pumps, auto-catalytic networks (protometabolism), and self-replication. Before proceeding, we note that a large majority of experimental studies using lipid vesicles as model protocells have been conducted by proponents of the RNA-world hypothesis; far fewer experimental studies involving model protocells have examined the metabolism-first theory, utilizing, for example, catalytic peptides and transmembrane electron transfer reactions (TMETRs) to simulate protometabolism. This is reflected in the present review. As we will see below, a synergistic co-evolution of RNA, proteins, and lipids is a more likely scenario, given that a complex mixture of starting inorganic and organic compounds would have been present in any geochemical environment.

7.2.2 SELF-ASSEMBLING COMPARTMENTS

7.2.2.1 SINGLE-CHAIN AMPHIPHILES

Single-chain amphiphiles possess a polar headgroup and a single, hydrophobic FA tail. Under specific conditions of temperature and solvent, SCA molecules aggregate and self-assemble into various morphologies or phases (Chen and Walde 2010). The phases can transform into other phases when these conditions are changed. In aqueous solution, the polar headgroups are oriented toward the solution, whereas the tails prefer to associate with each other. The concentration at which SCAs aggregate is called the critical aggregate concentration (CAC) (Figure 7.2.5, Budin et al. 2012).

Below the CAC, the molecules exist as monomers. Above the CAC, if solution pH is much lower than the apparent pK_a of the headgroup, the aggregate forms a structureless clump called an oil droplet, in which the molecules are randomly arranged. At pHs $>>$ apparent pK_a , the headgroups are deprotonated and form small (~10–50 nm), spherically structured aggregates

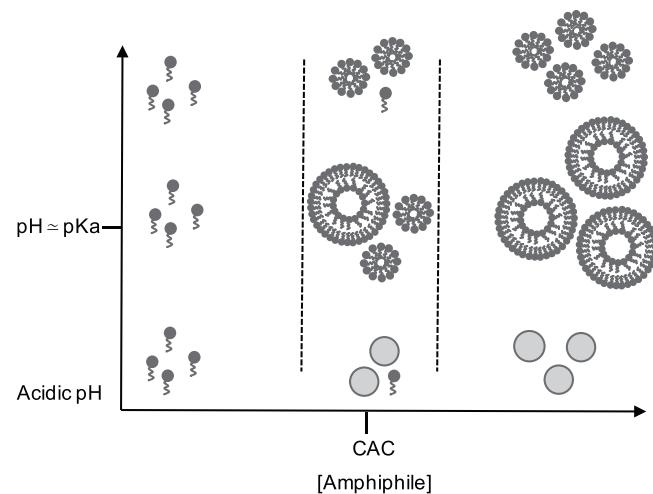

FIGURE 7.2.5 Schematic illustrating SCA phase transitions as a function of concentration and pH.

called micelles, which minimize headgroup-headgroup repulsion and maximize tail-tail interactions. A micelle has a single layer of amphiphilic molecules arranged in a sphere, with the headgroups oriented toward the aqueous solution and the hydrophobic tails in contact with each other. Around the apparent pK_a , the headgroups are partially protonated and can form large, spherical bilayer structures called vesicles. Vesicles may be unilamellar, which refers to a single bilayer, or multilamellar, which indicates that they possess multiple bilayers. The CAC is called the critical micelle concentration (CMC) or the critical vesicle concentration (CVC), depending on the phase regime of the system. The CAC is a thermodynamic property of a system.

For OoL protocell studies, vesicles are typically prepared by evaporating the chloroform solvent, which leaves behind a residue of a thin lipid film. The film is rehydrated with buffer solution to the desired concentration above the CVC, which causes the lipid to self-assemble into vesicles. The buffer pH is usually ~7–8.5 for FA self-assembly to yield vesicles. The suspension may be vortexed gently to break up lipid lumps and disperse the vesicles. Another way to prepare vesicles is to rehydrate the thin film with highly alkaline pH buffer (pH ~12), which results in the formation of micelles. This solution is then acidified to circum-neutral pH to yield vesicles. Both methods typically yield polydisperse (wide size distribution) vesicles that are predominantly in the 150- to 400-nm-size range, but a few are as large as 0.8–1.0 μm . The vesicles are also usually multilamellar. Extrusion through specific pore-size membrane produces unilamellar and more monodisperse vesicles.

If a specific solute such as a nucleotide, peptide, or fluorescent dye is to be encapsulated within the vesicles, it is added in the buffer during the dried-film rehydration step. The vesicle suspension is then passed through a separation (size exclusion) column, and fractions of vesicles that contain the solute are collected, as ascertained by Ultraviolet-Visible (UV-Vis) or fluorescent peaks for each fraction. The background solute is left behind on the column and elutes later.

7.2.2.2 STABILITY OF MODEL PROTOCELL MEMBRANES

It is assumed in the OoL literature that SCAs delivered exogenously by meteorites or endogenously synthesized at hydrothermal vents, if concentrated sufficiently to values above their CVCs, self-assembled to form vesicles in aqueous solution. Hydration-dehydration cycles simulating lagoons, salt-marshes, or tidal pools provide some geological environments where the dilution problem could be overcome by concentrating amphiphilic molecules, thus allowing protocell membrane self-assembly (Deamer and Barchfeld 1982). The stability of the protocell membrane would have depended on properties of the SCA as well as on environmental factors.

In OoL studies, stability is estimated in terms of the CVC and the integrity (or permeability) of the membrane to the solutes. While FA membranes demonstrate some behaviors such as growth and division, which are similar to modern PL membranes, FAs tend to have much higher CVCs (mM versus μM or nM). Also, SCA vesicles are much more permeable and sensitive to a wide range of environmental conditions than PL (especially phosphatidylcholine, which has a zwitterionic headgroup) membranes. It is expected that, as on modern Earth, the early Earth conditions would have spanned a wide range of dissolved ion concentrations, speciation, ionic strengths, pHs, and temperature conditions.

7.2.2.2.1 Effect of Acyl Chain on Critical Vesicle Concentration

Acyl chain length and the degree of unsaturation of the hydrocarbon chain are key factors in determining the CVC of a lipid at a given temperature. Short-chain FAs up to about C_{10} – C_{12} form bilayers at very high concentrations compared with longer-chain FAs with $\geq \text{C}_{18}$. For example, the CVC of decanoic acid (DA) is 20–40 mM compared with 20–200 μM for oleic acid (OA). For a given chain length, the CAC increases as the amount of unsaturation in the chain increases. The CVC of OA (C_{18} , 1 C=C) is 0.02–0.2 mM and that of the linolenic acid (LA, C_{18} , 3 C=C) is ~1 mM (Teo et al. 2011). Unsaturation increases the bilayer fluidity and mobility. Vesicle size also decreases significantly as the degree of unsaturation increases. The average sizes of OA and LA vesicles were ~200 nm and ~150 nm, respectively, after 5 days (Teo et al. 2011).

7.2.2.2.2 Effect of Co-surfactants on Critical Vesicle Concentration

Amphiphiles with tails longer than 10 carbon atoms have not been detected in meteorites. Although SCAs with tails up to C_{22} have been synthesized in simulated hydrothermal vent conditions, concentrating the lipid sufficiently to form vesicles may be difficult in an ocean environment. Hence, short-chain FA ($\leq \text{C}_{10}$) might be the appropriate choice for the earliest cell membranes. The presence of pure amphiphiles vesicles was probably unlikely in the natural environment, and mixed amphiphile vesicles are a more realistic approach for model protocells. The introduction of co-surfactants, such as fatty alcohols, fatty amines, and fatty glycerol monoesters, to FAs can significantly increase vesicle stability, as reflected

in a lower value of the CVC. Mixtures of FA of varying chain lengths also have lower CVC than the corresponding pure components. The CVC of pure DA is 20–40 mM, whereas the CVC is only to ~1 mM in the presence of 1-decanol (DOH) in 2:1 molar ratio of DA-DOH, thus allowing vesicles to form at a lower concentration (Maurer and Monnard 2009; Maurer et al. 2009; Sahai et al. 2017). A mixture of DA-OA in 95:5 molar ratio forms vesicles at 15 mM, which is significantly lower than that for DA alone (Budin et al. 2014).

The geological environments in which protocells would have self-assembled by wetting-drying cycles, which is required to sufficiently concentrate the lipids, would also have resulted in the intermittent concentration of ions dissolved in solution. Thus, high ionic concentrations would have been present even in sub-aerial aqueous environments. In such environments, as well as in salty oceans, the ability to form bilayers could have decreased due to the generally deleterious effects of salts, especially multivalent cations (valence >1), on lipid self-assembly. Happily, the stability of vesicles against higher ionic strength, pH, and extreme temperatures is also enhanced by co-surfactant addition, as summarized in Sections 7.2.2.2.3–7.2.2.5.

7.2.2.2.3 Salt Tolerance

Vesicles constitute a separate phase from water and stay in suspension. For charged headgroup SCAs, the vesicles remain suspended partly because of repulsion between vesicles. In the presence of dissolved ions, especially monovalent cations, charge screening allows vesicles to approach close enough, so that van der Waals interactions may take over and the vesicles may form amorphous aggregates and the lipid settles out of solution. Additionally, divalent cations may bind directly to negatively charged FA headgroups, thus causing charge neutralization and settling out of the lipids.

Modern seawater has mildly alkaline pH (~8.5) and an ionic strength of 0.5 M from the presence dissolved ions, mainly Na^+ , Cl^- , Mg^{2+} , and SO_4^{2-} . In contrast, freshwater has a neutral pH and ionic strength of only about 0.1–1 mM, mainly due to Ca^{2+} , HCO_3^- , and soluble silica. The early oceans would have been enriched in dissolved Fe^{2+} from hydrothermal vents and Mg^{2+} from weathering of komatiite, basalt, and peridotite (Schoonen et al. 2004; Schoonen and Smirnov 2016). It is estimated that the early oceans were twice more saline than the present oceans (Knauth 2005) and were probably slightly acidic (pH 6) because of the equilibrium with high atmospheric level of carbon dioxide. Surface water would also have been acidic (Schoonen et al. 2004; Schoonen and Smirnov 2016). Evaporative environments on land would have concentrated all salts to even higher levels. The extensive presence of monovalent and divalent ions has also been detected directly on Mars, and the presence of a subsurface, briny ocean on Enceladus has been inferred indirectly.

Dissolved ions are required for various biological processes such as RNA polymerization, RNA folding, Na^+/H^+ transmembrane pumping involved in ATP generation, and co-factors of various enzymes. In the OoL context, magnesium is one of the most important divalent cations, as it is required at high concentrations (~75 mM) for both prebiotic,

non-enzymatic, templated as well as prebiotic clay-catalyzed polymerization of RNA nucleotides (Ferris et al. 1996; Joshi et al. 2009; Joshi and Aldersley 2013; Adamala and Szostak 2013b). Recently, it has been demonstrated that Fe^{2+} can catalyze single-electron-transfer reactions by ribosomal RNA in anoxic atmosphere and at mildly acidic pH of 6.5 (Hsiao et al. 2013). Unfortunately, divalent ions have a deleterious effect on pure FA membranes, even at millimolar concentrations, owing to the interaction between deprotonated headgroups of FAs and the cation (Monnard et al. 2002; Chen et al. 2005). Hence, it is critical to understand the stability of protocell membranes in briny conditions.

Mixed SCA membranes are more robust than pure FA vesicles. The increased stability of mixed FA vesicles, consisting, for example, of DA-DOH or of DA-DN (decylamine), is due to hydrogen bonding provided by the co-surfactant to deprotonated carboxylate headgroup of FA (Monnard and Deamer 2002; Monnard et al. 2002). Moreover, addition of fatty alcohol co-surfactant decreases the overall negative charge on the bilayer, thus decreasing the electrostatic interaction between FA headgroup and cations. Decanol, when added to DA (DA-DOH 37:1 mM), decreases its sensitivity against monovalent cation (Na^+ and K^+) up to 400 mM; however, divalent cations (Mg^{2+} and Ca^{2+}) still cause the precipitation of such a system at ion concentrations of only 1–5 mM (Monnard et al. 2002). Similarly, the addition of DN to DA forms more salt-tolerant vesicles up to 100 mM MgCl_2 and CaCl_2 concentrations at acidic (pH 11) conditions (Namani and Deamer 2008), but the prebiotic plausibility of DN is not known. The increased stability of mixed DA-DN vesicles is because of the charge-charge repulsion between the cations and positively charged DN. Similarly, DA and glycerol monodecanoate (GMD) in 2:1 mixture was tolerant up to 100 mM Na^+ and 1 mM each of Mg^{2+} and Ca^{2+} (Monnard et al. 2002; Chen et al. 2005). Chen et al. (2005) observed that 4:1 mixtures of myristoleate (MA, C₁₄) and glycerol monomyristoleate (GMM) increased the vesicle stability against Mg^{2+} to 2–3 mM in contrast to MA alone (only 0.5 mM MgCl_2), as determined by dye leakage and turbidity assay.

Fatty acid (OA, MA-GMM [2:1] and DA-DOH-GMD [4:1:1]) vesicles could be protected from the disruptive effects of Mg^{2+} cation effects (up to 50 mM MgCl_2) in the presence of citrate (200 mM), where citrate chelated the Mg^{2+} (Adamala and Szostak 2013b). The high Mg^{2+} is necessary for non-enzymatic polymerization and replication of the encapsulated RNA. However, the prebiotic availability of such a high concentration of chelates is an open question. Indeed, the prebiotic availability of DN, MA, GMD, GMM, and OA is debatable; hence, one must view the model protocell studies as precisely that – a model. In a separate study, increased stabilization of DA vesicles was found in the presence of nucleobases and sugars in 300 mM NaCl (Black et al. 2013). It was proposed that the amine of the nucleobase or the hydroxyl groups of sugars form hydrogen bond with the carboxyl groups of the FAs, thus stabilizing the vesicles.

Dalai et al. (2017) have demonstrated that mixed FA-PL vesicles are immune to the presence of magnesium up to 40 mM MgCl_2 . Oleic acid and palmitoyl-2-oleoylphosphatidylcholine (POPC) vesicles in various ratios were subject to increasing MgCl_2 concentrations. The Mg^{2+} concentration at which nearly all vesicles were disrupted, as estimated by fluorescence spectrophotometry, dynamic light scattering, and phase-contrast microscopy, was termed the “fatal” magnesium concentration ($[\text{Mg}^{2+}]_{\text{fatal}}$). The $[\text{Mg}^{2+}]_{\text{fatal}}$ was found to increase dramatically by an order of magnitude from ~5 mM for pure OA to ~15–30 mM for mixed OA-POPC vesicles (10:1 and 5:1, respectively). A $[\text{Mg}^{2+}]_{\text{fatal}}$ was not detectable for OA-POPC (3:1, 1:1) and pure POPC vesicles up to a magnesium concentration of 50 mM. The increased resistance to Mg^{2+} was due to selective binding of Mg^{2+} to OA and abstraction of OA from the mixed OA-POPC vesicle, thus relatively enriching the resultant vesicle in POPC, which is more tolerant to cations. Thus, Mg^{2+} acted as an environmental selection pressure in the evolution of mixed FA-PL membranes toward an increasingly PL-enriched composition, which is more similar to modern cell membranes. It was shown for the first time that the previously determined deleterious effect of divalent cations may actually have helped in membranes’ evolution toward modern membranes in mixed-lipid systems, where the initially minor lipid component is more tolerant to cations.

7.2.2.4 pH Tolerance

Various extreme local pH conditions are known to be present on modern Earth. The crater lake of Kawah Ijen volcano, Indonesia, has a pH of <0.3 and is enriched in H^+ , SO_4^{2-} , and Cl^- . Similarly, the monovalent ion-rich crater lakes of the East African Rift Valley are highly alkaline (pH 11–12). Submarine hydrothermal vents or black smokers emit fluids at high temperatures of ~250°C–400°C and very acidic pH values of ~2–3. The vent solutions, when mixed with cool, alkaline ocean water, create concentration, redox, and thermal gradients that can be an important site for organic synthesis reactions. In comparison, white smokers emit fluids at milder temperatures (60°C–90°C) and alkaline pH of ~9–11. All the above-mentioned sites representing extreme pH and temperature conditions are home for modern biodiversity.

Similarly, the pH of surface waters and the ocean on early Earth was probably mildly acidic (~6–6.5), because of equilibrium with a high partial pressure of atmospheric CO_2 gas and weathering of komatiite or tonalite rocks by surface waters. Highly acidic or highly alkaline solutions may have existed around the primitive analogs of hydrothermal vents. The presence of various monovalent and divalent soluble minerals, carbonates, silica, and clays on the Martian surface also suggests a variety of pH environments, and the inferred sub-surface saline ocean of Enceladus is believed to be highly alkaline (pH ~12).

Fatty acid membranes are sensitive to the pH of a solution. As discussed earlier, at concentrations above the CAC, FAs form an oily phase at acidic pH, whereas at alkaline pH, the fully deprotonated acids form micelles (Cistola et al. 1988).

Fatty acid vesicles are formed in the pH range of 7–9 (Figure 7.2.5; Cistola et al. 1988; Apel and Deamer 2005; Morigaki and Walde 2007). In general, vesicular structures are formed when the pH of the solution is near the apparent pK_a of the surfactant, which decreases the electrostatic repulsion between adjacent protonated and ionized carboxylates by hydrogen bonding (Apel et al. 2002). Thus, a change in the solution pH can induce phase transitions. Pure fatty alcohols do not form vesicles on their own in the normal pH range.

Adding fatty alcohol to FA increases the immunity of vesicles against alkaline pH 11, where micelles would normally exist (Apel et al. 2002). Hargreaves and Deamer (1978) first observed that mixed FA-alcohol (C_8 – C_{18}) vesicles were stable under a wider range of pH than either pure lipid. This is because alcohol functional groups replace neutral carboxylic acid groups as proton donors to the deprotonated carboxylate of FA and alcohols do not deprotonate under alkaline conditions, thus providing stabilized hydrogen bonds at significantly higher pH conditions (Gebicki and Hicks 1976; Hargreaves and Deamer 1978; Apel et al. 2002; Monnard and Deamer 2002).

A major limitation of FA amphiphiles is that their self-assembly occurs in a narrow range of pH conditions around 7–9. Compared with the carboxylic acid group, a phosphoryl headgroup should have stability over a wider pH range, because phosphate is a multiprotic acid. Recently, phosphate amphiphiles (Figure 7.2.2) were synthesized, and it was shown that they form vesicles that are stable over a wide pH range (2–12) in the presence of co-surfactants such as DOH and DN (Albertsen et al. 2014). Polypropenyl phosphates (Figure 7.2.2) also showed pH-dependent vesicle formation over a pH range of 3–13 (Takajo et al. 2001; Gotoh et al. 2006; Streiff et al. 2007). The pH stability of polypropenyl phosphates also increases by mixing up to 50 mol% of polypropenyl alcohol (Streiff et al. 2007).

7.2.2.5 Temperature Tolerance

In addition to oil, vesicle, and micelle phases, which depend on pH at concentrations above the CAC, lipids also demonstrate temperature-dependent phase transitions. The fluidity and semi-permeability of the membrane in vesicles depends on a liquid-crystal structure; membrane becomes a less useful gel-like phase at lower temperatures. Generally, increasing temperatures increases membrane permeability and may also decompose organic molecules encapsulated within the vesicles.

Extant extremophiles have altered lipid structures to survive temperatures much different from the mesophiles, which thrive at 20°C–45°C. Many extremophiles are members of the archaeal domain of life. The hydrocarbon acyl chains of PLs and glycolipids are adapted to low-temperature conditions (~20°C to 10°C) in psychrophiles (Russell et al. 1995). The acyl chains in the lipids of these low-temperature-loving organisms demonstrate unsaturated and branched bonds, whereas the chain length decreases to maintain the membrane fluidity (Russell 1990). Additionally, there is increased incorporation of lipids with a lower gel-to-liquid

crystalline (e.g., 16:1Δ⁹, palmitoleic acid) transition temperature (Russell 1984). Thermophiles contain a higher content of saturated straight- and branched-chain FAs, as well as membrane-spanning lipids, in their membranes to enhance the membrane stability at elevated temperatures (Chan et al. 1971).

It is widely accepted that the global Archaean Earth had average surface temperatures of ~50°C–85°C (Knauth 2005), most likely with local environments that reached freezing or temperatures >85°C at surface of hot springs or hydrothermal vents. Thermostability or change in permeability of OA vesicles as a function of temperature has been assessed by estimating leakage of encapsulated self-quenching fluorescent dyes (carboxyfluorescein or calcein) or adenine oligonucleotide (up to 10-mer) up to a temperature of 90°C. Vesicles of short-chain FA, such as DA, tend to have greater leakage at ~45°C in comparison with long-chain (< C_{14}) FA (Maurer et al. 2009). Single-chain amphiphiles with unsaturated bonds in their hydrocarbon chain are more susceptible to oxidation. Interestingly, lauric acid (C_{12}) vesicles are stable at higher temperatures but tend to precipitate at lower temperatures (30°C) (Monnard and Deamer 2002). In our laboratory, we have found that DA or DA-DOH (2:1) vesicles are highly leaky, even at room temperature (Sahai lab., unpublished results). In comparison, OA vesicles are relatively impermeable up to 90°C, but some leakage is detected at higher temperatures >90°C (Mansy and Szostak 2008). Leakage could be prevented by the addition of GMM as a co-surfactant. In experiments mimicking diurnal temperature cycles, vesicle containing encapsulated DNA was heated to 90°C and cooled to 20°C (for 1 minute at each temperature). The DNA strands inside the vesicle showed separation and reannealing, which are important properties for replication (Mansy and Szostak 2008). This result shows the potential for the amplification of information molecules inside the thermostable lipid compartment.

7.2.2.6 Pressure Tolerance

We are unaware of pressure-dependent stability date for SCA membranes. Phospholipid membranes exhibit a less sensitive response to changes in pressure. Pressure ~2 kbars in 1,2-dipalmitoyl-sn-glycero-3-phosphatidylcholine (DPPC) resulted in a change from liquid crystalline to gel phase and, finally, to an “interdigitated phase,” accompanied by a 5% decrease in the bilayer volume in the latter two phases (Braganza and Worcester 1986). In the non-interdigitated phase, both ends of the hydrocarbon chains meet in the membrane midplane, thus forming a thick hydrophobic region. However, in the fully interdigitated membrane, the thickness of the membrane is greatly reduced and there is the loss of the midplane (Smith and Dea 2013). This change was a result of straightening of the acyl hydrocarbon chains (Stamatoff et al. 1978; Kato and Hayashi 1999). Such an effect would be potentially relevant in the hypothetical scenario where life evolved at oceanic hydrothermal vents after the earliest mineral-wall stage into the stage where the cells had started to produce PL membranes.

7.2.2.2.7 Effects of Minerals on Model Protocell Stability

Most extant prokaryotes live at the mineral/water interface to exploit the advantages offered by this microenvironment, such as inorganic nutrients for chemoautolithotrophs, reduced wave and current turbulence than in a free-standing column of water, and a surface for attachment to facilitate biofilm community living. It is, therefore, logical to propose that protocells may also have preferred to remain in contact with mineral surfaces. This raises the question of whether the self-assembly and permeability of SCA membranes are affected by mineral surface properties.

Sahai et al. (2017) examined the CVC and permeability of pure DA and of DA-DOH (2:1) vesicles at pH 7 and 8.5, respectively, in the presence of 10 minerals and 2 rocks representative of the early Earth. The minerals were chosen to represent a range of particle sizes, isoelectric points, and chemical compositions such as oxides, hydroxides, carbonates, sulfides, and aluminosilicates. It was found that negatively charged minerals, including silica, quartz, montmorillonite, anatase, rutile, and pyrite, did not affect the CVC of the lipids. Positively charged minerals such as $\gamma\text{-Al}_2\text{O}_3$, goethite, and siderite with surface coating of goethite increased the CVC three-fold at high mineral loadings (1 mg.mL^{-1} and higher) but not at lower loadings. It was also found that lipids adsorb to the negatively charged minerals and positively charged minerals, but adsorption on the latter was significantly greater. The positively charged minerals and adsorbed lipids at higher loadings tended to aggregate and settle out of solution, so more lipid had to be added to solution, thus apparently increasing the CVC. At lower mineral loadings, the lipid-mineral aggregates did not settle out appreciably. Thus, the apparent CVC can be affected by some minerals under specific conditions of high loading. Permeability was not affected by the presence of minerals, as determined by leakage of calcein fluorescent dye encapsulated within the vesicle, either at room temperature or up to 80°C .

In summary, increasing hydrocarbon chain length and the addition of co-surfactants with alcohol, amine, or phosphate headgroups enhance the stability of FA membranes toward extremes of pH, dissolved ion concentrations, and temperature.

7.2.2.3 OTHER COMPARTMENT-FORMING SYSTEMS

Besides SCAs, other molecules such as peptides have been explored as plausible membrane components. Amphiphilic peptides formed by heating a mixture of amino acids (aspartic acid, glutamic acid, and other 16 amino acids) at 160°C – 180°C were shown to form membranous structures or microspheres that resembled protocells (Fox and Harada 1960). These structures were termed proteinoids, and it was suggested, though not shown, that they may have catalytic properties, which are required to develop a protometabolism (Fox 1980).

In another study, a proteolipid (protein-lipid complex) membrane supported onto mesoporous silica particles was

synthesized and compared to lipid vesicles (Nordlund et al. 2009). These surface-templated mesoporous silica structures with proteolipid could maintain a proton electrochemical gradient across the membrane. This means that the membranes were proton-tight in the surrounding aqueous medium. These structures were developed for potential drug-delivery applications, but it is conceivable that similar architectures may have existed prebiotically.

Others have suggested that the earliest protocell boundaries were not composed of organic molecules at all but rather of mineral surfaces, specifically, pores in mineral chimneys at low-temperature hydrothermal vents (Russell and Hall 1997; Barge et al. 2014; Lane 2015; Saladino et al. 2016; Hansma 2017). The maintenance of a natural geochemical pH gradient across the pore wall is proposed to be a result of the flow of acidic ambient seawater and highly alkaline vent fluid. This is proposed to have provided the chemiosmotic energy for organic molecule synthesis, eventually including specialized ion channels and active pumps.

In a related but different idea, it has been proposed that “membraneless organelles” may have formed in the spaces between mica sheets (Hansma 2017). This mineral-bound space is suggested to have advantages over organic membranes, because they are not affected by the environmental factors as compared with fragile organic molecules. Hansma does not elaborate on what is meant by membraneless organelles, so we speculate here what these might have been. Normally, an organelle is a eukaryotic sub-cellular structure bounded by a lipid membrane that performs a specific function. The ribosome, a large RNA-protein macromolecular complex, is sometimes called a “membrane organelle” simply because it is large enough to be resolved by transmission electron microscopy (TEM) and is the fundamental machinery of the cell that provides a link between RNA and protein synthesis. The ribosome’s structure and functions are highly conserved across all species of life, and its core is believed to be highly ancient, perhaps having evolved even at the protocell stage (Petrov et al. 2015). This idea is consistent with the co-evolution of functional RNA oligomers and peptides by synergistic catalysis, which has been proposed recently (Kaddour and Sahai 2014). It has been shown that Na-exchanged montmorillonite clay, when pretreated in a specific manner, is capable of catalyzing the polymerization of activated RNA mononucleotides in the presence of $\sim 75 \text{ mM MgCl}_2$ and 0.1 M NaCl (Ferris et al. 1996; Joshi et al. 2009). Amino acid adsorption and oligomerization (up to 5–8 mers) in the presence of various clays was also studied (Hashizume, 2012; Dalai et al. 2016a). Thus, combining the ideas of various workers, we speculate that, perhaps, a primitive precursor of the ribosome core evolved in the space between mica or clay sheets. On the other hand, the interlayer spacing in swelling clays is only ~ 1.2 – 1.8 nm , so the extent to which even a small, primitive ribosome could have been accommodated is limited. This is sheer speculation without any experimental or computational evidence but provides avenues for future research.

7.2.3 GROWTH AND DIVISION OF PROTOCELLS AND COMPETITION BETWEEN PROTOCELL POPULATIONS

One of the most important characteristics of a protocell is its ability to grow and subsequently divide to form daughter cells. Various factors affecting model protocell growth and division have been examined in the literature. Studies on the competition between different populations of model cells in primitive predator-prey type relationships, which may lead to some prebiotic evolutionary advantage for the predator protocells, are now beginning to be conducted.

7.2.3.1 MINERAL EFFECTS ON INITIAL RATE OF VESICLE FORMATION

Hanczyc et al. (2007) examined the potential effect of mineral surfaces on the rate of SCA vesicle formation by the acidification of an alkaline (pH ~12) micelle solution (see Section 7.2.2.1 on methods to prepare vesicles). It was found that the initial vesicle formation rates were enhanced in the presence of all the minerals studied and even a hydrophobic

surface like polystyrene beads (Hanczyc et al. 2003, 2007). Furthermore, direct contact between the surface and lipid micelles or vesicles was apparently not required to obtain the surface-promotion effect. The authors did not identify any relationship with the chemical or physical properties of the surfaces. Furthermore, the mechanism was not established for the surface promotion effect.

Recently, Sahai et al. (2017) confirmed Hanczyc's findings, identified mineral-specific trends for initial rates of vesicle self-assembly from micelles and also for *de novo* vesicle formation by rehydration of a lipid thin film (see Section 7.2.2.1), and provided a model for the surface-promoting effect without direct contact. In detail, it was shown that the initial vesicle-formation rates correlated with isoelectric point and particle size of the minerals (Figure 7.2.6).

The isoelectric point (IEP) is the pH at which the mineral surface has net zero charge. At the experimental pH (~7 and 8), some minerals are negatively charged while others are positively charged. Rapid lipid adsorption occurs on all mineral surfaces, as controlled by a combination of electrostatic, H-bonding, and van der Waals hydration forces. A greater amount of FA lipid adsorption was observed on positively

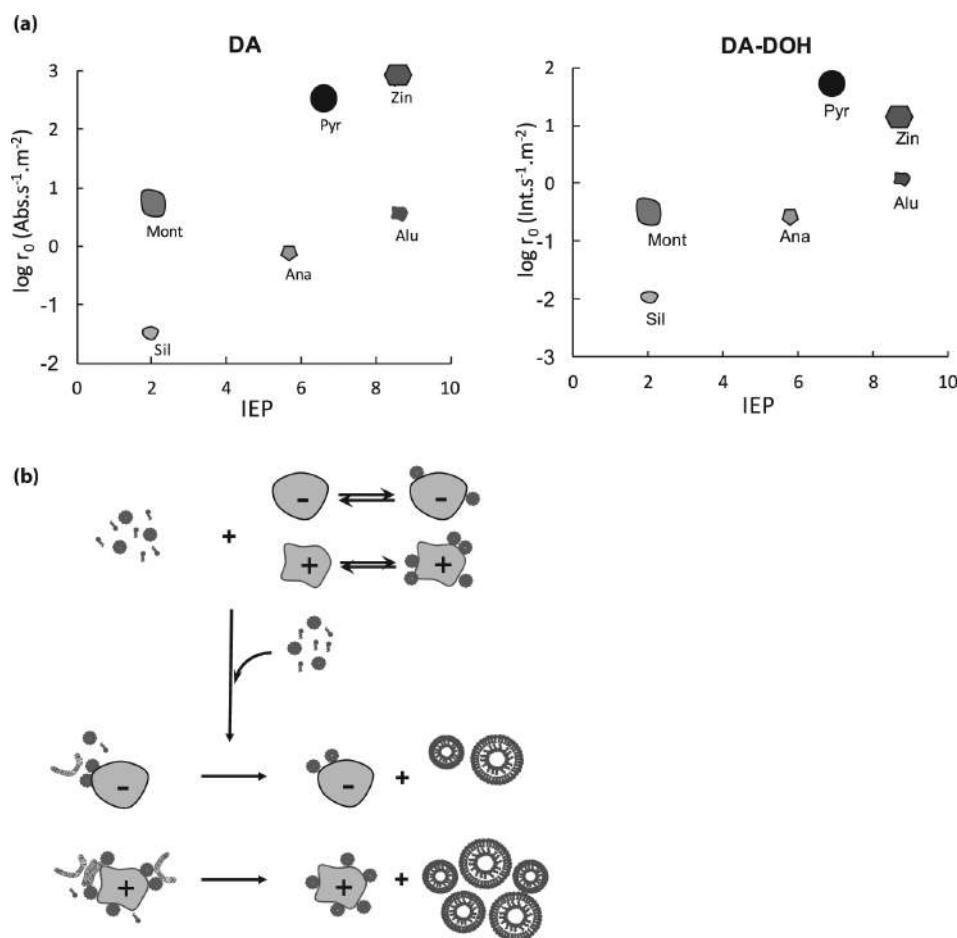

FIGURE 7.2.6 Mineral surface promoted vesicle formation. (a) Initial rate of DA and DA-DOH vesicle formation (r_0) normalized to the mineral surface area as a function of the IEP of the mineral. (b) Schematic of the proposed model for mineral enhancing effect on the rate of vesicle formation. (Modified from Sahai, N. et al., *Sci. Rep.*, 7, 43418, 2017.)

charged mineral than on negatively charged minerals due to electrostatic forces. Some FA adsorption occurred even on negatively charged minerals, despite electrostatic repulsion, because of H-bonding and van der Waals forces. The adsorbed lipid islands on the partially coated mineral were then proposed to serve as a template for more lipid to attach from solution and rapidly transform into vesicles (Figure 7.2.6b).

Hence, the initial rate of vesicle formation was greater on both negatively and positively charged minerals as compared with rates in the absence of any mineral.

The reason that catalysis works even without direct contact with the mineral surface is based on modified Derjaguin-Landau-Verwey-Overbeek (DLVO) theory for colloidal stability that includes the steric hydration force (Oleson and Sahai 2010; Israelachvili 2011). Depending on the mineral, two or more lipid bilayers (up to 12–15 nm away from the surface) may adsorb because of van der Waals interactions between the surface of the lipid bilayers and between the bilayers themselves. The physical size of the bilayers excludes solvent and counterions from the region immediately proximal to the mineral surface, thus effectively extending the electric double layer. Hence, the electrostatic effect of a mineral's surface charge is felt even up to ~12–15 nm away from the surface through two or three stacked lipid bilayers (Oleson and Sahai 2010). The surface-induced rate enhancement is an example of the “matrix effect,” which was first identified by Luisi and co-workers (Blöchliger et al. 1998; Lonchin et al. 1999; Berclaz et al. 2001; Cheng and Luisi 2003; Thomas and Luisi 2005). In the studies involving minerals, the surfaces promote rapid initial formation of the lipid islands, which serve as the matrix or template for subsequent vesicle formation.

7.2.3.2 SIZE EFFECT

As described in Section 7.2.2.1, a polydisperse suspension of vesicles is formed when a dry lipid film is rehydrated. Protocells are also expected to have had a distribution of sizes. One may question whether medium-sized protocells (vesicles) grew at the expense of smaller vesicles by fusion or

whether growth by uptake of monomers or micelles from the environment was the preferred mechanism. Conversely, did the largest protocells form during spontaneous self-assembly during film rehydration as a result of fusion and then subsequently divide to form smaller ones? What forces might have driven growth and division?

Interaction between vesicles of different size distribution was studied by Cheng and Luisi and co-workers (Blöchliger et al. 1998; Lonchin et al. 1999; Berclaz et al. 2001; Cheng and Luisi 2003; Thomas and Luisi 2005) and Szostak and coworkers (Chen and Szostak 2004b). It was found that pure FA or pure POPC vesicles of different sizes could coexist, without the smaller ones fusing with each other to form larger vesicles of a single size. The relative stability of smaller vesicles compared with larger ones was also probed using t-RNA-loaded POPC vesicles of different sizes. A small amount (10%) of positively charged surfactant (cetyltrimethylammonium bromide [CTAB]) was added to the vesicle suspension. The presence of CTAB was expected to cause vesicle aggregation. This was observed for the 160-nm-sized POPC vesicles, whereas the smaller vesicles (~80 nm) were stable against CTAB-induced aggregation (Thomas and Luisi 2005).

These findings were in accordance with the “kinetic trap” concept, which suggests that vesicles are not in thermodynamic equilibrium but rather are kinetically trapped systems (Yan et al. 2016). In a kinetically trapped system, small vesicles of different sizes occupy local energy minima and are prevented from fusing by large energy barriers between the various local minima (Figure 7.2.7a).

Therefore, small vesicles of different-size vesicles tend to remain unfused for a long time (Cheng and Luisi 2003; Yan et al. 2016). In contrast, the energy barriers between larger vesicles is small, so larger vesicles can divide to achieve a lower energy state more easily (Figure 7.2.7a) (Yan et al. 2016). Thus, FA vesicles grew when fed with FA micelles and divided easily by simple physical agitation (Figure 7.2.7b) (Chen and Szostak 2004b; Zhu and Szostak 2009).

The growth of preformed FA vesicles upon the addition of micelles occurred by two pathways. At low micelle-to-vesicle

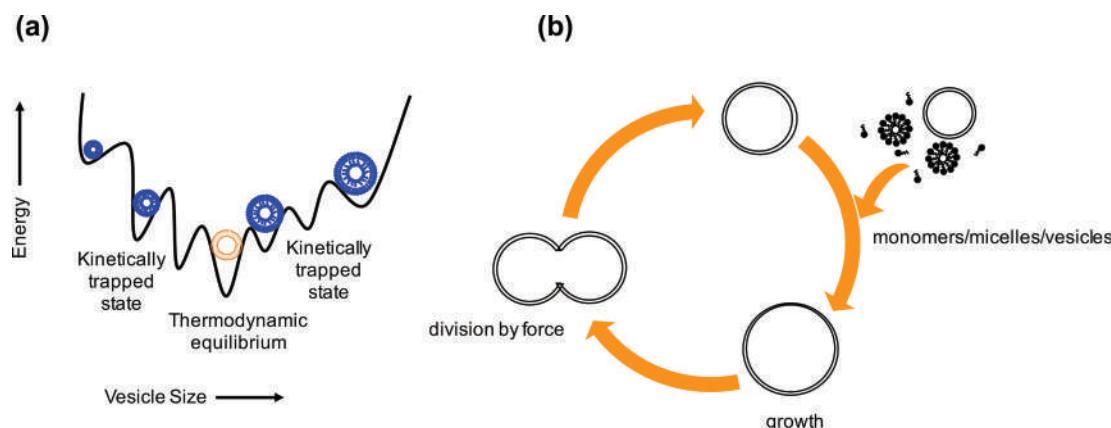

FIGURE 7.2.7 Growth and division of model protocells. (a) Schematic free-energy profile for vesicle fusion from smaller to larger equilibrium size or vesicle division from larger to smaller equilibrium size. (Modified from Yan, Y. et al., *Chem. Commun.*, 52, 11870–11884, 2016.) (b) Growth of vesicles by adding monomers, micelles or vesicles to preexisting vesicles and subsequent division induced by agitation.

ratio (<0.4), micelles were incorporated into the existing lipid bilayer (Chen and Szostak 2004b). However, when the micelle to vesicle ratio exceeded 0.4, micelles aggregated to form the “seeds” or templates for *de novo* vesicle formation. These vesicles could then grow and divide into daughter vesicles. The latter pathway was first reported by Luisi and co-workers, who termed it the “matrix effect.” (Blöchliger et al. 1998; Lonchin et al. 1999; Berclaz et al. 2001; also see [Section 7.2.3.3](#) on co-surfactant effect).

7.2.3.3 CO-SURFACTANT EFFECT

Phospholipid membranes are more robust than SCA membranes toward the deleterious effects of divalent cations and pH extremes and are also much less permeable. Hence, PL vesicles formed by small quantities of abiotically produced PLs may be considered to have an evolutionary advantage over less evolved SCA vesicles. The competition between OA and POPC to form vesicles when mixed together has been studied (Lonchin et al. 1999; Berclaz et al. 2001; Cheng and Luisi 2003; Fujikawa et al. 2005). Oleate vesicles were found to fuse to the POPC vesicles, eventually causing the disappearance of OA vesicles. This effect was observed regardless of the relative sizes of the OA and PL vesicles. Oleic acid micelles (small) were incorporated when added to a suspension of extruded (unidisperse size) POPC vesicles (large) (Lonchin et al. 1999; Berclaz et al. 2001). The resulting mixed vesicles were significantly smaller in size, suggesting that the mixed vesicles had presumably grown very large and then divided (Berclaz et al. 2001). When premixed MA-POPC micelles were added to large unilamellar MA vesicles, MA molecules were abstracted, resulting in a decrease in MA vesicle size (Fujikawa et al. 2005).

The above results showed that the size effect (*i.e.*, relative size of the FA vs. the PL phase) was not the factor controlling which phase grew. Rather, the FA phase was consistently at a disadvantage in the presence of a pure PL or mixed FA-PL phase. This effect can be explained based on the relative CVCs of FAs compared with that of PLs. The SCAs have CVCs that are three to six orders of magnitude larger than the CVCs of PLs, and mixed FA-PL systems with even a small relative PL content have substantially lower CVCs than pure FAs (see [Section 7.2.2.2](#)). Hence, it is the FA molecules that are incorporated into the PL or mixed FA-PL phase.

7.2.3.4 ENCAPSULATED SOLUTE EFFECT

It is generally believed that protocells containing a higher concentration of solutes would have had an advantage for growth over those containing a lower concentration, because this allows for a greater amount of products to be synthesized within the former population. But the question arises as to how different populations are created in the first place. When lipids self-assemble in a solution containing solutes, the concentration of solutes within the vesicles is equal to the bulk concentration outside the vesicles, and, moreover, all the vesicles are expected to have the same concentration.

In a fascinating study, Luisi et al. (2010) demonstrated that a solute, ferritin, when encapsulated in lipid vesicles, is not uniformly distributed. Rather, diverse vesicle populations having different amounts of encapsulated solute were identified. A large number of “empty” vesicles and a small population of ferritin-enriched vesicles were observed. Ferritin was chosen for encapsulation because it contains many electron-dense Fe³⁺ ions; this makes it suitable for visualization using cryo-TEM ([Figure 7.2.8](#)).

It was proposed that, if more ferritin molecules were randomly bound to the initially forming membrane, it might have slowed the rate of membrane closing, thus allowing even more solute to be encapsulated. Conversely, those initially forming membranes, which randomly did not bind ferritin molecules, closed quickly to form empty vesicles. These experiments demonstrated that solute encapsulation at high concentrations is possible even from dilute surroundings. If these solutes are nutrients- or information-carrying molecules, the concentration phenomenon could potentially allow the compartment to eventually develop functionality.

Protocell populations capable of exchanging nutrients and transfer of information may evolve as a result of Darwinian evolution (Szathmáry and Demeter 1987; Szostak et al. 2001). This was demonstrated for model protocells that encapsulate RNA or peptide oligomers (Chen et al. 2004; Adamala and Szostak 2013a). Fatty acid (OA or MA-GMM) vesicles with encapsulated RNA grew by incorporating membrane components from “relaxed” membranes that are devoid of nucleic acid. The growth of the vesicles was driven by the osmotic pressure exerted by the RNA inside the vesicle. Thus, the RNA-encapsulated vesicles showed growth advantage over empty vesicles. The advantage of solute-encapsulating vesicles over empty vesicles was also

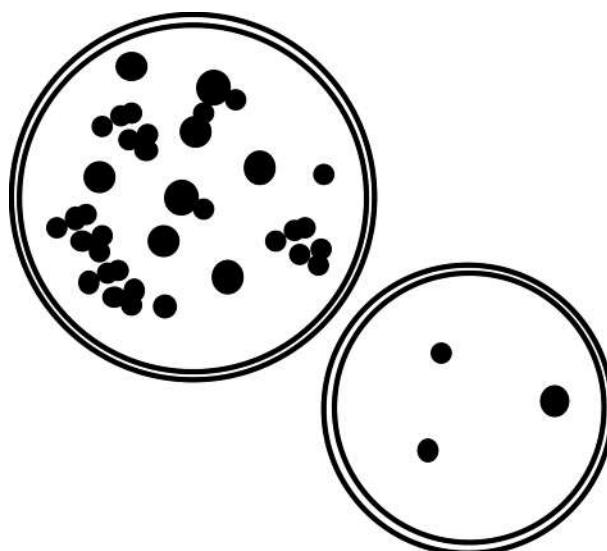

FIGURE 7.2.8 Schematic representation of solute-rich and relatively empty vesicles. The original work showed the cryo-TEM images of “superfilled” and empty unextruded OA-POPC vesicles with electron-dense ferritin molecules. (From Luisi, P. L. et al., *ChemBioChem*, 11, 1989–1992, 2010.)

demonstrated for a peptide solute. The OA vesicles encapsulating AcPheOEt, LeuNH₂, and Ser-His dipeptide catalyzed the intra-vesicular formation of a hydrophobic peptide, AcPheLeuNH₂ (Adamala and Szostak 2013a). Vesicles with the newly formed AcPheLeuNH₂ dipeptide, localized in the membrane bilayer, then grew at the expense of added FA micelles. In comparison, empty vesicles grew much less in size upon addition of FA micelles. Interestingly, AcPheLeuNH₂ peptide synthesis also occurred at a higher efficiency in vesicles than in bulk solution, potentially suggesting some catalytic property of the lipid monomer or the lipid membrane for peptide synthesis.

Homeostasis is a physiological process by which organisms maintain intra-cellular steady state such as constant pH and Na⁺, K⁺, and Ca²⁺ ion concentrations regardless of the extra-cellular environmental conditions. This is a critical feature of cells for survival in changing environmental conditions. Engelhart et al. (2016) have demonstrated a primitive type of homeostasis for ribozyme activity in MA-glycerol monomyristoleate (GMM)-dioleylphosphatidic acid (DOPA) vesicles. Ribozymes and short oligonucleotides (5–7 mers) were co-encapsulated at high concentrations in the vesicles. Enzymatic activity of the ribozyme was inhibited due to duplex formation between the ribozyme and complementary oligonucleotides. Subsequent addition of MA-GMM vesicles led to the growth of the MA-GMM-DOPA vesicles at the expense of the FA vesicles. The growth resulted in dilution of vesicle contents, thus inhibiting ribozyme and oligonucleotide complexation and regaining ribozyme activity. These results indicate that short oligonucleotides were capable of controlling ribozyme functionality preceding modern RNA regulatory machineries, under changing environmental conditions, in this case, lipid concentration.

Competition between two non-lipid populations consisting of coacervates and “proteinosomes” was also recently demonstrated (Qiao et al. 2017). Proteinosomes are membranes consisting of a closely packed monolayer of conjugated amphiphilic protein-polymer building blocks. The amphiphilic construct was composed of bovine serum albumin (BSA) and polymer [poly(N-isopropylacrylamide)], or PNIPAAm. The proteinosomes were loaded with sugar, DNA, or platinum nanoparticles as cargo. Coacervates were assembled from a mixture of cationic polymer [poly(diallyldimethylammonium chloride)] and anionic ATP and were loaded with protease. When mixed together, the proteases in the coacervates digested the protein boundary of the proteinosomes. Thus, the coacervates “fed” on the proteinosomes. Note, however, that in this study, the number of predators (coacervates) remained unchanged after consuming the prey (proteinosomes), thus differing from natural predator-prey relationships, where the predator population (number) grows by feeding on its prey. Also, the proteinosomes, coacervates, and their cargo are too complex to represent model protocells or contemporary cells, but some analogous systems may have existed.

7.2.4 MEMBRANE PERMEABILITY AND SOLUTE TRANSPORT

The transport of solutes across the plasma membrane, that is, of essential nutrients into the cell and of waste products out of the cell, is an essential feature for metabolism. Solutes are exchanged by both passive and active transport mechanisms in modern cells. In passive diffusion, molecules move down the concentration gradient, that is, from high to low concentration, to maintain the equilibrium between inside and outside the cell, without using energy. Passive transport occurs by both non-carrier- and carrier-mediated diffusions. Water, ions, and gases such as CO₂ and O₂ are transported by simple non-carrier-mediated passive diffusion. Carrier-mediated passive transport requires channel proteins and carrier proteins for diffusion of ions and small organic molecules, for example, sugars. In contrast, active transport uses ATP as an energy source to pump molecules (*e.g.*, Na⁺/K⁺) against the concentration gradient, from low to high concentration of the solute. Protons, amino acids, complex sugars, and lipids need specialized proteins, ion channels, and endo- and exocytosis mechanisms for active transportation of solutes. These specialized transport machineries for mass exchange likely evolved later in the evolutionary process. The earliest protocell membranes were likely composed of simple short-chain FAs, perhaps along with some small amount of prebiotically synthesized PLs. Short-tail FA (C ≤ 12) membranes are highly leaky. In the absence of complex transport machineries, nutrient (nucleotides, sugars, amino acids, ions, and dissolved gases) uptake into protocells and expulsion of waste products would have occurred through passive mechanisms, including simple diffusion, lipid flip-flop, defects in the bilayer, and transient pore mechanisms (Paula et al. 1996; Wilson and Pohorille 1996; Paula and Deamer 1999; Mansy et al. 2008). Regardless of the mechanism, the permeation rate across a membrane is dependent on the properties of both the membrane-forming lipid and the solute.

7.2.4.1 FACTORS CONTROLLING PERMEATION RATE

7.2.4.1.1 Lipid-Dependent Factors

The factors associated with the lipid molecule include the type of headgroup, hydrophobic chain length, and lipid packing density, which determine the membrane thickness, hydrophobicity, and fluidity (Paula and Deamer 1999; Mansy 2010). Phospholipids are composed of two acyl chains, which impart greater stability but slower dynamics than a single-chain FA in a membrane. Fatty acid membranes are orders of magnitude more permeable than PL membranes. For instance, the permeability coefficient of K⁺ through OA membranes is 10⁻⁶ cm s⁻¹ compared with 10⁻¹⁰–10⁻¹² cm s⁻¹ for various phosphatidylcholine (C₁₄-C₂₄) membranes (Paula et al. 1996; Chen and Szostak 2004a). Amino acid permeability of PL membranes also depends on the acyl chain length, with shorter-chain lipids being more permeable, and is independent of the solution

pH from pH 2–9 (Chakrabarti and Deamer 1992). Nucleotides are permeable across FA membranes in the presence of Mg²⁺ (Mansy et al. 2008).

7.2.4.1.2 Solute-Dependent Factors

Among solute properties, several factors such as solute charge, hydrophilicity, and isomeric structures affect permeability. Charged molecules are relatively impermeable to PL membranes because of the high energetic cost of desolvation, which is required to cross the hydrophobic membrane interior composed of the hydrocarbon lipid tails. This charge-dependent permeability could have been beneficial for accumulating biomolecules within the protocell compartment. Thus, phosphate in its neutral form at highly acidic pH of 1 has higher permeability (permeability coefficient, $P = 3 \times 10^{-11} \text{ cm s}^{-1}$) across a phosphatidylcholine membrane than in its monoanionic form at pH ~4 ($P = 5 \times 10^{-12} \text{ cm s}^{-1}$) (Chakrabarti and Deamer 1992). Lysine methyl ester, a derivative of lysine, which is neutral at higher pH values and positively charged at lower pH values, translocates faster ($P = 2.1 \times 10^{-2} \text{ cm s}^{-1}$) than does positively charged lysine ($P = 5.1 \times 10^{-12} \text{ cm s}^{-1}$) across PL membranes. Permeability of lysine methyl ester is dependent on the transmembrane pH gradient (Chakrabarti and Deamer 1992; Chakrabarti and Deamer 1994). Also, activated nucleotides can cross a FA vesicle membrane more rapidly than negatively charged natural nucleotides, as activated forms are less polar and have reduced negative charge (Mansy et al. 2008).

The relative hydrophilicity of a molecule also influences its permeation rate through PL membranes. Hydrophobic amino acids (*e.g.*, phenylalanine and tryptophan) exhibited transmembrane permeability by two orders of magnitude greater than hydrophilic amino acids (*e.g.*, glycine, serine, and lysine) (Naoi et al. 1977; Chakrabarti and Deamer 1992; Chakrabarti et al. 1992).

Isomeric structures of neutral sugars were also found to affect permeability across FA membranes (Sacerdote and Szostak 2005). Ribose was found to have much faster permeability than its diastereomers, arabinose and xylose. Thus, early cell membranes might have had a better access to ribose, which could have been used subsequently to synthesize nucleic acids inside the protocell. Using molecular dynamics simulations, Wei and Pohorille (2009) found that the free energy of transferring ribose in its β-pyranose form from water to the lipid bilayer was more favorable than the other aldopentoses. The difference in the free energy of transfer between ribose in its β-pyranose and its diastereomers was attributed to inter- and intramolecular interactions between consecutive exocyclic hydroxyl groups. However, their results showed that ribose crosses the bilayer in the β-pyranose form, and permeation of the biologically more relevant furan form was thermodynamically unfavorable. Thus, the simulation and experimental results are not entirely consistent.

Monnard and Deamer (2001) have demonstrated the permeation of ATP in the presence of a low concentration of magnesium (1.75 mM), through PL and mixed FA-PL

membranes at the transition temperature of the lipid. While the vesicles are permeable to ATP monomer, it was found that dimers and large tRNA molecule showed neither uptake nor release (Monnard and Deamer 2001). They suggested that ATP passively diffused across bilayers according to the transient defect model (Mouritsen et al. 1995; Paula et al. 1996). Therefore, it may have been possible to supply ATP and other nutrients for polymerization inside the protocell in the absence of complex transport machineries. Surprisingly, increasing Mg²⁺ concentration inhibited ATP permeation in contrast to previous results (Petkau and Chelack 1972; Stillwell and Winter 1974), and this discrepancy was not further explained.

7.2.4.2 MECHANISMS OF TRANSPORT ACROSS FATTY ACID MEMBRANES

7.2.4.2.1 Lipid Flip-Flop

Flip-flop refers to the translocation of FA molecules from the outer leaflet to the inner leaflet of the bilayer membrane. Flip-flop dynamics are influenced by the chemical properties of lipid molecules. Flip-flop of a FA molecule is significantly faster ($t_{1/2} = \text{milliseconds}$) than that of a PL molecule ($t_{1/2} = \text{days}$) (McLean and Phillips 1981; Hamilton 2003). When a FA monomer in solution attaches to a vesicle, it first partitions into the outer leaflet and, subsequently, may flip into the inner leaflet of the membrane. Thus, a lipid molecule with a protonated headgroup from the outer membrane can be flipped into the inner membrane or vice versa. It was found that OA membranes cannot maintain a pH gradient in the presence of alkali-metal cations, and this phenomenon was attributed to rapid flip-flop dynamics (Chen and Szostak 2004a). However, the pH gradient could be maintained in the presence of a larger cation, arginine, for several hours, and this was attributed to arginine being non-permeating. The alkali metal ions followed the trend of decreasing permeability with increasing size through the OA membranes (Chen and Szostak 2004a). A high degree of flip-flop dynamics would have rendered protocells permeable to alkali cations and protons. Phospholipid vesicles have the advantage of maintaining a transmembrane pH gradient due to the slower flip-flop rate, as compared with FAs.

7.2.4.2.2 Transient Pores and Local Defects

The surface tension associated with a vesicle membrane may experience a temporary and local increase due to association with another surface or insertion of a peptide or other large molecule. The lipids rearrange in the bilayer to accommodate this change in surface tension, resulting in transient pores or local defects, to allow some solution to leak out, thus easing the increased tension. The lifetime of transient pores depends on the solution viscosity and lipid mobility. Studies examining the effects of membrane-spanning peptides and RNA oligomers are discussed in Section 7.2.7 on co-evolution of lipids, RNA, and proteins.

7.2.5 TRANSITION FROM SINGLE-CHAIN AMPHIPHILE TO PHOSPHOLIPID MEMBRANES

At some stage in the evolutionary process, simple protocell membranes composed of SCAs evolved into predominantly PL membranes. Budin and Szostak (2011) have shown that low levels of dioleoyl phosphatidic acid (DOPA), a PL, could drive the growth of mixed OA-DOPA vesicles, which was deemed an evolutionary step, because mixed OA-DOPA vesicles grew at the expense of pure OA vesicles. However, the resulting vesicles would have higher OA content than the starting vesicles, so they would still be subject to the disadvantages of FA membranes. Recently, the transition of mixed OA-POPC with low POPC content to OA-POPC with high POPC in the presence of Mg²⁺ as an environmental selection pressure was shown (Dalai et al. 2017). It was found that Mg²⁺ preferentially binds to and selectively abstracts OA from OA-POPC mixed lipid membranes, resulting in relatively more POPC in the vesicle. Thus, Mg²⁺ could change the composition of surviving vesicles toward PL enrichment. Additionally, vesicles with higher POPC content were shown to be more robust to the potential effects of divalent cations. These results were reconfirmed by Jin et al. (2018). Therefore, Mg²⁺ ions provided a clear selective pressure for the earliest steps in evolution toward modern cell membranes. The transition of FA vesicles to PL-enriched membranes would be limited by supply of prebiotically synthesized PL. These membranes would provide improved compartmentalization for peptide amphiphiles or replicating machineries to evolve protometabolism and replication cooperatively (discussed in [Section 7.2.7](#)).

Before the complex cell walls and biofilms of extant bacteria evolved possibly as armor against cytotoxicity of some minerals (Xu et al. 2012, 2013), the simple PL membranes of early (proto)cells would have come in contact with mineral surfaces. The stability of PL membranes at various mineral surfaces has been examined by studying model vesicles of zwitterionic DPPC and ditridodecanoylethanolphosphatidylcholine (DTPC), anionic dipalmitoylphosphatidylserine (DPPS), and cationic dipalmitoylphosphatidylcholine (DPEPC). The minerals examined were silica (amorphous silica and quartz), α -TiO₂ (rutile), α -Al₂O₃ (corundum) and mica. The PL-mineral interactions were studied at low and high ionic strengths (17 and 217 mM NaCl), in the presence and absence of dissolved Ca²⁺ ions (Oleson and Sahai 2008; Xu et al. 2009; Oleson et al. 2010, 2012). For the PLs with charged headgroups, adsorption was found to be driven primarily by electrostatic interactions with the mineral surface and was limited to a single adsorbed bilayer. The adsorption of DPPC was controlled in addition by van der Waals interactions, and the effect of solvent and counterion exclusion from the vicinity of the mineral surface (“hydration force”), which allowed multiple layers (up to three on alumina and up to two bilayers on silica) to be adsorbed at low ionic strength. Thus, the mineral was able to exert its electrostatic effect up to 12–15 nm away from the surface.

7.2.6 PROTOMETABOLISM

Most of the studies summarized previously assume the prebiotic availability of FAs, more difficult yet possible PL synthesis, and an RNA world. The existence of the RNA world has been questioned because non-enzymatic synthesis of polynucleotides, long enough to have catalytic functionality, is unlikely under plausible early Earth conditions. Also, RNA is easily hydrolyzed and would have been unstable (Shapiro 2006, 2007). Furthermore, almost all experiments involving nucleotide polymerization first require the monomers to be activated by the addition of a good leaving group. This process usually involves prebiotically implausible reactions, but in the lack of other, viable alternatives, it is implicitly agreed upon by workers in the field that the monomers were somehow activated (Kaddour and Sahai 2014). The “Polymer Transition” stage of the RNA world theory, in which proteins eventually took over the function of catalysis from ribozymes, has also been critiqued (Bowman et al. 2015).

Because of these difficulties associated with the RNA world hypothesis, it has been proposed that primitive metabolism, or “protometabolism,” might be an answer to the first ordered chemistry capable of surviving. However, in contrast to the RNA world hypothesis, which is being actively examined experimentally, a very limited number of studies have examined protometabolism in model protocells. One of the problems is to define metabolism in a conceptually simple yet robust way that can be used to design experiments.

Metabolism includes the sum of all chemical reactions performed by an organism. These reactions include biosynthesis of the molecules required for replication and self-maintenance, a process known as anabolism, as well as release of energy from specific nutrient molecules in order to drive the biosynthetic pathways during the process of catabolism. The pathway for both synthesis and breakdown of a biomolecule is a complex network of reactions involving key intermediate molecules and is catalyzed by enzymes at almost every step. A key question in the OoL field is whether the earliest metabolism was chemoautotrophic or heteroautotrophic. In this section, we first provide a brief introduction to the common themes in modern metabolism, followed by a summary of different approaches in the OoL field to address the metabolism-first or protein-world scenario.

7.2.6.1 MODERN METABOLISM

The discussion in this section follows from an excellent introductory textbook by Tortora et al. (1995).

7.2.6.1.1 Shared Features of Metabolism

Modern metabolism in all forms of life share some key features. Anabolic reactions are often dehydration reactions and require energy (activation) to form new chemical bonds. Polymerization of monomers is a class of anabolic reactions. Catabolic reactions involve breakdown of molecules, often by hydrolysis, and release energy, *for example*, the breakdown of

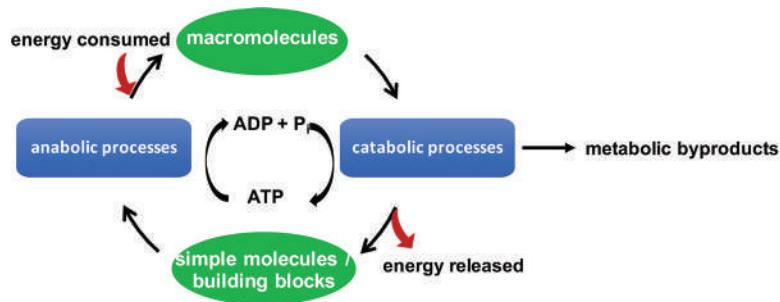

FIGURE 7.2.9 Schematic of modern metabolism showing the ATP-linked anabolic and catabolic processes. Reactions in both processes occur through a series of enzyme-mediated steps.

carbohydrates, in which CO_2 and H_2O are generated as waste products. The energy derived by catabolism is stored in the ATP molecule in the high energy P-O-P bond, wherein ADP combines with AMP to form ATP. Biosynthesis of molecules requires energy, which is provided by the breakdown of ATP back to ADP and AMP. Thus, ATP is a “concentrated” carrier of energy.

Metabolic reactions are usually electron-transfer (redox) reactions, which are often slow and need to be catalyzed. Specific enzymes are required to catalyze almost every intermediate compound in the complex anabolic or catabolic reaction networks (Figure 7.2.9).

Enzymes are assisted by cofactors, which are either organic compounds called coenzymes or metal ions. Nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP) are the most important cofactors in redox reactions. They get reduced to NADH and NADPH, respectively. These electrons can be donated back to an oxidant in a subsequent step, thus converting the coenzymes back to their oxidized forms. Thus, NAD and NADP act as electron carriers or shuttles. They are utilized predominantly in anabolic and catabolic reactions, respectively. Inorganic ions also act as cofactors. For example, Mg^{2+} assists enzymes that catalyze the transfer of phosphate from ADP to another substrate or the transfer of a nucleotide triphosphate to a growing nucleic acid chain, with the release of the corresponding nucleotide diphosphate. Iron sulfide clusters (Fe_3S_4 and Fe_4S_4) are found at the active site of some enzymes such as ferredoxin, NADH dehydrogenase, and coenzyme Q-cytochrome c reductase. Glycolysis required five Mg^{2+} - and one Zn^{2+} -dependent enzymes (Belmonte and Mansy 2016).

7.2.6.1.2 ATP Synthesis (Phosphorylation) and Chemiosmosis

The generation of ATP is a key step in storing the chemical energy derived from catabolism in a form that can be used efficiently at a later stage for an anabolic reaction. The addition of a phosphate group to ADP or other substrate is called phosphorylation. Three mechanisms are utilized by all forms of life to generate ATP. In substrate-level phosphorylation, an existing phosphorylated compound containing a high-energy C-O-P bond transfers the energy to ADP, with the formation of ATP. In oxidative phosphorylation, electrons

are transferred from reduced organic or inorganic compounds (e.g., glucose and CH_4) to electron carriers such as NAD in an electron chain to a terminal electron acceptor (e.g., O_2 and CO_2). Energy is released in each electron transfer reaction of the electron transport chain. Some of this energy is used to convert ADP into ATP by a process known as chemiosmosis. The third mechanism for ATP generation is known as photophosphorylation. It is the mechanism in which organic compounds are synthesized from CO_2 as a carbon source during photosynthesis. Energy from UV light is transferred by light-trapping pigments such as chlorophyll and electron carriers (flavin mononucleotide (FMN), cytochromes, and ubiquinone or coenzyme Q) in an electron transport chain, finally to ATP. This process also involves chemiosmosis.

Chemiosmosis is a process in which the energy released by the movement of a solute (specifically, H^+) down a concentration gradient is used to synthesize ATP during oxidative phosphorylation or photophosphorylation. As electrons from NADH generated by photocatalysis (sunlight and chlorophyll) are passed down the electron chain, some of the energy is used to drive protons out of the PL membrane by using specific proteins called proton pumps. This builds up a high H^+ concentration outside the cells, which results in both a pH and an electrical charge gradient across the membrane. This electrochemical gradient is called the proton motive force. The H^+ then diffuse back across membrane, assisted by a special protein channel called ATP synthase. The down-gradient movement of H^+ releases energy, which drives ATP synthase to phosphorylate ADP to ATP inside the cell. In most prokaryotes, the relevant membrane is the plasma membrane, whereas it is the mitochondrial membrane in eukaryotes and the thylakoid membrane in cyanobacteria and eukaryotic chloroplasts. In summary, ATP generation requires (1) terminal electron donors such as pigment molecules and sunlight in photosynthesis, or glucose or reduced inorganic redox species such as H_2O , elemental S^0 , Fe(II), Mn(II), H_2 , NH_3 , and CH_4 ; (2) electron transfer by electron carriers, such as NAD, NADP, and FMN; and (3) terminal electron acceptors. The electron acceptors may be O_2 in oxidative respiration, or oxidized inorganic species such as SO_4^{2-} , Fe(III), Mn(III), NO_3^- , CO_2 , and even elemental S^0 in anaerobic respiration, or organic compounds in fermentation (Konhauser 2007). Aerobic and anaerobic respirations utilize substrate-level and oxidative

phosphorylation to generate ATP for every glucose molecule metabolized. Aerobic respiration generates 36 (prokaryotic) or 38 (eukaryotic) ATP molecules per glucose molecule, and anaerobic respiration generates between 3 and 38 ATP molecules per glucose. Fermentation, which is also an anaerobic process, relies on substrate-level phosphorylation to generate two ATP molecules per glucose molecule.

7.2.6.1.3 Metabolic Classification

The metabolisms of extant organisms have been classified based on the electron source and the carbon source. Organisms that use light energy are called phototrophs, and those that use chemical energy from redox reactions are called chemotrophs. The organisms may be autotrophs, wherein the source of carbon is inorganic carbon (CO_2), or they may be heterotrophs, which use another organic compound (reduced carbon) to synthesize their biomolecules. Combinations of these modes yield different metabolic categories. Photoautotrophs use light as their energy source and CO_2 as the carbon source. Examples include photosynthetic purple and sulfur bacteria, cyanobacteria, algae, and plants. Photoheterotrophs, such as purple and green nonsulfur bacteria, use sunlight as their energy source and organic compounds for carbon source. The RNA world hypothesis for the OoL is generally consistent with a heterotrophic metabolism. Chemoautotrophs use electrons from inorganic compounds, and their carbon source is CO_2 , for example, hydrogen, sulfur, iron, and nitrifying bacteria. Methanogens, acetogens, and methanotrophs are some examples of chemoautotrophic metabolisms that have been proposed to comprise the primordial metabolism (Martin and Russell 2007; Martin et al. 2008; Lane 2015). When both electrons and carbon sources are organic compounds, the organisms are called chemoheterotrophs, including many bacteria, all fungi, protozoa, and animals.

7.2.6.2 CONCEPTUAL DEFINITION OF METABOLISM

Several conceptual definitions of metabolism have been attempted. The first metabolic pathways were described as involving monomers and small molecules in networks of an autocatalytic set (Segré et al. 2000; Shapiro 2006, 2007; Kauffman 2007). In an autocatalytic set, molecules involved in a reaction catalyze other reactions of the set. In Figure 7.2.10, under a constant supply of A and B reactant molecules, the initial products AB and BA can be formed. Once the starting products are formed, they can catalyze the synthesis of other molecules, *for example*, ABB from AB and B with BA as a catalyst. Thus, the reactions in the set become collectively autocatalytic (Segré et al. 2000; Shapiro 2006; Kauffman 2007).

Autocatalytic networks can develop inside a compartment selectively permeable to prebiotically formed molecules, a key process in the transition from chaos to an ordered form. These compartments could have been simple vesicles composed of amphiphilic organic molecules or mineral surfaces (Wächtershäuser 1988, 1990; Russell and Hall 1997; Lane 2015; Saladino et al. 2016; Hansma 2017).

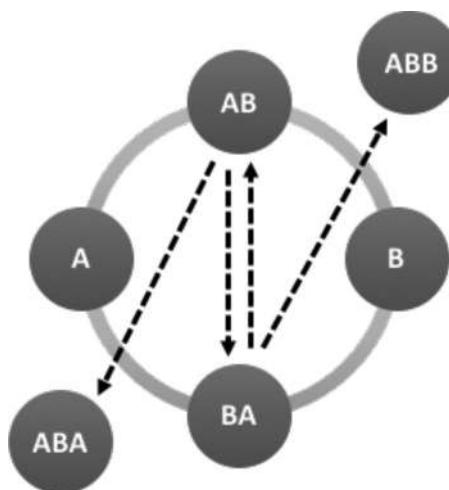

FIGURE 7.2.10 A simple autocatalytic set, with A and B as starting reactants. The dotted arrows represent catalysis. (Modified from Kauffman, S., *Orig. Life Evol. Biosph.*, 37, 315–322, 2007.)

Shapiro (2007) has defined five minimal requirements for small molecules to form a simple metabolism-based form of life, without the need for information-storing molecules such as RNA. A source of energy, such as a photocatalytic mineral and sunlight, is necessary, which drives an exothermic chemical reaction. A chemical reaction network must develop and become more complex to allow for adaptation and evolution. The rate of mass used in the reaction network to make complex organic molecules must be faster than the rate of degradation of these molecules in the environment, so that the system can grow and reproduce.

7.2.6.3 CORE METABOLISM

It has been proposed that a small reaction network pathway with connected internal sub-cycles, whose intermediates are capable of giving rise to all other biosynthetic molecules and is widely distributed among all species, must have formed a primitive core metabolism (Tortora et al. 2004). The tricarboxylic acid (TCA) or citric acid cycle fits this bill. The TCA is an amphibolic pathway (Figure 7.2.11).

It can function in a forward sense to produce intermediate molecules, used for amino acid and other biomolecule synthesis (anabolism). In reverse, the TCA can be used for ATP generation (catabolism). For the anaerobic conditions present on prebiotic Earth, the reverse citric acid cycle or reductive tricarboxylic acid cycle (rTCA) has been proposed to constitute the core universal metabolism (Hartman 1975; Corliss et al. 1980; Kandler and Stetter 1981; Wächtershäuser 1990; Smith and Morowitz 2016). Acetyl-coenzyme A (coA) and succinate are among the key molecules in this pathway. A small core group of metabolites or “sparse metabolism” consisting of acetate, pyruvate, oxaloacetate, succinate, and α -ketoglutarate has been proposed as the “standard universal precursors” for all biosynthetic pathways (anabolism) (Smith and Morowitz 2016). This selection is believed to be

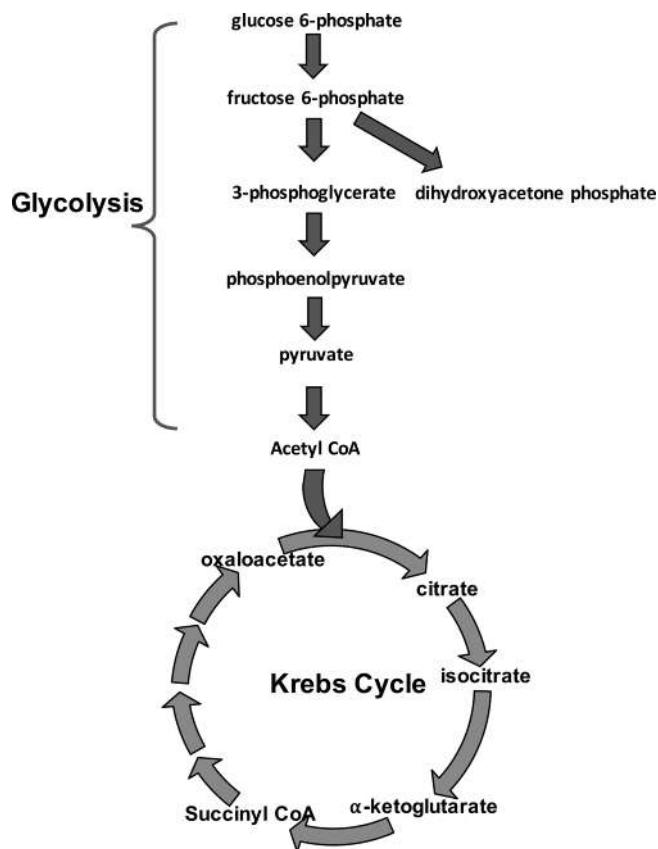

FIGURE 7.2.11 Schematic for an amphibolic pathway that involves both anabolism and catabolism.

based on chemical kinetic arguments. Smith and Morowitz (2016) recognize that while the rTCA is common in the eubacterial and eukaryotic domains, archaea possess the dicarboxylate-4-hydroxybutyrate cycle. This cycle shares the same reactions from acetyl-coA to succinate. Acetyl-coA is significant not only because it drives organic molecule synthesis but also because it reacts with phosphate to form acetyl phosphate, which may have been a precursor to ATP (Lane 2015).

A different primordial metabolism was proposed by other workers (Martin and Russell 2007; Nitschke and Russell 2013; Weiss et al. 2016). These authors proposed the Wood-Ljundahl (WL) pathway, which leads to acetyl-coA and is used by acetogens, methanogens, and methanotrophs. The WL pathway combines both catabolism and anabolism, *that is*, energy harvesting and carbon fixation, respectively, and requires H₂ as the terminal electron donor and CO₂ as the carbon source with iron sulfide clusters in protoenzymes.

As with most issues in the OoL field, there is also a different perspective on whether a core or sparse metabolism was a feature of protocells, at all. Virgo and Ikegami used computer algorithms of abstract model reactions to show that intersecting and branching autocatalytic reaction networks form easily, without the need for an initial catalytic molecule to be present. They argued that the earliest metabolisms were “maximal” and that the rTCA or other minimal metabolic systems were derived by later evolution (Virgo and Ikegami 2013).

7.2.6.4 CHEMOAUTOTROPHIC PROTOMETABOLISM

7.2.6.4.1 Chemoautotrophy at Acidic, High-Temperature Hydrothermal Vents

Soon after the discovery of acidic hydrothermal vents, a chemoautotrophic origin of life on mineral surfaces was proposed. According to this model, the energy required to fix carbon is provided at high-temperature hydrothermal vent systems by iron-rich minerals such as pyrite (FeS₂), formed by the combination of pyrrhotite (FeS) and H₂S or HS⁻ (Corliss et al. 1980; Wächtershäuser 1988, 1990). These dark-colored sulfide minerals give such vents their nickname as “black smokers.” Carbon monoxide or carbon dioxide was the proposed carbon source. The products of the reactions were proposed to remain fixed to the pyrite surface, where they subsequently developed a network of surface-based reactions in an early “surface metabolism.” Following this hypothesis, aliphatic hydrocarbons, aromatic hydrocarbons, and carboxylic acids have been produced under simulated hydrothermal conditions by FTT reactions, in which a solid surface catalyzes the reduction of CO or CO₂ by H₂ (reviewed in McCollum et al. 1999; McCollom 2013; Dalai and Sahai 2016b). Amino acid oligomers (*e.g.*, alanine oligomers) were detected in experiments simulating hydrothermal systems from alanine monomer (Kawamura et al. 2005). Pyruvate has been synthesized from formic acid in the presence of pyrrhotite under hydrothermal vent conditions at 250°C and 50–20 MPa pressure (Cody et al. 2000). Reaction of pyruvate with H₂S, H₂, and NH₄⁺ in the presence of various transition metal sulfide minerals, including pyrite, pyrrhotite, arsenopyrite, marcasite, and sphalerite, at 25°C–100°C, yielded a small number of molecules (pyruvate, lactate, thiolacetate, thiolacetate disulfide, thiolacetate persulfide, propionate, and alanine) rather than a large number of potential products (Novikov and Copley 2013). This result seems to be consistent with the concept of a small set of core metabolites or sparse metabolism. The carboxylic acids and their thiolated derivatives (thioacids and thioesters) produced in these types of reactions are high-energy molecules that are regarded as prebiotic analogs to acetyl-CoA, a key molecule in many biosynthetic pathways.

These are very interesting results, and the plausibility of such systems has been examined. In one study combining experiments with density functional theory modeling of the thermodynamics and kinetics of thioacetate and methylthioacetate hydrolysis, it was shown that these species could not have accumulated abiotically to concentrations sufficient for maintaining metabolic networks (Chandru et al. 2016). However, based on the kinetics of thioester exchange reaction, it was concluded elsewhere that theories invoking thioesters as prebiotic analogs of acetyl-coA can neither be accepted nor be rejected *a priori* (Bracher et al. 2011). The studies summarized here provide promising avenues for future research. An especially important step would be to show how these early metabolic molecules could be encapsulated and sustained within a membrane.

7.2.6.4.2 Chemoautotrophy at Alkaline, Low-Temperature Hydrothermal Vents

In the low-temperature hydrothermal vent theory, it is hypothesized that the earliest membranes were not organic, but rather, the walls of pores in the mineral chimneys precipitated at alkaline hydrothermal vents or white smoker vents (Russell and Hall 1997; Martin et al. 2008; Lane 2015; [Figure 7.2.12](#)).

The energy for organic molecule synthesis is proposed to have been provided by the geothermal and geochemical gradients at these vents. At such sites, highly alkaline ($\text{pH} \sim 11\text{--}12$) water is produced by hydrothermal alteration of seafloor peridotites that would come in contact with ambient seawater, which would have been mildly acidic ($\text{pH} \sim 6\text{--}6.5$) because of equilibrium with a CO_2 -rich atmosphere. The flow of water with two very different pHs across the pores in the precipitated mineral chimneys would have produced an ancient geochemical equivalent of the chemiosmotic gradient, which is apparently a universal feature of all extant life-forms. This geochemical gradient would have provided the energy required for the synthesis of organic compound precursors from inorganic starting compounds such as dissolved CO_2 , CH_4 , and NH_3 . Thus, a deep sub-aqueous, hydrothermal vent environment is proposed, eventually leading to the emergence of chemoautotrophic metabolism and replication.

The question of metabolism and encapsulation within a membrane has been approached creatively by proponents of a chemoautotrophic origin of life at low-temperature, alkaline hydrothermal vents, wherein the walls of pores in the mineral precipitates at the vent are proposed to have formed the first “mineral membranes” (Russell and Hall 1997; Russell and Martin 2004; Martin and Russell 2007; Martin et al. 2008; Lane 2015). This kind of vent produces highly alkaline fluids at temperatures of $60^\circ\text{C}\text{--}90^\circ\text{C}$, and carbonate minerals

precipitated result in the so-called “white smokers.” The process involves the reaction of seawater with the olivine and pyroxene in upper mantle peridotite and the formation of the secondary minerals, serpentine, magnetite, brucite, and carbonates, along with the release of H. The H₂ gas reacts with CO₂ in the seawater and reduces it to methane. Ferrous iron present in the ambient seawater would have formed iron sulfides. Russell and Hall (1997) first proposed that the walls of pores in the iron sulfide precipitates might have served as the first inorganic membranes. Under simulated white smoker hydrothermal conditions, “chemical gardens” were produced from the precipitation reaction in which the concentrations of the reactants (e.g., dissolved Fe²⁺ in the acidic primordial ocean and dissolved sulfide in the alkaline hydrothermal fluid) are far from equilibrium (Barge et al. 2014). The transition metal sulfide chemical gardens can generate electrochemical energy and act as a catalyst. Molecules produced in these conditions were proposed to be concentrated by the process of thermophoresis, wherein larger molecules will have lower kinetic energy than smaller ones and, with a thermal gradient, will accumulate in the cooler region. This was shown experimentally for various protonated states of phosphate ion (Duhr and Braun 2006; Reichl et al. 2014).

The mineral pore walls are proposed to have constituted a leaky membrane, which would have allowed H⁺, OH⁻, Na⁺, Cl⁻, and ions present in seawater to enter and leave the volume of space defined by the pore wherein the protocell is hosted. However, a proton gradient would have been maintained across the inside and outside of the pore space across the mineral wall, because it separates the acidic ocean water ($\text{pH } 5\text{--}6$) from the alkaline hydrothermal fluid ($\text{pH } 9\text{--}11$) (Lane 2015). The availability of energy in the form of the pH gradient was proposed to have played a key role in the development of metabolism based on acetyl-coA, which begins with the reaction of H₂ and CO₂, eventually leading to an intermediate stage involving an Na⁺/H⁺ antiporter and, finally, a free-living cell that could escape the vent environment. Acetogens and methanogens are proposed to have been the bacterial and archaeal ancestors. These are very interesting and provocative ideas that provide avenues for future experimental research.

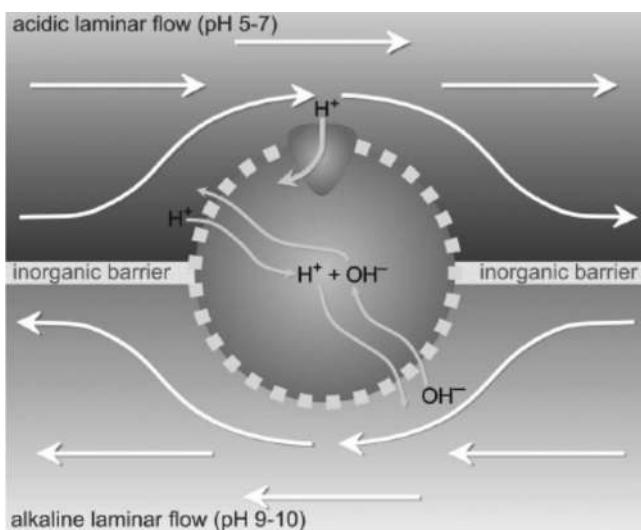

FIGURE 7.2.12 Hypothetical protocell with mineral pore walls, as membrane formed at a low-temperature alkaline hydrothermal vent. Ambient fluid flow of two different pHs establishes a chemiosmotic potential across the mineral wall. (From Sojo, V. et al., *PLoS Biol.*, 12, e1001926, 2014.)

7.2.6.5 HETEROTROPHIC PROTOMETABOLISM

Heterotrophs use external sources of organic molecules from their surroundings. These organisms are classified as chemoheterotrophs if the energy source is electrons from other organic compounds and as photoheterotrophs if the energy source is from pigment molecules activated by UV light. A large literature exists on the synthesis of lipids, nucleotides, and amino acids and their oligomers under Earth’s surface conditions, without or with UV light as the energy source. Most conceptualizations of the RNA world require a heterotrophic protometabolism. For example, Mansy et al. (2008) have shown the permeability of charged and polar molecules such as activated nucleotides (AMP and ADP) and ribose across specific mixture of FA membranes (e.g., MA-GMM, DA-DOH-GMD, and OA). Eventually, the activated mononucleotides

can participate in oligomerization by copying the template encapsulated in the vesicle interior. Thus, it was possible for heterotrophic protocells to have utilized nutrients from their environment in the absence of any transport machinery. However, autotrophy was not completely ruled out, because it is also possible that metabolites produced inside the protocell may have leaked out and not have been available for use.

In an interesting new study, it was shown that iron-sulfur clusters can be formed simply by UV irradiation of ferrous ions and photolysis of organic thiols in solution. These Fe_2S_2 and Fe_4S_4 clusters are stabilized by cysteine-containing peptides (Bonfio et al. 2017). Thus, iron-sulfur bearing protoenzymes may have evolved on prebiotic Earth to support a heterotrophic protometabolism.

Some experimental attempts have been made to mimic a photoheterotrophic protometabolism by using lipid vesicles as model protocells. In general, an artificial photoheterotrophic energy-transducing system is composed of (1) an extra vesicular reductant/terminal electron donor (*e.g.*, EtOH, EDTA, and ascorbic acid) analogous to water in natural photosynthesis, (2) a photosensitizer organic compound or photocatalytic mineral comparable to the calcium-manganese complex in chlorophyll (*e.g.*, ruthenium bipyridinium, TiO_2 , CdSe, and FeS_2), (3) a transmembrane electron shuttle incorporated into the bilayer (*e.g.*, PAHs, which mimic the quinones in the photosynthesis electron transfer chain), and (4) an encapsulated oxidant or terminal electron acceptor analogous to O_2 (*e.g.*, rhodium bipyridinium, $\text{Rh}(\text{bpy})_3^{3+}$, or ferricyanide, $\text{Fe}(\text{CN})_6^{4-}$, or NAD) (Figure 7.2.13).

Using PL (dihexadecyl phosphate [DHP]) vesicles, Fendler and coworkers demonstrated TMETRs in the presence of $\text{Ru}(\text{bpy})_3^{3+}$ as photosensitizer and photocatalytic minerals or quantum dots (CdSe) (Tunuli and Fendler 1981; Horváth and Fender 1992) (Figure 7.2.13a). When irradiated by UV light, these mineral nanoparticles generate an electron-hole pair

and can pass the electrons via $\text{Ru}(\text{bpy})_3^{3+}$ to various electron transfer reactions. A TMETR was also reported across an FA membrane by using only an intramembrane PAH and no photosensitizer (Figure 7.2.13b). Thus, the PAH appears to have played the role of both photosensitizer and transmembrane electron shuttle in an FA membrane (Cape et al. 2011). These authors showed that an anionic hydrophilic species such as ferricyanide could be retained for long periods inside the negatively charged DA membranes. The long retention time was ascribed to charge-charge repulsion between the anionic solutes and the carboxylate headgroups. Further, PAH probably increased the stability of the membrane (Groen et al. 2012). While transmembrane electron transport is a key step in the simulation of a photoheterotrophic metabolism, it is only a single reaction. The demonstration of a coupled reaction network inside a model protocell remains a grand challenge in the field.

In contrast to a TMETR, electron transfer reaction with the photocatalyst, oxidant, and reductant, all encapsulated within the volume of a PL membrane, has also been shown (Summers et al. 2009; Summers and Rodoni 2015) (Figure 7.2.13c). However, these were not transmembrane redox reactions.

7.2.6.6 PREBIOTIC PHOSPHORYLATION

Phosphorylation using the orthophosphate anion is generally thermodynamically unfavorable in aqueous medium and ambient temperatures, because it is a dehydration (condensation) reaction. Activated phosphorylated molecules such as ATP are the energy-rich molecules that conduct phosphorylation in modern metabolism. The importance of phosphorous bioenergetics and the requirement for compartmentalization have been highlighted (Kee and Monnard 2016). As we have seen previously, ATP is generated in extant life-forms by substrate-level phosphorylation, oxidation phosphorylation,

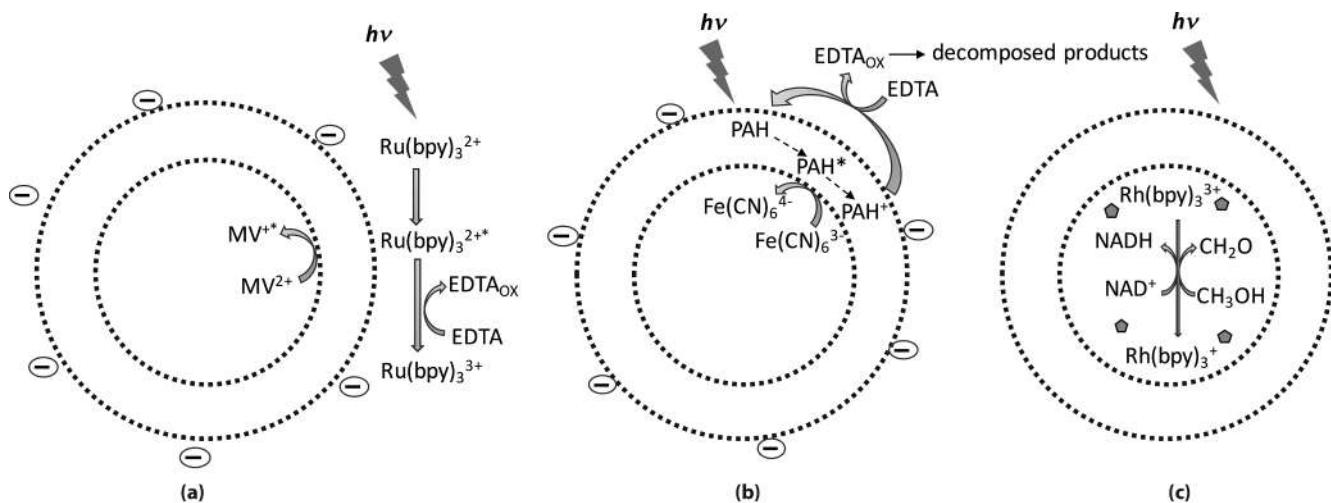

FIGURE 7.2.13 Schematic representation of model photoheterotrophic protometabolism across or within PL or FA vesicle membranes, as reported in the literature. Transmembrane electron transfer reactions across (a) a PL membrane with $\text{Ru}(\text{bpy})_3^{3+}$ as a photosensitizer (Tunuli and Fendler 1981); (b) a FA membrane with PAH as a photosensitizer (Cape et al. 2011); and (c) redox reaction within PL vesicle without transmembrane electron transfer (Summers and Rodoni 2015). See text for details and description of abbreviations.

or photophosphorylation. The latter two mechanisms involve chemiosmosis and the phosphorylation of ADP to ATP, whereas substrate-level phosphorylation involves phosphorylated organic compound containing a high-energy C-O-P bond, transferring its phosphate group to ADP. Model prebiotic phosphorylation studies have been reviewed recently (Pasek and Kee 2011; Gull 2014). Several studies in the OoL field have attempted to mimic prebiotic substrate-level phosphorylation, where the high-energy bond or phosphate moiety is part of a phosphate mineral. Unfortunately, most common metal phosphate minerals such as hydroxyapatite are orthophosphates and do not possess high-energy bonds, and geologically common phosphate minerals are not very soluble. These two issues have been addressed in different ways in the OoL field.

Polyphosphates are oligomers of phosphate having high-energy P-O-P bonds similar to those in nucleoside di- and tri-phosphates. Inorganic pyrophosphate and trimetaphosphates have been synthesized in experiments, representing model volcanic environments, and pyrophosphate (P_2O_7) concentration of $\sim 0.45 \mu M$ was measured in fumarole gases (Yamagata et al. 1991). Cyclic trimetaphosphate were also studied as potential phosphorylating organic molecules (Krishnamurthy et al. 1999). Trimetaphosphates and larger polyphosphates can phosphorylate adenosine, but pyrophosphate cannot (Schwartz and Ponnamperuma 1968). Diamidophosphate has been shown recently to have facile phosphorylation capability, but the molecule requires trimetaphosphate for its own synthesis (Gibard et al. 2017). Trimetaphosphates and higher polyphosphates are rare in ambient aqueous environments.

Another interesting proposal involves the mineral schreibersite $[(Fe,Ni)P]$, which contains an active, reduced form of phosphorous (Pasek and Lauretta 2008). This mineral is found in meteorite impact sites and lightning strike sites. It was estimated that schreibersite might have contributed up to $\sim 10\%$ of the Earth's crustal phosphorus (Pasek and Lauretta 2008; Pasek et al. 2008; Bryant et al. 2013; Gull et al. 2014). Schreibersite oxidizes to form phosphite, hypophosphate, pyrophosphate, and orthophosphate, which, in turn, could have directed surface-mediated chemistry, *for example*, phosphorylation.

The low solubility of phosphates (as insoluble metal phosphates) has limited their use as phosphorylating agents (Gilbert 1986; Hud et al. 2013). However, eutectic solutions containing formamide increase the solubility of phosphates, and solutions containing urea promote condensation reactions because urea is hydrolyzed in the process. Costanzo et al. (2007) have demonstrated the phosphorylation of nucleosides by various phosphate minerals in liquid non-aqueous formamide environment. They have characterized phosphate minerals as inactive (*e.g.*, herderite $Ca[BePO_4F]$), low-level (*e.g.*, pseudomalachite $Cu^{2+}_5(PO_4)_2(OH)_4$), and active phosphorylating agents (*e.g.*, libethenite $Cu^{2+}_2(PO_4)(OH)$ and hydroxylapatite $Ca_5(PO_4)_3(OH)$), based on their phosphorylating efficiency. Phosphorylating minerals act as phosphate donors to nucleosides, yielding 5'- and 3'-AMP in formamide conditions.

Urea:choline chloride (3:1) eutectic and urea-ammonium formate-water (1:2:4) eutectics or simple non-eutectic aqueous solutions have been employed successfully to phosphorylate biomolecules and to promote DNA and RNA secondary structure formation (Mamajanov et al. 2010; Albertsen et al. 2014; Gull et al. 2015; Burcar et al. 2016).

Although phosphorylation by monomeric phosphate anion is unfavorable at normal temperatures and phosphate concentrations, synthesis of phosphorylated biomolecules was achieved by using very high (1 M) phosphate concentration (Powner et al. 2009; Patel et al. 2015). Whether such a high concentration of phosphate could have been reached under plausible early Earth conditions is an open question.

7.2.7 CO-EVOLUTION OF PROTOMETABOLISM, REPLICATION AND MEMBRANES

The above-mentioned summary of studies involving model protocells in either the RNA world or the metabolism-first world shows that both hypotheses have several problems when actually tested experimentally. Thus, a growing number of workers are turning to the idea that the protocell membrane, RNA, and proteins may have co-evolved in a mutualistic manner. This makes sense from the point of view that natural environments are multicomponent systems. Charles Darwin first suggested that life may have spontaneously generated in a "warm little pond" in the presence of ammonia, phosphorus, and other inorganic salts with various energy sources (Peretó et al. 2009). Later, Oparin and Haldane independently developed the "primordial soup" hypothesis (Fry 2006; Kwolek 2013). Further, simple organic molecules either formed abiotically on Earth and/or exogenously transferred to the Earth's surface could have accumulated in the primordial soup. These organic molecules adsorbed on the various minerals would have increased their local concentration. Thus, components needed for the OoL may have been present in the same local environment. Indeed, it is difficult to imagine how molecules produced under one specific set of solvent or pH or temperature conditions, say RNA nucleotide or polymer, would be transported and remain stable in another environment where some other essential molecule, such as a lipid, had been synthesized in order to provide the molecular building blocks of a protocell. Following this idea, simultaneous, one-pot abiotic synthesis of RNA mononucleotides, amino acids, and lipid precursors (*e.g.*, glycerol-1-phosphate) has been successfully demonstrated by reductive homologation (chain extension) of hydrogen cyanide driven by UV light (Patel et al. 2015), although a caveat is that a very high concentration of dissolved phosphate (up to 1 M) is required. Achieving such high concentrations under plausible early Earth environmental conditions is a challenge. Nonetheless, up to one order of magnitude less total dissolved phosphate ($\sim 80 \text{ mM}$) may be achievable under specific environmental conditions of temperature and specific atmospheric gas composition, including a particular carbon dioxide content after numerous wetting-drying cycles (Sahai and Schoonen unpublished data).

7.2.7.1 MEMBRANE-BOUND PEPTIDES AND NUCLEOTIDE OLIGOMERIC COMPLEXES

One example of co-evolution is offered by membrane-bound peptides. Membrane-spanning molecular complexes are proposed to have been the first “information-rich” molecules, which may have played important functions such as signal transduction and material transport across membranes by creating pores or defects (Pohorille et al. 2005; Bywater 2009; Wilson et al. 2014). These peptides would be more stabilized in lipid bilayer than in aqueous solution because of decreased interaction between water molecules and those N–H and C=O groups that are in the membrane, thus protecting the peptide from hydrolysis. More complex peptides with catalytic activity and channel-forming ability would have developed later in evolutionary history. The evolution of early membrane-bound peptides, which may have promoted transmembrane solute transport and energy transduction, could have eventually led to ATP synthases (Mulkidjianian et al. 2009).

The association of peptides with the protocell membrane may have affected protocellular processes such as enhancing RNA polymerization and replication. Positively charged arginine-rich peptides are well-known antimicrobial compounds to modern bacterial cells. These peptides associate with negatively charged cell membranes and hydrophobic amino acid portions of the peptide insert into the PL membrane leaflets (Bechara and Sagan 2013; Herce et al. 2014; Takeuchi and Futaki 2016). In a similar manner, basic and amphipathic/lipophilic peptides (with arginine, histidine, isoleucine, tryptophan, and phenylalanine residues) were found to associate with OA-POPC and pure POPC membranes (Kamat et al. 2015). In the process, the peptide was able to cross the PL bilayer and attract negatively charged RNA nucleotides encapsulated in the vesicle. This localized the RNA to the membrane. The extent of nucleotide localization was dependent on the number of positively charged and hydrophobic amino acid residues (Kamat et al. 2015). Increased cationic and hydrophobic characters in the peptide increased nucleotide localization. These results obtained in PL membranes were compared with FA (OA) membrane by using the same peptides. While some localization was observed, the extent was lesser in FA than in PL membranes. This is because of the electrostatic repulsion between the negatively charged RNA nucleotides in the vesicle and the OA in the inner leaflet of the membrane. Furthermore, strong electrostatic binding of the cationic peptide to the outer leaflet of the OA membrane compared with weaker interactions with the zwitterionic PL membrane would also have limited translocation of the peptide into the membrane. These experiments suggest a possible route by which RNA could have been localized at protocell membranes, thus increasing their concentration at the inner leaflet, ultimately favoring subsequent RNA polymerization or replication.

Yarus and coworkers have found that PL membrane-bound supramolecular (trimeric) RNA complexes increased vesicle permeability to Na⁺ (Khvorova et al. 1999; Vlassov et al. 2001; Janas and Yarus 2003). Specific conformations of RNA

were needed for the ability to bind and change permeability. The RNA molecules probably interacted with the positively charged choline moiety of the PL membranes and remained external to the vesicles. These experiments were conducted on pure PL membranes, which probably do not reflect the earliest protocells.

7.2.7.2 SYNERGISM AMONGST CATALYSTS AND CO-EVOLUTION OF THE MOLECULAR BUILDING BLOCKS OF LIFE

Non-enzymatic RNA polymerization promoted separately by minerals, lipids, and peptide catalysis has been reported (Ferris and Ertem 1992; Rajamani et al. 2008; Wieczorek et al. 2013). Various possible interactions between the reaction catalysts or promoters are possible when they are present together (Kaddour and Sahai 2014). For instance, in synergism, one catalyst helps the other catalyst and the combined catalytic effect in the system is greater than the effect by the addition of the individual catalysts. In antagonism, one catalyst inhibits or decreases the activity of the other. In an additive effect, each catalyst can operate without the influence by the other, and thus, the combined catalytic effect is similar to the effect when added together (Kaddour and Sahai 2014). Synergism among prebiotic oligonucleotides, oligopeptides, and lipid molecules may have initiated protometabolic network and the co-emergence of self-replication and protometabolism (Copley et al. 2007; Li et al. 2013).

7.2.7.3 THE RNA-PROTEIN WORLD AND THE RIBOSOMAL PEPTIDYL TRANSFERASE CENTER

One of the proposals within the RNA-world hypothesis is that RNA ribozymes were eventually replaced by protein enzymes; this is known as the polymer transition stage. This assumption has been challenged because it is deemed strange that all putative ribozymes except one, the ribosome, have been replaced by random Darwinian evolution (Fox 2010; Bowman et al. 2015; Petrov et al. 2015). Williams, Hud, and co-workers argue that it is more likely that the ribosome and, specifically, the peptidyl transferase center (PTC), which constitutes the catalytic core of the ribosome, predated other RNA ribozymes (Hud et al. 2013; Bowman et al. 2015). The PTC core is proposed to have grown by accretion, ultimately resulting in the ribosome as we know it.

The above-mentioned hypothesis is based on observations about the ribosome in extant organisms. The size of ribosomal RNA (rRNA) tends to increase with increasing complexity of organisms, and the large ribosomal subunit is significantly greater in eukaryotes than in prokaryotes. However, a common core, which is structurally very similar across organisms, is maintained (Melnikov et al. 2012; Petrov et al. 2015). In this common core, the regions of the PTC, the decoding center, and tRNA-binding sites have not changed during billions of years of evolution (Ben-Shem et al. 2010; Petrov et al. 2015).

Petrov et al. (2015) have presented a molecular-level model for the origin and evolution of the translation system. Their model explains the evolution of the large and small ribosomal subunits, tRNA, and messenger RNA (mRNA) by accretion and adding expansion segments. The ribosome is proposed to have survived by existing in symbiotic relationship between protein and nucleic acid, suggesting early cooperation between polymers (polynucleotide and polypeptide) of different functions. Similar RNA-protein mutualism has also been suggested by others (Li et al. 2013; Carter 2015).

7.2.8 FROM PROTOCELLULAR TO PROKARYOTIC MEMBRANES

The transition of protocell membranes, whether composed of SCAs or “mineral walls,” to PL membranes was a key step in evolution. As discussed earlier, divalent cations may have acted as an environmental selection pressure in the transition of mixed FA-PL membranes, where small amounts of PLs were provided by abiotic synthesis, to predominantly PL membranes (Dalai et al. 2017). Many theories have been proposed for evolution and emergence of the three domains of life, namely, bacteria, archaea, and eukarya, with the widely accepted notion of the existence of the last universal common ancestor (LUCA) from which extant organisms have diverged (Woese and Fox 1977). These hypotheses are mainly based on the membrane composition of the LUCA.

Since bacteria and prokaryotes have PL membranes, it is widely accepted that the LUCA had a PL-based membrane. However, according to the phylogenetic tree of life, bacteria and archaea comprise the deepest branches of life and the archaeal cell membrane differs in both lipid composition and lipid biogenesis pathways (Koga and Morii 2007; Thomas and Rana 2007; Sojo et al. 2014). The bacterial and eukaryotic cell membranes are made up of FA chains linked to an *sn*-glycerol-3-phosphate (G3P) skeleton by ester bonds (Koga and Morii 2007; Thomas and Rana 2007). The archaeal cell membrane is generally composed of isoprenoid chains linked by ether bonds to an *sn*-glycerol-1-phosphate (G1P) backbone. The mevalonate or isoprenoid metabolic pathway

operates in archaea, in which isopentenyl pyrophosphate and dimethylallyl pyrophosphate are produced, which are eventually used for isoprenoid synthesis involving prenyltransferases (Figure 7.2.14).

Biosynthesis of G3P and G1P is catalyzed by different enzymes that are not evolutionarily related (Koga et al. 1998). Further, the glycerol units of PLs in all archaea and bacteria have opposite stereochemistry. These differences in their membrane chemistry is considered as one of the great unsolved problems in biology (Peretó 2005).

According to Wächterhäuser (2003), the LUCA might have had an unstable membrane with both the G1P and G3P backbone, which slowly diverged into organisms with more stable homochiral membrane. Thus, the LUCA might have existed with both the G1PDH (G1P dehydrogenase) and G3PDH (G3P dehydrogenase). It has been proposed that environmental factors may have led to the divergence of archaea and bacteria with different hydrocarbon chains (Valentine 2007; Lombard et al. 2012; Koga 2014). Supporting this proposal is the observation that archaeal and bacterial membranes reflect some similarities in their biosynthetic pathways. The glycerol phosphate (GP) backbone in both domains is synthesized by a reduction of dihydroxyacetone phosphate (DHAP), using NADH (Jain et al. 2014). Further, the headgroup attaches through a cytidine-diphosphate intermediate in both archaea and bacteria (Koga 2014).

A different perspective is that the LUCA had a cell wall composed of mineral pore surfaces, and its survival depended on the natural pH gradient of seawater mixing with alkaline white smoker vent fluids (Lane 2015; Sections 7.2.3 and 7.2.4.2). With the eventual evolution of an Na^+/H^+ antiporter pump, bacteria and archaea were able to diverge and escape from an “attached” mode of existence at mineral surfaces (Sojo et al. 2014).

Finally, the eukaryotes presumably emerged as a consequence of endosymbiosis (Margulis 1970, 1981), in which a bacterial cell hosted an archaeal cell (Lake and Rivera 1994). However, a large number of variations of the endosymbiont theory have been proposed, which are outside the scope of the present chapter. The reader is referred to an excellent recent review on the topic (Martin et al. 2015).

7.2.9 SUMMARY

The membrane is the defining boundary of a cell, the basic unit of life. Compartmentalization offered many potential benefits to the emergence of protocells of increasing complexity, from simple amphiphilic vesicles or mineral pore walls to modern cell membranes. Model protocell membranes exhibit a wide spectrum of interesting properties similar to, yet distinct from, those of modern PL membranes. Concentration of solutes within the membrane, competition between different populations of cells, development of bioenergetics, and cooperative interactions between different molecules ultimately leading to more complex ones with simple functions have all been shown to be promoted by membranes. Many of these elegant experiments have been conducted in special solvents, solution compositions, or temperature. The co-evolution of the molecular building blocks of life, and the development of folding and function, in the presence of the many cations and anions in geochemical aqueous solutions is one of the challenges in the OoL field.

ACKNOWLEDGMENTS

8.1.1 INTRODUCTION

8.1.1.1 THE TREE METAPHOR TO DESCRIBE EVOLUTION

Trees have a long history to depict genealogies of individuals (family trees) and interactions between living systems, including the biblical tree of life, the world tree in Mesoamerican cultures, and Yggdrasil in Norse mythology (Gogarten et al. 2008; Anonymous 2017). Mark Ragan in a well-illustrated article (Ragan 2009) describes trees and network diagrams that were used before Darwin to depict relationships between plants and animals. The first explicit description of evolution as a tree goes back to Jean-Baptiste Lamarck, although Peter Simon Pallas's description of the gradation between organisms came close to depicting evolution. Lamarck's tree-like diagram overlaid multiple chains of progress, each for a different lineage, into a single diagram (Lamarck 1809). Charles Darwin in his *Origin of Species* (Darwin 1859) provides a poetic description of the Tree of Life as an image of evolution, and the tree diagrams in his notebooks (Darwin 1836) illustrate the use of trees to depict shared ancestry. In his notebook, Darwin expressed concern about the tree metaphor, because in a botanical tree, the whole tree is alive, including the root, whereas in the tree-of-life image only the top layer is represented by living organisms (Darwin 1836; Olendzenski and Gogarten 2009), and his concern gained new prominence with the realization that molecular-based phylogenies usually only access data from extant or recently extinct species and that most organisms that ever existed on this planet belong to lineages that are now extinct (Zhaxybayeva and Gogarten 2004; Fournier et al. 2009; Fournier et al. 2015; Weigel 2017).

8.1.1.2 THE TREE IN LIGHT OF GENE TRANSFER

The exchange of genetic information between independent lines of descent and the fusion of independent lineages are deviations from a tree-like structure. The evolution of genomes is undoubtedly a highly reticulated network. While gene transfer is indeed rampant in most bacterial and archaeal lineages, and even appears to be frequent in eukaryotes (Soucy et al. 2015), most genes are transferred between closely related organisms (Andam and Gogarten 2011b). The transfer rate to organisms belonging to different orders and classes is several orders of magnitude lower than that of within genus transfers (Williams et al. 2012). Over short periods of time, most genes are passed on vertically (from mother to daughter cell). This majority signal over short periods of time can define the organismal lineage, even in the presence of rampant gene transfer. Garry Olsen used the metaphor of a rope to describe this. In a rope (the lineage), each fiber (the gene traveling through time) extends only over a very short distance. Nevertheless, the rope is a continuous reality. By analogy, the same can be said for the organismal lineage: Even if not a single gene travels through a lineage from beginning to end, the lineage can still be defined through the majority of genes being passed on over short time intervals (Zhaxybayeva and Gogarten 2004).

Instances of lineage fusion that occurred in case of the endosymbionts that evolved into mitochondria and plastids violate the tree paradigm, if one considers the host and the symbiont as equal contributors. However, these reticulations in the tree of life are rare (Martin and Herrmann 1998). In many or even all instances, the host cells genome dominates the gene content persisting in the symbiosis. In most instances, the phylogenetic signals resulting from shared

ancestry and from biased gene transfer reinforce one another (Andam et al. 2010; Pace et al. 2012). Therefore, while the history of genomes is highly reticulated, hope persists that careful examination of the phylogenetic signal retained in molecular phylogenies may result in an improved inference of life's early history (Williams et al. 2011). The phylogenetic information provided through transferred genes that persist in the recipient lineage might improve the reconstruction of early cellular evolution (Huang and Gogarten 2006; Szollosi et al. 2012) and allows to correlate evolutionary events in different parts of the tree of life (Gogarten 1995). However, emphasis has to be placed on "careful," because the uncritical application of computational screening tools may lead to unwarranted conclusions (Gogarten and Deamer 2016).

8.1.1.3 MOST RECENT COMMON ANCESTORS, ROOTS, AND STEM GROUPS

With the introduction of ribosomal RNA as a marker molecule, it became possible to place unicellular anucleate organisms onto a tree-like phylogeny (Woese and Fox 1977a). One immediate realization was that prokaryotes fall into two groups, now known as Bacteria and Archaea, previously labeled as Eubacteria and Archæabacteria. Willi Hennig developed a natural taxonomy, in which proper groups are defined by a common ancestor that is ancestor only to members of this group (Hennig 1966). Such a group is known as monophyletic. A group whose members all trace back to the same ancestor but this ancestor also gave rise to organisms that are not part of the group is known as paraphyletic, and is usually not considered as monophyletic. (However, see [Ashlock 1971], who defines monophyletic to include both para- and holophyletic groups.) In the now-traditional tree of life, the Archaea are the sister group to the eukaryotic nucleoplasm, and the ancestor of the bacteria and archaea is also the ancestor to the eukaryotes. Therefore, in a cladistics classification system, the prokaryotes are a paraphyletic group, and the name prokaryotes describes a grade (developmental stage) and not a proper group in a natural taxonomic system. However, naming groups based on properties has a long history and often makes intuitive sense, and many of these group labels are in common use (e.g., reptiles, whose most recent common ancestor (MRCA) is also ancestor to birds and mammals). Before the availability of molecular data, grades were often the only available classification scheme. For further discussion, see the exchange of opinions between Mayr (1998) and Woese (1998).

As an aside, a similar debate concerns the archaea: if the eukaryotic nucleoplasm emerged from within the archaeal domain ([Zaremba-Niedzwiedzka et al. 2017]; see [Da Cunha et al. 2017; Levasseur et al. 2017] for conflicting opinions), then either the archaea will need to be considered paraphyletic and/or eukaryotes and archaea need to be united into a single taxonomic group.

In considering a tree, or part of a tree, the MRCA of a group is the organism placed at the deepest (earliest) split between lineages leading to members of the group. In the field

of evolutionary biology, this MRCA is often described as the root of the group. In case of the tree of life that includes all cellular organisms, the root of the tree of life refers to that organism that existed at the deepest split, and this organism is also known as the Last Universal Common Ancestor (LUCA), the MRCA of all cellular life, or the organismal cencestor (Fitch and Upper 1987). This root of a phylogenetic tree is very different from a botanical tree, where the root is located at the base of the stem.

The stem group of a taxon is defined as the group of those extinct organisms that branch off the lineage leading the MRCA of that taxon. In case of the organismal LUCA, molecular evidence suggests that deeper branching lineages existed and contributed some genes through horizontal gene transfer to extant lineages (Fournier et al. 2009, 2015).

8.1.2 PLACING THE ROOT IN THE TREE OF CELLULAR LIFE

The tree of cells is embedded into network of gene trees. To find the root of a phylogenetic tree, different approaches are employed. The most common and widely accepted approach is to use an outgroup. In case of the tree of life, no organism can function as an outgroup, because in case of the tree of life, all organisms by definition are part of the ingroup. However, ancient gene duplications that occurred before LUCA can provide an outgroup to molecular phylogenies (Gogarten et al. 1989; Iwabe et al. 1989; Brown and Doolittle 1995; Gribaldo and Cammarano 1998). Dayhoff (1972) first had suggested the approach to use an ancient gene duplication to provide an outgroup. For most ancient duplicated genes, this approach places the root between bacteria on one side of the root and the archaea and the eukaryotic nucleoplasm on the other side. Using the unrooted tree of the translation machinery as reference, the root is placed on the branch leading from the central trifurcation to the bacterial domain; therefore, this placement of the root is also known as placing the root on the bacterial branch. The placement of LUCA on the branch connecting bacteria and archaea was also inferred by using ancestral sequence reconstruction for ribosomal proteins and by identifying the place in the unrooted tree of ribosomal proteins that has an amino acid composition that likely reflects the signal from the assembly of the genetic code; that is, proteins that evolved before the genetic code evolved to include all of today's genetically encoded amino acids should not include the later-added amino acids in conserved positions (Fournier and Gogarten 2010). A few scientists place LUCA in different places in the tree of life, either within the bacteria (e.g., Cavalier-Smith 2002; Skophamer et al. 2007) or within the archaea (Di Giulio 2007; Kim and Caetano-Anollés 2011). Often, these rootings are based on singular characters, for example, split genes (Di Giulio 2007) and the outer membrane of the Gram-negative bacteria (Cavalier-Smith 2002) or on novel approaches to reconstruct evolution (Cejchan 2004; Skophamer et al. 2007; Swithers et al. 2011). While the placement of the root remains under debate, most scientists,

including former critics of the rooting on the bacterial branch, agree that the root of the cellular tree of life is located between Bacteria and Archaea, and with the eukaryotic nucleoplasm grouping on the archaeal side of the tree (Puigbò et al. 2013; Forterre 2015).

8.1.3 THE PROGENOTE CONCEPT

Woese and Fox (1977b) defined the progenote as a hypothetical stage in evolution that existed before a strict coupling between genotype and phenotype had emerged, that is, before the typical features characteristic of today's prokaryotes had emerged: "Eucaryotes did arise from prokaryotes, but only in the sense that the prokaryotic is an organizational, not a phylogenetic distinction. In analogous fashion prokaryotes arose from simpler entities. The latter are properly called progenotes, because they are still in the process of evolving the relationship between genotype and phenotype". The progenote concept is related to the Darwinian threshold (Woese 2002) or Darwinian transition (Goldenfeld et al. 2017). After living systems passed this threshold, natural selection acting on cells drove the optimization of transcription and translation of genetically encoded systems. Below this threshold, life is assumed to have been characterized by a high rate of gene exchange. A high gene transfer rate in communal entities also allows for smaller genomes (Lawrence 1999) and may help to avoid an error catastrophe (Eigen 1971; Biebricher and Eigen 2005). Kandler (1994) described the same concept under the term pre-cell populations.

8.1.4 INFERRING PROPERTIES OF THE LAST UNIVERSAL COMMON ANCESTOR

Confusion regarding the term progenote resulted from Woese and Fox's assumption that the most recent ancestor of the three domains was a progenote (Woese and Fox 1977). In their and Kandler's vision (Kandler 1994), all three cellular domains independently trace their ancestry back to the progenote phase of life (see Figure 8.1.1 panel A).

In contrast, the many properties shared by all cells, and the fact that all ancient duplicated genes, including the aminoacyl tRNA synthetases themselves (Wolf et al. 1999; Woese et al. 2000; Fournier et al. 2011), make use of the same 20 genetically encoded amino acids and the observation that among the ancient duplicated genes are two subunits of the ATP synthase that translate transmembrane gradients for ions (sodium or hydrogen ions) into chemical energy stored in the ATP molecule (Gogarten et al. 1989) suggest that the LUCA was a cellular entity not too dissimilar from a modern prokaryote that possessed ribosomes for mRNA-directed protein biosynthesis, aminoacyl tRNA synthetase proteins to charge tRNAs, and membranes that were used for chemiosmotic coupling (Gogarten and Taiz 1992) (see Figure 8.1.1 panel B).

As discussed in Section 8.1.1.2, gene transfer has not erased all information that can be used to trace the evolutionary history of cell, and in many instances, gene transfer has generated

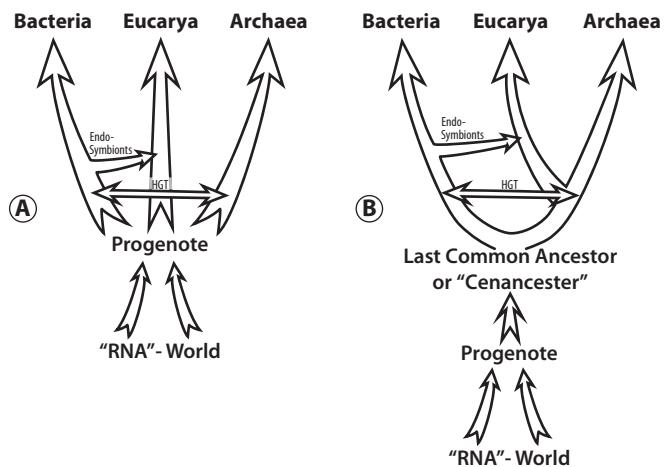

FIGURE 8.1.1 Two versions of the tree of life indicating the possible relations between the Last Universal Common Ancestor (LUCA) or cenancestor of all extant cellular life and the progenote phase of early evolution. The progenote describes a period in the evolution of cells before a strict coupling between genotype and phenotype had been established. During this phase, cells or pre-cells frequently exchanged genes with one another (see text for discussion). The sketch in panel A reflects the view popularized through the work of Carl Woese and Otto Kandler (Woese and Fox 1977b; Kandler 1994). In this version of the tree of life, the three domains of life evolved independently from the progenote. The sketch in panel B recognizes that the LUCA was a complex organism with an established coupling between genotype and phenotype (Gogarten and Taiz 1992; Delaye et al. 2005; Kim and Caetano-Anollés 2011; Goldman et al. 2013) and depicts the progenote as an earlier phase preceding the LUCA.

signals that allow to define groups and correlate evolutionary events in different parts of the tree. However, when trying to infer LUCA's properties from molecular phylogenies, wrong conclusions can be reached, when gene transfer events are mistaken for lines of vertical descent. In case of proteins with nearly universally distribution, such as amino acyl tRNA synthetase or the F/V/A-ATPases, careful analysis and comparison with other conserved proteins allow identification of branches in a molecular phylogeny that correspond to gene transfer event (Ibba et al. 1999; Wolf et al. 1999; Zhaxybayeva et al. 2005; Lapierre et al. 2006). However, this task is more challenging when genes are considered that do not have near-universal distribution. The automated detection of genes that were present in the LUCA faces two difficulties: either too many gene families are removed from consideration, because they show signs of horizontal gene transfer, or a gene transfer event that took place between archaea and bacteria is mistaken for the branch containing the LUCA (Gogarten and Deamer 2016). Weiss et al. (2016) used a computational pipeline to identify genes present in the LUCA. Many of the genes they identified as being present in the LUCA mistook a gene transfer event between the domains for the location of the LUCA. This is even true for genes that, according to more careful analyses, were present in the LUCA, such as the phenylalanine amino acyl tRNA synthetase (pheRS) subunits. The LUCA branch identified in Weiss et al. (2016) for these gene families

corresponds to a known transfer of the archaeal version of this enzyme to Spirochetes (Andam and Gogarten 2011a), whereas most of the bacterial pheRS genes were not included in the analysis. At present, reliable inference of genes to be present in the LUCA is limited to genes with nearly universal distribution. Analysis of less conserved genes encoding functions in metabolism faces hurdles, such as the decay of phylogenetic information and difficulties to identify gene transfer events. However, progress in gene tree-species tree reconciliation (Boussau et al. 2013; Sjostrand et al. 2014; Bansal et al. 2015; Wen and Nakhleh 2017) may make further progress possible.

Another source for inferring properties of early life is the analysis of genes that diverged before LUCA. At present, these analyses are restricted to ATP synthase and aminoacyl tRNA synthetase subunits (Fournier and Gogarten 2007), and information gleaned from these data is restricted to the assembly of the genetic code and the way tRNAs were charged during the early expansion of the genetic code (Fournier et al. 2011). While sequence data for most gene families may not be sufficiently conserved for this type of analyses, consideration of conserved protein folds might provide alternative avenues to characterize pre-LUCA evolution (see Koonin et al. 2006).

8.2.1 INTRODUCTION

Horizontal gene transfer (HGT) can be described as the transfer of genetic information between cells that are not in an ancestor-descendant relationship. In bacteria, this sharing of genetic information was first discovered in the 1940s (Tatum and Lederberg 1947). The comparison of molecular phylogenies with those of ribosomal RNA (rRNA) revealed that most gene families are not in complete agreement with the ribosomal tree of life (Hilario and Gogarten 1993; Woese et al. 2000). The best explanation for these conflicts is the HGT. While gene transfers between divergent lineages allow to correlate evolutionary events in different parts of the tree of life (Gogarten 1995), frequent and especially biased gene transfer also poses a problem for phylogenetic reconstruction (Gogarten et al. 2002). Advances in genome sequencing have revealed the HGT as the most important driving force in microbial evolution; however, gene transfer also occurs between eukaryotes and from bacteria and archaea to eukaryotes, often in the context of a close symbiotic association (see Soucy et al. 2015 for a recent review). In bacteria and archaea, transfer of small DNA fragments that integrate into the recipient genome through homologous recombination prevents genome-wide selective sweeps that would purge within-population diversity; the transfer of genes and operons can provide new capabilities to the recipients and allow them to

move into new ecological niches. The HGT is also an innovative force in microbial evolution (see Swithers et al. 2012 for a recent review): it is the main process for gene family expansion in bacteria (Treangen and Rocha 2011), and it played a role in extending existing and assembling new metabolic pathways (Boucher et al. 2003; Fournier and Gogarten 2008; Khomyakova et al. 2011).

8.2.2 DEFINITIONS OF PAN- AND CORE GENOMES OF TAXONOMIC GENOMES (STRICT AND EXTENDED)

Only a decade ago, most biologists, including microbiologists, expected that genomes from members of the same species had about the same gene content. Species definitions in plants, animals, algae, and fungi are linked to type specimen, and this rule has been extended to microbial taxonomy: type strains are used in the description of bacterial and archaeal species; they are deposited in culture collections, and they and their genomes serve as important taxonomic and phylogenomic reference points (Kyrpides et al. 2014). However, in contrast to eukaryotes, the genome of an individual type specimen captures only a tiny fraction of the gene content within a population. The pan-genome of a taxon or group refers to the sum of all genes present in

each individual (Tettelin et al. 2005; Lapierre and Gogarten 2009). Pan-genomes comprise the core genome, that is, the genes that are found in all members, and the accessory genome, that is, the genes that are present in only one or a few members of the group. Welch et al. (2002) provided the first illustration that genome content in bacteria changes rapidly. Comparing three *Escherichia coli* strains, they found the shared core to be less than 40% of the gene families present in all three genomes. More recently, the size of this core was further reduced to less than 10% of gene families present in 61 *Escherichia coli* genomes (Lukjancenko et al. 2010). When the number of gene families per genome encountered in a taxon is plotted as function of the number of genomes sampled, the resulting curve approaches a line that continues to rise. Pan-genomes that are characterized by these non-saturating rarefaction curves are considered open (Lapierre and Gogarten 2009; Lobkovsky et al. 2014; Puigbò et al. 2014). Obviously, pan-genomes cannot really have an infinite size, and rarefaction curves will saturate eventually. Baumdicker et al. (2012) provided a realistic estimation of the size of the pan-genome: taking population size and time since divergence into account, they estimated that the *Prochlorococcus* pan-genome contains about 58,000 genes—recently, this estimate was increased to 84,872 genes (Biller et al. 2015), whereas the individual *Prochlorococcus* genomes encode only about 2000 genes each.

The pan-genome concept was originally developed to describe the fluidity of prokaryotic genomes (Tettelin et al. 2005). Because HGT is more frequent between close relatives (Ravin 1963; Dykhuizen and Green 1991; Vulic et al. 1997; Gogarten et al. 2002; Andam and Gogarten 2011), the pan-genome also represents a set of genes that is more readily available via HGT to any member of the group. The pan-genome may then be thought of as a shared genetic resource of a population.

Large “open” pan-genomes are found for most bacterial and archaeal species. The most detailed study of population genomics was performed in *Prochlorococcus* (Kashtan et al. 2014; Biller et al. 2015), which showed that even in the presence of gene transfer within and between subpopulations, divergent subpopulations exist for long periods of time. These marine nanocyanobacteria provide about 50% of CO₂ fixation on this planet and constitute the largest known bacterial population (Lynch and Conery 2003; Baumdicker et al. 2012; Kashtan et al. 2014); the overall population is differentiated in high-light and low-light ecotypes, but within each of these ecotypes, many stable subpopulations exist (Kashtan et al. 2014). Gene flow between *Prochlorococcus* subpopulations, and between low-light-adapted *Prochlorococcus* and *Synechococcus* occurs frequently, transferring even DNA that encodes genes for ribosomal proteins and rRNA (Zhaxybayeva et al. 2009; Shapiro et al. 2012). For example, the internal transcribed spacer (ITS) region in the rRNA operon, while usually a good predictor and classifier for subpopulations, failed in two out of 96 instances compared with a strong coherent signal from whole genome sequences (Kashtan et al. 2014).

8.2.3 DESCRIPTION OF PROCESSES THAT LEAD TO GENES WITH LIMITED DISTRIBUTION

8.2.3.1 THE BLACK QUEEN HYPOTHESIS

The black queen hypothesis proposed by Morris et al. (2012) is built on the premise of “leaky” common good functions, that is, gene encoded processes that lead to products that benefit a population or community, not only the producer. This hypothesis suggests that leaky functions combined with selection for small genomes may lead to a situation in which these leaky functions are encoded in only a fraction of the genomes comprising the community. The name “Black Queen” originates from the card game “hearts,” where two winning strategies exist, one is to acquire all hearts and the most valuable queen of spades, and the other strategy is to divest as many hearts and the queen of spades as possible. Applied to genomes, these strategies correspond to (A) maintaining a keystone genome that includes all necessary genes or (B) to lose as many genes encoding leaky functions as possible.

1. The cell can retain all genes encoding leaky functions (in the game of hearts, this strategy is known as “shooting the moon”). The cost is a large genome and, consequently, a lower growth rate and a decreasing frequency in the population. The advantage is that following a population bottleneck, all genes encoding leaky functions are available in the genome. If they exist, these members of a community may be thought of as analogous to keystone species.
2. The cell loses some or all of its leaky functions and increases its growth rate (in hearts, this represents the usual strategy of taking as few point cards as possible). The cell that no longer produces the leaky function relies on a common good provided by other cells. If a bottleneck occurs, a cell following this strategy is unlikely to survive on its own, provided the leaky product is not provided by other species. A possible outcome of all cells in a population following strategy B is that all members of a population cheat on some leaky functions.

Division of labor rather than cheating may be a more appropriate description, especially in those cases where a keystone genome is no longer present in the population and all individuals in the population are dependent on some common good produced by others (black queen hypothesis [Fullmer et al. 2015]). Widespread cheating can lead to the tragedy of the commons; Oliveira et al. (2014) found that stable cooperation through reciprocal exchange was unlikely to emerge in evolution under the models and parameters tested; however, experimental work by Morris et al. (2014) has shown that producers and consumers of the leaky product, in their case H₂O₂ detoxification, can enable the stable co-existence of two very similar organisms that use the same resources. Additionally, most bacterial and archaeal cells live in biofilms or small aggregates (Kolter and Greenberg 2006;

Stemmann and Boss 2012) and therefore are more likely to be close to cells with whom they share recent ancestry and are more likely to have the same genotype with respect to leaky functions. These neighborhood relations are expected to increase frequency-dependent selection on genes encoding these functions. For example, Drescher et al. (2014) showed that *Vibrio cholerae* can avoid the public goods dilemma by strengthening relationships between cells of the same genotype through creation of a thick biofilm, leading to larger benefits of the producers, when the overall concentration of the public good decreases.

Not all cheating leads to mutual collaboration. In addition to frequency-dependent selection, other mechanisms exist to slow the emergence of cheaters. In the production of common goods, for which lower levels of synthesis are detrimental for the whole population and that are under the control of quorum sensing, the emergence of cheaters that ignore the quorum sensing signal was found to be counter-selected through quorum sensing signals also controlling the synthesis of private goods (Dandekar et al. 2012), in this case adenosine catabolism.

8.2.3.2 THE RED QUEEN HYPOTHESIS—GENES ALTERING THE INTERACTIONS WITH VIRUSES AND OTHER PARASITES

Van Valen (1973) proposed the red queen hypothesis. It was proposed to describe the necessity for ongoing evolution in the arms race between biological species. Bacteria and archaea are under severe virus predation (Thurber 2009); in addition, members of the same population compete for limited resources. Therefore, selection pressure to evade predation and outcompete niche rivals causes a constant genetic arms race in cellular and viral populations, hence the analogy to the Red Queen from Lewis Carroll's *Through the Looking-Glass* (Carroll 1871; Carroll and Gardner 1993), who states that *it takes all the running you can do, to keep in the same place* (Van Valen 1973). The analysis of phage metagenomes and rank abundance curves indicated that phage predation follows the *kill the winner* strategy (Hoffmann et al. 2007), where successful strains in a population are targeted more frequently. The surprising stability of species composition, despite phage predation, suggests that cycling between different susceptible target cells is more frequent within a population than between populations from different species (Rodriguez-Brito et al. 2010). Consequently, within a population, host genes that are utilized by phage and virus to enter the cell are expected to turn over quickly, creating within-population diversity (Chaturongakul and Ounjai 2014), as will genes that are costly otherwise but provide anti-viral resistance (Hille and Charpentier 2016).

Chemicals and peptides that act as antibiotics are often produced by separate members of the same species and population, resulting in a fitness advantage of resistant bacteria. Conflict is more commonly observed between isolates from

different locations, and cooperation dominates between conspecifics (Cordero et al. 2012); however, this does not mean that conflict does not arise in populations: the observation by Cordero et al. of conflict between conspecifics being largely absent may be due to selection for antibiotic resistance having already successfully occurred within populations (*i.e.*, the non-resistant members of the population have died out).

8.2.3.3 SELFISH GENETIC ELEMENTS AND SELECTIVELY NEARLY NEUTRAL GENES RANDOMLY ACQUIRED

In most lineages, genomes constantly acquire and lose genes. Some genes provide a selective advantage to the recipient and will become fixed in the population. However, many of the transferred genes do not find permanent homes in recipient genomes (Lawrence and Ochman 1997; Mira et al. 2001). Among these genes are parasites (prophages) and selfish genetic elements. Most, but certainly not all (Lobkovsky et al. 2013), of the transferred genes are selectively neutral or nearly neutral to the recipient (Gogarten and Townsend 2005; Baumdicker et al. 2010; Haegeman and Weitz 2012). These genes do not persist in the genomes they "visit," and their loss also has little impact on fitness (Bolotin and Hershberg 2015, 2016).

8.2.3.4 NICHE-ADAPTING GENES AND WEAKLY SELECTED FUNCTIONS

In the case when a population is present in different neighboring ecological niches, genes that adapt their carrier to a particular niche, such as virulence genes and genes that encode metabolic pathways, may be present in a subpopulation only. In addition to spatial heterogeneity, many genes are used only temporarily under some circumstances; for example, a phosphatase that releases phosphate from extracellular macromolecules is under purifying selection only when inorganic phosphate is a limiting nutrient. Lawrence and Roth (1996) in developing the selfish operon theory describe these genes as encoding a weakly selected function.

8.2.3.5 COLLABORATION AND UNITS OF SELECTION

For many decades, especially since the formulation of the Gaia hypothesis by Lovelock and Margulis (Lovelock 1972; Lovelock and Margulis 2011), some considered microbial communities, and in the extreme all bacteria and archaea existing on Earth, as a single superorganism. This idea was spearheaded by Sorin Sonea (1988a, 1988b) and is based on the observation that bacteria and archaea can share genes between cells that are not in a parent—descendent relationship. Related is the question on units and levels of selection (gene, individual organism, population, and community) (Soucy et al. 2015). Dawkins (1976) introduced a gene-centered view of evolution, in which all genes are selfish, although most express their selfishness in collaboration with other genes to build an organism with increased fitness. Evolution can be studied and described by selection acting

on individuals, resulting in changing gene frequencies within populations (Graur 2016). In the case of selfish genetic elements (non-cooperating genes, molecular parasites), at least initially, the benefit or cost to the individual is small, especially in case of self-splicing elements, and the element can spread in the population as a parasite, limited only by its transmissibility. Levels of selection are often intertwined, and selection at the gene level (e.g., spread of metal- or antibiotic-resistance genes or Ti plasmids that allow utilization of a particular food source) often also provides a strong benefit at the group level (e.g., avoiding severe bottlenecks, thereby maintaining within-population diversity); however, in most instances, it is doubtful that group-level selection was the driving force to share these genes (Olendzenski and Gogarten 2009; Naor et al. 2016). Life is a densely woven fabric: viruses, plasmids, and selfish genetic elements contribute to constructing the fibers, composition, and pattern of life's fabric.

8.2.4 MECHANISMS FOR GENE TRANSFER

Genes can be transferred horizontally by a variety of mechanisms. Traditionally, conjugation (DNA is transferred between cells through a specialized machinery), transduction (DNA is transferred through phages), and transformation (DNA is taken up from the environment into a cell) are distinguished. Related to these are gene transfer agents (GTAs) and cell fusion and, in eukaryotes, introgression and endosymbiotic (aka, intracellular) gene transfer. Some of these categories are not clearly separated, and, in many instances, rather different processes and machineries are lumped together into a single category. In case of multicellular eukaryotes, the fact that genes were transferred has been established in many instances, (e.g., Stewart et al. 2003; Graham et al. 2012). Mechanisms for these transfers have been proposed (e.g., the weak-link model, Huang 2013); however, the details for these transfers remain to be established.

8.2.4.1 CONJUGATION

Conjugation was first described by (Lederberg and Tatum 1946). Cells make contact through a pilus, and a newly synthesized strand of DNA is transferred through a pilus into the recipient cell. The dedicated conjugation machinery often is plasmid-encoded, and often, only the plasmid is transferred into the recipient. However, if the plasmid is integrated into the chromosome, or if the machinery is encoded on the chromosome (Derbyshire and Gray 2014), chromosomal DNA is transferred.

A single bacterial cell can possess multiple conjugation machineries, for example, *Agrobacterium tumefaciens* possesses a machinery that it uses to transfer T-DNA into plant cells (Joos et al. 1983) and another system for conjugation with other bacteria (Alt-Mörbe et al. 1996) that is under control of quorum sensing and following the successful transformation of a plant catalyzes the transfer of the Ti-plasmid between different *Agrobacterium* strains (White and Winans 2007).

8.2.4.2 CELL FUSION

Many archaeal cells often form intricate networks with connections between individual cells (Rosenshine et al. 1989; Stetter 2013). During mating in *Haloferax volcanii*, these connections lead to exchange of cytoplasm between the mating cells. Fused heterodiploid cells can be recovered, in which recombination between the two parental chromosomes has been detected (Naor et al. 2012).

8.2.4.3 TRANSDUCTION

Phage particles can pack host DNA in addition or instead of the phage DNA. In case of generalized transduction, a random piece of host DNA is packaged into the phage particle and delivered to a recipient cell; in specialized transduction, a prophage imprecisely excises itself from the host genome and delivers neighboring genes to the host. In addition, many phages include genes in their genome that do not play a function in phage replication. These genes have been termed morons, and in case of lysogenic phage, these genes can have a large impact on the host bacteria (Hendrix et al. 2000; Cumby et al. 2012). For example, the toxins in botulism, diphtheria, and cholera all are encoded as morons in prophage genomes (Brussow et al. 2004), reflecting the interrelation between selection on the phage, the bacterial symbiont, and the eukaryotic host.

8.2.4.4 GENE TRANSFER AGENTS

Gene transfer agents can be described as prophages that have lost the ability to recognize and preferentially package their own DNA. They were described in five different groups of bacteria and archaea. The best studied GTA is the one in *Rhodobacter capsulatus*. See Lang et al. (2017) for a recent review. The frequency of occurrence in some groups of Alphaproteobacteria argues that the GTAs are more than defective prophages; however, the mechanisms of GTA maintenance remains under debate (Lang et al. 2012; Omer et al. 2017). The GTA head is too small to package all of the GTA encoding genes, and the release of GTAs is accompanied by the lysis of the bacterium. The latter thus constitutes an ultimate fitness cost to the bacterium activating its GTA, and the former makes it impossible that a complete GTA gene cluster can be transferred to a new host.

8.2.4.5 TRANSFORMATION

Transformation is the uptake of exogenous DNA from the environment. This was first demonstrated by Fredrick Griffith (1928) in *Streptococcus pneumoniae*; the transforming principle was later shown to be DNA (Avery et al. 1944). Transformation has been described for both archaea and bacteria (Chimileski et al. 2014; Johnston et al. 2014). Some bacteria are naturally competent (Johnston et al. 2014), while others can be transformed after special treatment. Naturally competent bacteria often have an uptake bias in favor of DNA

similar to their own, preferentially taking up DNA that contains motifs that bind to the uptake machinery (Mell and Redfield 2014). In other cases, DNA uptake is biased by being under the control of quorum sensing and occurring (by definition) only when there are many nearby conspecific donors that often were the victims of fratricide (Claverga and Håvarstein 2007; Borgeaud et al. 2015).

8.2.4.6 INTROGRESSION

In eukaryotes, hybridization between species, followed by repeated backcrosses to one of the parent species, allows for gene flow across species boundaries. This process is of concern in case of transgenic crops that grow in the neighborhood of their non-domesticated relatives (Stewart et al. 2003). Adaptive introgression also has occurred in human evolution through hybridization between archaic human lineages and modern humans (Racimo et al. 2016).

8.2.4.7 ENDOSYMBIOTIC OR INTRACELLULAR GENE TRANSFER

Gene transfer in eukaryotes is frequently between symbionts and their host. In case of the endosymbionts that evolved into mitochondria and plastids, only a few genes remain in the organellar genome; most genes are transferred to the nucleus, where they are transcribed and translated in the host cell's cytoplasm, and the encoded proteins are transported into the organelle. This transfer from endosymbiont to host has been described as intracellular or endosymbiotic gene transfer (Adams et al. 1999; Timmis et al. 2004). Many other transfers likely have happened from symbiont to host (see Soucy et al. 2015 for discussion); for example, many chlamydial genes found in Archaeplastida (plants and algae with primary plastids) were suggested to have contributed to integrating plastid and host (Huang and Gogarten 2007; Tyra et al. 2007), and in case of secondary plastids that evolved from endosymbiotic eukaryotic algae, gene transfer from many other sources occurred (Archibald et al. 2003); however, in many other cases, once the endosymbiont is lost from a lineage, only the transfer from a bacterium to a eukaryote remains detectable.

8.2.5 CONCLUSION

Gene transfer has turned the evolution of genomes into a network. The tree of cells is embedded in this network. Gene transfer is biased and can create patterns of apparent relationships between genomes that are undistinguishable from patterns due to shared ancestry. However, because a strong bias is toward close relatives, gene transfer tends to reinforce the patterns due to shared ancestry. Gene transfer allows for the spread of selfish genetic elements and the acquisition of neutral and slightly deleterious genes, but it also allows for the long-term persistence of weakly selected functions, turning the population pan-genome into shared genetic resource.

8.3.1 BASIC CONCEPTS OF VIRUSES IN RELATION TO EVOLUTION

8.3.1.1 VIRUSES AND THE DEFINITION OF LIFE

It is strange that entities so small that they can only be visualized under the extreme magnification of the electron microscope may have played a key role in the origins of life and may have continued to play a key role in the evolution of biodiversity to the present day. We call these entities “viruses.” But what are viruses? In reality, they are difficult

to define. Most folks’ opinions on viruses are somewhat negative. They associate them with disease, such as AIDS, smallpox, and polio. Life is usually defined as “cellular” in form and function. Viruses are non-cellular. Yet they have many properties of what we think of as organismal. They are “born” within the living cells of their hosts. They reproduce themselves, albeit with the assistance of host molecular chemistry. They can be killed by viricidal drugs and through a range of physical insults. The majority of viruses have genomes based on DNA, although a significant minority

has genomes based on RNA. Only recently have we discovered that viruses outnumber all other organisms in the biosphere, including bacteria (Koonin and Dolja 2013). Indeed, the introduction of viral metagenomics has demonstrated that the dominant viruses in environmental communities are poorly represented in the traditional studies of cultured viruses in existing sequence databases (Rosario and Breitbart 2011). Viruses evolve through the same established mechanics of evolution as cellular life. They are commonly defined as “obligate parasites,” but this definition is now seen to be too narrow to accommodate the wide range of interactive relationships that viruses share with their hosts. In recognizing viruses as organismal, Forterre and Prangishvili (2009) suggest that they represent capsid-encoding organisms, as opposed to the ribosomal-encoding organisms, which denote cellular life-forms. Others argue that, while useful, even this capsid-related definition may be too restrictive to cover the field of viruses (Koonin et al. 2015). To understand viruses, and this more comprehensive role of viruses in the origins of life and its subsequent diversity, we need to examine the fundamental processes of evolution.

8.3.1.2 THE BASIC MODALITIES OF EVOLUTION

When Darwin proposed his theory of natural selection to explain the origins and subsequent diversification of life, he knew that it depended on both a system of heredity—in his days referred to as “pedigree”—and some mechanism, or range of mechanisms, capable of altering heredity. Nature could only select for advantages in the struggle for existence between individuals, or populations, where it was presented with a range of variations between those individuals and populations. For Darwinian selection to operate, the advantageous variation had to be inherited by subsequent generations. Today, we know that somatic characters are determined by the particulate hereditary nature of genes, and those genes, together with the machinery that regulates them, are

intrinsic to the genetic and epigenetic inheritances that pass from parents to offspring. In sexually reproducing organisms, this involves a mixing of the heredity of the parents through sexual homologous recombination during the formation of the germ cell through meiosis. In Darwin’s days, the particulate nature of genes was unknown. Instead, it was assumed that sexual mixing was somewhat akin to the blending of liquids and that the variation resulting from sexual mixing within a species was sufficient, over lengthy periods, to give rise to speciation. But by the early years of the twentieth century, with the growing understanding of genes and genetics, biologists realized that sexual recombination was not a credible source of the hereditary variation needed to give rise to speciation. Speciation demanded definable and measurable mechanisms capable of changing heredity—mechanisms sufficient to give rise to the dramatic differences that we now witness in the great diversity of genomes throughout biodiversity.

Evolutionary change does not begin with natural selection. It begins with genomic change arising in individuals, then spreading to family groups through asexual and sexual reproductions, and then being incorporated into the species gene pool through being selected as an advantage for survival by natural selection. Four distinct and definable mechanisms capable of changing heredity are listed in Table 8.3.1. These include mutation, epigenetic inheritance systems, genetic symbiosis, and hybridogenesis (MESH).

Mutation, in this classification, is defined as errors in copying DNA during meiosis and mitosis. We have gathered these mechanisms under the collective umbrella of “genomic creativity.” We employ the term “genomic” and not merely “genetic” to include epigenetic inheritance systems, which do not necessarily imply change in DNA sequences, and we employ the term “creativity” to emphasize the fact that these mechanisms are creative in themselves. Mutation includes a variety of different patterns of change, including, for example, point mutations, where the error comprises the erroneous copying of a single nucleotide, and frameshift mutations,

TABLE 8.3.1

This Table Illustrates the Important Differences Between the Four Mechanisms that Create Hereditary Change as Part of the Evolutionary Process. Mutation Is Defined as Mistakes in Copying DNA During Meiosis and Mitosis. Epigenetic Change Implies Change in Epigenetic Inheritance Systems. Symbiogenesis Is Explained in the Text. Hybridogenesis Is Genetic Change Through Sexual Crossing Between Closely Related Species that Gives Rise to Reproductively Fertile Offspring

Operative Mechanism	Genetic Change	"GENOMIC CREATIVITY"			
		Nature of Genomic Change	Level at Which Selection Works	Pattern of Phylogeny	Amenable to Environmental Influences
Mutation	Yes	Usually random, cumulative	Mainly individual gene, organism	Linear, branching	No
Epigenetic	No	Change in gene expression	Epigenetic inheritance system	Linear, branching	Yes
Symbiogenesis (genetic)	Yes	Non-random, rapid	Holobiont	Reticulate	No
Hybridogenesis	Yes	Non-random, rapid	Hybrid genome	Reticulate	No

which derive from a deletion or insertion of nucleotides, which disrupts the subsequent triplet coding system and renders the protein non-functional.

Epigenetic inheritance systems are a less familiar, yet uniquely important source of hereditary variation, including methylation of C-G couplets in gene promoter areas, the histone code, RNA interference, and long- and short-chain non-coding RNAs. Hybridogenesis, which implies evolution through sexual crossing of dissimilar species, is also a powerful evolutionary force in its own right, with a single hybridization event capable of creating a major increase in genomic complexity in subsequent generations. Viruses may be involved in several of these mechanisms. For example, genetic symbiosis involving endogenous viruses has played a key role in the evolution of animal and plant genomes.

Symbiosis was first defined in the 1870s by de Bary as the “living together of dissimilar organisms.” Today, this might be translated to significant interaction between different organisms, which are referred to as symbionts. When it gives rise to evolutionary change, this is termed “symbiogenesis.” While sometimes mistakenly assumed to refer exclusively to mutualism, in fact, symbiosis embraces commensalism, where one or more organisms benefit from the association, without causing harm to their partners; parasitism, where the parasite benefits at the expense of the partner; as well as mutualism, where two or more partners benefit from the symbiotic relationship. Mutualisms often begin as parasitism and evolve to include stages somewhere between the two extremes. Mutualistic symbiosis involves life-supporting exchanges between partners. For example, mycorrhizal “root-fungus” interactions are vital to all terrestrial plants, where the plant benefits from the fungal absorption of water and minerals from the soil, meanwhile the fungus benefits from the energy-giving products of photosynthesis carried from leaves to roots. This is termed a “metabolic symbiosis.” Some symbioses involve mutually supportive behavioral interactions. An example of this is seen in the feeder stations on the floor of the ocean, where large fish, such as sharks and groupers, benefit from having their skins and mouth cavities cleansed of parasites by shrimps and small fish. A third, and very important, level of symbiotic interaction is at the genetic level. At its simplest level, this may involve the transfer of a single pre-evolved gene, or a package of genes, from one evolutionary lineage to another. At its most powerful, it involves the union of whole disparate genomes, to create a novel “holobiontic genome,” usually uniting the genome of a host with the whole genome of a microbial symbiont. This was the mechanism of origin of chloroplasts and mitochondria, which involved the union of microbial genomes with what is believed to have been a protist host some 2 billion or so years ago (McFadden 2001; Ryan 2009). It was also the mechanism of origin of the endogenous retroviruses (ERVs) that have repeatedly invaded the nuclear genomes of animals and mammals, in particular over the whole of their evolutionary time, with considerable implications for animal evolution (Ryan 2016). From these, and many other examples, viruses have engaged in a wide variety of symbioses with their hosts, including parasitisms, commensalisms, and mutualisms (Ryan 2007). For this reason, we suggest that it is no longer sufficient

to define viruses as “obligate parasites” but rather as “obligate symbionts.” This widening of definition makes possible a more comprehensive enlightenment of the role of viruses in the origins and subsequent diversification of life.

8.3.1.3 EXTRAPOLATING TO THE PREBIOTIC STAGE OF EVOLUTION

Darwin envisaged that natural selection must have operated from the very earliest stages of the evolution of life. Indeed, several of these basic mechanisms of evolution would readily extrapolate to the purported stage of prebiotic evolution that led to self-replicating chains of nucleotides. There has been much debate as to the nature of such prebiotic evolution, in particular the possibilities that might have led from basic chemistry to molecular evolution (Lazcano and Miller 1996; Cronin et al. 2017; Shirt-Ediss et al. 2017). The discovery that RNA can serve genetic, catalytic, structural, and regulatory roles led to the proposal of an RNA-based world as a key stage in prebiotic evolution (Rich 1962; Gilbert 1986). Proponents have outlined how, from the presumptive stage of competing RNA polynucleotides, the more complex stages of proteins, DNA, and protocellular life might have arisen (Alberts et al. 2002; Copley et al. 2007). In the half century or so, since this theory was first proposed, the idea has gained traction, provoking scientific debate and criticism (Robertson and Joyce 2012; Lehman 2015; Patel et al. 2015). For example, Bernhardt, who detailed the contradictions implicit in the argument and labeled it the “worst theory of the early evolution of life” was nevertheless forced to admit that it remains the best theory we can currently envisage (Bernhardt 2012). Mutation of RNA polynucleotide chains, through copying errors during replication, would be capable of giving rise to heritable change in the sequences of daughter chains, just as it does in biotic evolution today. Where two different pre-evolved chains coalesced to create a larger and more complex informational chain, this might be seen as the prebiotic equivalent of genetic symbiogenesis. If, as we can assume, natural selection then operated on the resultant mutants, or genetic holobionts, the more successful self-replicators would be more likely to dominate the local population. There are additional implications for the self-replicator stage of evolution that might be extrapolated from current theories of evolution and that are specific to viral patterns of evolution.

8.3.1.4 AN ALTERNATIVE PERSPECTIVE OF EVOLUTION IN THE FORM OF BIOLOGICAL INFORMATION SYSTEMS

Philosophically inclined authors have offered an alternative to the traditional organismal perspective, proposing that evolutionary biology can be viewed as an epiphenomenon of integrated self-referential information management (Miller 2017). In extrapolating the biocommunicative approach to role of viruses in the tree of life, Villarreal and Witzany (2009) look at evolutionary genomics from the bioinformatic perspectives of biolinguistics and biosemiotics. Viruses share sequences

with, and have a close affinity to, transposable elements (TEs), which are found throughout the genomes of living organisms. In examining the contribution of viruses and transposable elements to adaptation and evolution, Oliver and Green (2012) have developed a comprehensive and predictive hypothesis, the “TE-Thrust” hypothesis, which examines the holobiotic potential of such elements to generate genetic novelties. This includes an active mode using transposition—the mobility within and between genomes first mooted by Nobel Laureate Barbara McClintock (1956, 1984)—which includes the exaptation of TE sequences as promoters, exons, or genes. It also includes a passive mode, which when present in large homogeneous populations, can cause ectopic DNA recombination, resulting in genomic duplications, deletions, or rearrangements.

In developing the importance of the virosphere to the evolution of life and biodiversity, it is important to grasp that viruses not only transfer *genes* between themselves and their hosts. It is still much commoner for viruses to transfer *virus-derived information* (Villarreal 2014). Stable transfer of the entire informational content of a virus is a definition of viral persistence. Even transfer of partial (defective) viral information can lead to virus-host persistence at a population level. This stable colonization of host leading to viral persistence is in fact a form of genetic symbiosis.

8.3.1.5 AN A PRIORI ROLE FOR "AGGRESSIVE SYMBIOSIS"

Symbiosis, like nature, is assuredly not benign. When different organisms enter into a symbiotic evolutionary partnership, the partners arrive with pre-evolved abilities specific to each partner that, in the case of mutualism, contribute improved chances of survival to the other partners and thus to the survival of the symbiotic relationship. It seems somewhat counter-intuitive to consider that one of the properties that protoviruses, like their successor viruses, were capable of contributing is a lethal aggression. The fact that, again like their successor viruses, they inhabit the landscape of the genome of their host cells, or prototypical self-replicators, affords them a powerful means for such “aggressive symbiosis.” We shall examine the concept of aggressive symbiosis in relation to the viruses of eukaryotes in a later section.

8.3.2 A VIROCENTRIC APPROACH TO THE ORIGINS OF LIFE

8.3.2.1 THE VIRUS-FIRST MODEL FOR THE ORIGINS OF LIFE

The origin of viruses is essentially unknown, leading to a variety of theories for viral origins. Four main theories have been posited: the “virus first” theory proposes a primal origin in the prebiotic era of the Earth’s evolution; the “reduction” hypothesis proposes a viral origin from a previous unicellular stage of evolution; the “escape” hypothesis proposes an origin from genetic material that escaped from the control of cellular life-forms to become parasitically self-driven; and a fourth theory proposes that viruses may have polyphyletic origins (Bremermann 1983;

Villarreal 2005; Forterre 2006; Koonin et al. 2006; Fisher 2010). While acknowledging that all four theories have their pros and cons, and also while accepting the possibility of polyphyletic origins for viruses as a whole, we favor a virus-first hypothesis for the origin of RNA viruses. A major criticism of the virus-first hypothesis has been the belief that viruses could not have evolved before there were cellular hosts for them to parasitize (Nasir et al. 2012). We suggest that this is based on a mistaken premise.

When the self-replicating stage of evolution is set up in microbiological laboratory settings, or as “digital organisms” settings in computer simulations, parasitic elements are seen to invade and then interact with the self-replicators (Bremermann 1983; Takeuchi and Hogewoog 2008; Bansho et al. 2012; Zaman et al. 2014; Colizzi and Hogeweg 2016). We see such parasites of self-replicators as prototypes of RNA virus evolution. Those who promote the concept of viruses as originating from cellular ancestry would need to explain how several genes coding for key proteins involved in viral replication and morphogenesis are shared by RNA- and DNA-based viruses but are missing from cellular life-forms (Koonin et al. 2006). They would also need to explain how the vast majority of viral genes, and viral proteins, including the major capsid protein of icosahedral DNA- and RNA-based viruses, are found to have no cellular homologues (Prangishvili and Garrett 2004; Koonin et al. 2006).

The virus-first hypothesis is also supported by the strongly inverse relationship between genome size and mutation rates across all replication systems, suggesting that the earliest genomes were likely small and highly error prone—a situation that typifies RNA viruses (Holmes 2011). This prompts us to suggest that RNA viruses are likely to have evolved from ancestral forms that existed during the very earliest phase of protolife, that of self-replicating RNA-based molecules. In this, we are largely in agreement with Forterre (2006) and Koonin et al. (2006). We suggest that the virus-first model offers a logical construct for the evolution of viruses as well as their ever-present and continuing role in the evolution of their natural hosts.

We propose that the prebiotic stages of evolution must have operated in an environment of aggressively symbiotic protoviral genetic agents, the prebiotic equivalent of what, in the biotic era, we call the “virosphere” (Ryan 2009; Koonin and Dolja 2013; Villarreal 2014). Current opinion raises the possibility that life may have evolved in the vicinity of deep-sea hydrothermal vents. A search of such environments, at temperatures above 80°C, revealed a morphological diversity of virus-like particles greatly exceeding the number found in aquatic systems at lower temperatures. Viruses are potentially aggressive, a property that, conferred on a symbiotic partnership of virus and host, has powerful evolutionary potential (Ryan 1997). As aggressive symbionts, viruses are eminently capable of both killing and protecting their hosts. Such biological and evolutionary power, combined with the extraordinary genomic creativity of viruses, makes them the ultimate aggressive symbionts (Ryan 1997, 2009). The fact that self-replicating entities with properties suggestive of prototypical viruses so readily manifest in laboratory and computer simulations that resemble the presumptive RNA world and the

fact they are such powerful players in the killing or survival sense, combined with their genomic creativity, suggest that virus-host interactivity is likely to have been a fundamental driving mechanism in the origins of life and also in its subsequent diversification. Viruses are adept at transferring genetic “information” between themselves and their hosts. Indeed, judging from metagenomic analysis, the transfer of genetic information is far commoner from virus to host rather than from host to virus (Koonin 2001). The only organisms with RNA-coded genomes today are RNA-based viruses, suggesting that we might derive helpful insight into the prototypical RNA world from the study of RNA-based viruses. One such clue is their potential to evolve as quasispecies in the form of genetically interrelated consortia.

8.3.2.2 THE CONCEPT OF RNA-BASED QUASISPECIES BEHAVIOR

In 1977, Eigen and Schuster introduced the concept of “quasispecies” as an explanation for the self-organization of clusters of prebiotic macromolecule chemicals, such as polynucleotides, in such a way as to conform to Darwinian natural selection (Eigen and Schuster 1977, 1978a, 1978b, 1979). This was subsequently extrapolated to the concept of “viral quasispecies theory,” in which swarms of viruses, all closely related to one another through shared mutations, compete for existence in a highly mutagenic environment. While such a high mutation rate would normally be predicted to result in non-viable virions, quasispecies theory posits that, in the case of RNA viruses, it creates a “cloud of potentially beneficial mutations” at the population level, which affords the viral quasispecies an advantage of adapting to novel environments and existential challenges (Holland et al. 1992; Vignuzzi et al. 2006). The theory predicts that in such a scenario, quasispecies will compete with one another. The theory further predicts that a viral quasispecies operating at a low but evolutionarily neutral and highly connected (graphwise flat) region of the fitness landscape will outcompete a quasispecies located at a higher but narrower fitness peak, in which the surrounding mutants are unfit (Nimwegen et al. 1999; Wilke et al. 2001). Surprisingly, it has been observed experimentally that in the quasispecies situation, less fit viral mutants will even suppress more fit mutants (De la Torre and Holland 1990). This suggests that the evolving RNA virus population has a fitness associated with its quasispecies components rather than the conventional “master fittest” model. Quasispecies theory has been extrapolated to the evolutionary behavior of retroviruses, such as human immunodeficiency virus (HIV)-1, in infected patients. The virus-encoded reverse transcriptase enzyme has an error rate of about 10^{-4} to 10^{-3} per base, and thus, patients infected with HIV-1 are found to harbor a highly diverse viral population with many different mutant strains (Nowak 1992). We suggest that inherent to the evolutionary behavior of quasispecies is a collective function and group identity (Villarreal 2014). Indeed, we go further and suggest that a similar RNA-mediated group identity may have facilitated the origins of life during the presumptive RNA world stage.

We acknowledge that a virus-first emergence from the prototypical RNA world would the acquisition of “group identity” in the form of quasispecies consortia.

We have already suggested that, in the RNA world, the RNA-based self-replicators would inevitably be colonized by what would formerly have been termed RNA-based selfish elements; this we would now amend to aggressive RNA-based proto-symbionts behaving with quintessential virus-like behavior. These aggressive symbionts could function as a consortium, in the way clones of mutating retroviruses behave today, but to truly represent a concept of self, they would also need to have a second key development: the operation of what virologists call “an addiction module” that would equate to a prototypical equivalent of “self” (Villarreal, 2005, 2014). We shall deal with the addiction module strategy in more detail in relation to the prokaryotes later. Here, we argue that such key evolutionary features as group identity, addiction module, regulatory complexity, and virus-host ecology are fundamentally linked. In other words, we view the evolution of the whole as a key step in the establishment of life on Earth.

8.3.2.3 THE VIRAL ROLE IN THE EVOLUTION OF LIFE

We propose that proto-viruses arose during the stage of pre-biotic life. We now know that any genetic self-replicator, even a non-cellular prebiotic example, is susceptible to parasitism by other replicators adopting quintessentially virus-style behavior. This tendency for the “parasitic” replicators themselves to become further “parasitized” is a well-established phenomenon in virology (Villarreal 2005). Indeed, we can extend this understanding to the wider conceptualization of the symbiotic nature of viruses defined earlier. This virus-like invading sequence would potentially be capable not only of parasitic colonization type behavior but also of commensal and mutualistic interactions with the “host” self-replicator. This suggests that the earliest “proto-virus” may have come into being at the same time and quintessentially in a profound symbiotic interaction with the purported RNA world of self-replicators. Even at the pre-biotic stage of the RNA world, RNA-virus quasispecies patterns of behavior might offer further enlightenment on an important question in the evolution from chemical precursors to definable life.

8.3.2.4 THE RNA “GANGEN” HYPOTHESIS

The capacity of a particular RNA virus quasispecies to out-compete and displace any former quasispecies was observed in the 1990s (Clarke et al. 1994). In fact, the quasispecies is fitter than any individual member because of complementation, sharing of gene products among its members, and interference with some members and non-members, and hence, including the preclusion of prior quasispecies. The importance of such an evolutionary pattern was confirmed when it was further observed that to attain disease-associated fitness, the RNA virus needed to generate a virus diversity that acted cooperatively (Domingo et al. 2012). From an understanding of such RNA-based quasispecies evolution, it was possible

to construct a primary model of group identity, based on a complementary collective of stem-loop RNA molecules with group identity mediated by cooperative subfunctional agents that together provided both the replication and functional endonuclease features of an addiction module. This group identity, coupled with the distinguishing features of an addiction module, offers the possibility that it may have conferred on the evolving quasispecies the first primitive identification of “self.” Thus, a society of subfunctional RNA agents offers a logical theory for the predecessor of the first RNA-based life-form. This is the proposed basis for the “RNA gangen hypothesis” (Villarreal 2014).

8.3.3 VIRUSES, PROKARYOTES, AND THE ECOLOGY

8.3.3.1 VIRUSES IN THE EVOLUTION OF PROKARYOTES

Prokaryotes are microscopic organisms that lack a nucleus and possess no internal organelles other than ribosomes. Their genomes comprise a confluent circle, which is attached to the bacterial cell wall at a single fixation point. Prokaryotes were the first known cellular life-forms to evolve on Earth, roughly 3.8 billion years ago. Today, their descendants comprise two of Woese’s three domains of life, the Eubacteria and the Archaea. Woese painted a vivid scenario for the origins of cellular life when “genetic temperatures” were very high and the primitive cellular entities, which he called “progenotes,” were very simple (Woese 1998). He assumed that the boundaries of “self” were less strictly defined in such early stages of organismal evolution, so that information processing systems were somewhat inaccurate and mutation and lateral genetic informational flow were elevated in relation to what we see today. Viruses are likely to have played an important role in this evolution of complexity, since viruses have an extraordinary capacity both to generate complexity in terms of neogenes and to transmit such novelty to their cellular hosts (Villarreal 2005). In the last decade, microbiologists have belatedly come to realize the vital role of the viruses of prokaryotes as “a major component of the biosphere” (Krupovic et al. 2011). This new understanding, which one eminent authority has labeled “the great virus comeback” (Forterre 2013), has come about through the expanding fields of evolutionary biology, genetics, genomics, metagenomics, and population dynamics, opening our vision to the fact that viruses are both essential agents within the tree of life (Villarreal and Witzany 2009) and key to understanding the complex dynamics of major ecologies. Today, we have come to realize that the non-cellular capsid-encoding world of viruses and the three domains of cellular life have been entwined in a complex labyrinth of formative evolutionary interactions since the dawn of evolution (Durzyńska and Goździcka-Jósefiak 2015).

The full range and taxonomy of prokaryotic viruses have undergone a major expansion, with consequent reclassification and renaming in recent years (Krupovic et al. 2016). Both the Eubacteria and the Archaea are “parasitized” by DNA- and

RNA-based bacteriophage viruses, which follow two different cycles in how the parasitism—what we would term the aggressively symbiotic interaction—progresses. In the so-called “lytic cycle,” the virus hijacks the bacterial genetic machinery, so the prokaryotic cell becomes a factory for the manufacture of daughter viruses, which are released into the ecology with the destruction (lysis) of the cell. In the “lysogenic” cycle, the virus inserts its DNA into the prokaryotic genome, where the viral insert is now termed a “prophage,” and the phage DNA is reproduced in tandem with the prokaryotic host genome during the budding type of reproduction. Luria and Darnell, while acknowledging that bacteria and their viruses were likely to have shared a lengthy genetic inter-relationship, posited an origin of viruses after the origins of primitive cells and most likely deriving from mobile cellular genetic elements that were capable of transmissibility and self-replication from one cell to another (Luria and Darnell 1967). While it is likely that such creative evolutionary interactions between viruses and the prokaryotic domains have been ongoing and universal, there are difficulties with the Luria-Darnell theory of viral origins from mobile cellular genetic entities. Modern metagenomic analysis indicates that the direction of genetic transfer is far more commonly from virus to host (Koonin 2011). Forterre (2006), in an analysis of more than 250 cellular genomes from Archaea, Bacteria, and Eukarya, showed that most of the proteins detected in viral genomes have no cellular homologues. The most plausible explanation, deriving from this, is that viruses had a separate evolutionary origin from prokaryotic cellular life. The interesting recent discovery of a plasmid that transferred its genetic information to the host cell, an Antarctic haloarchaeon, was hailed by its authors as supporting the escape hypothesis for viral origins (Erdman et al. 2017). Perhaps, it does. But there is an alternative explanation, in which the evolution of all three cellular domains, together with their parasitizing viruses, was interactively complex, involving continuing and bi-directional genetic transfers that began at the very origins of life from protobiotic self-replicating chemicals and are continuing to the present day. We shall illustrate what we mean by this with some examples.

8.3.3.2 VIRAL PERSISTENCE AND AGGRESSIVE SYMBIOSIS

We have seen how viruses have an extraordinary ability to transfer genes, which might be regarded as genetic information, to their hosts (Koonin 2011). Stable transfer of the entire “information content” of the virus to the genome of the host could also be defined as “viral persistence” (Domingo et al. 1998). While viruses have, in the main, been considered from the perspective of disease, many viruses establish species-specific persistent, often unapparent, infections that are stable on an evolutionary timescale (Villarreal 2007, 2009a, 2009b). Such persistent infections can have large effects on relative reproductive fitness of competing host populations and, indeed, can promote host population survival. Viruses stably colonize their host genomes. In prokaryotes, virus killing and virus protection combine to become a truly creative and cooperative

force. In effect, we are witnessing a combination of both symbiotic and competitive behaviors, which is increasingly seen as key to understanding how evolution works.

Such viral persistence leads to stable interactions at metabolic, behavioral, and genetic levels (Villarreal 2005; Villarreal and Ryan 2011). This virus-host dynamic is very ancient in its origins, and it is ongoing and inherently symbiotic. One remarkable example of such virus-host interactions is the above-mentioned “addiction module.” P1 is a stable episomal DNA-based prophage of *Escherichia coli* frequently found in wild isolates, and it appears to be capable of interfering with infection of its host bacterium by other phages (Yarmolinsky 2004). First discovered by Yarmolinsky’s group at the National Institutes of Health, it was found to be a persistent and lysogenic phage with a remarkable stability, which was mediated by an addiction module. This comprises a stable protein toxin and a less stable protein antitoxin that act in a curious but very effective coordination. Loss of phage presence in daughter generations of *E. coli* as a result of cell division does not lead to “curing” of the daughter cells of the “infection” but rather to the killing of the same cells by the remaining stable toxin. This dynamic phage-bacterium interaction is further complicated by involvement with the cell’s own programmed death systems, which ensures maintenance of the P1 phage while also inhibiting its own lytic spread. The presence of P1 will also kill cells infected by other phages. Indeed, this system creates yet another primitive recognition of “self” in what might be seen as a forerunner of the acquisition of adaptive immunity (Villarreal 2005, 2009a, 2009b; Villarreal and Witzany 2009). Because a single virus type can be either lytic (harmful) or latent (protective) in a particular host, the virus itself has the capacity to promote a “virus mediated” addiction module by preventing the lysis of colonized host, as long as the latent virus is retained by the host, and this applies even to retention of a defective version of the virus. Thus, aggressive symbiosis emerges from stable virus colonization.

8.3.3.3 VIRUSES AS MAJOR PLAYERS IN THE ECOLOGY

Over the last decade or so, we have come to realize that the virosphere, which comprises the junctional zones where viruses interact with their myriad hosts, spans all environments where life is to be found. Viruses are the most abundant biological entities in many different environments, exceeding the numbers of cellular life-forms, including prokaryotes, by one or two orders of magnitude (Koonin and Dolja 2013). Genetic diversity of viruses is commensurately enormous and might substantially exceed the genetic diversity of cellular organisms (Hambly and Suttle 2005; Rosario and Breitbart 2011; Koonin and Dolja 2013).

The oceans teem with prokaryotic viruses (Suttle 2007). Marine virologists have estimated that there are 10^{31} tailed bacteriophage viruses on Earth (Krupovic et al. 2011). Equally surprising is the discovery, through metagenomic analysis of the marine virosphere of four different oceanic regions, that most of the viral sequences extracted from these ecologies

are unlike the known sequences in current databases. Global genetic diversity was very high, suggesting several hundred thousand of hitherto unrecognized species (Angly et al. 2006).

Such colossal numbers of phage viruses, with such high genetic diversity, make it likely that viruses play important roles in the planet’s ecosystems, exerting a significant, perhaps dominant, force on the evolution of their bacterial and archaeal hosts. Thus, it is not altogether surprising that, besides being a major cause of disease and mortality in every life-form, viruses are also drivers of global geochemical cycles (Suttle 2005; Rosario and Breitbart 2011). Through prokaryotic lytic and lysogenic cycles, phage viruses impact the oceanic carbon, nitrogen, and phosphorus ecological cycles, having a major effect on the availability of nutrients in the marine ecosphere and terminating algal blooms (Fuhrman 1999; Wilhelm and Suttle 1999; Wommack and Colwell 2000). Identical bacteriophage sequences have also been found in a wide variety of different marine environments, suggesting that there is an extensive circulation of viral genes among distantly related host populations. It is unlikely that the presence and importance of viruses are confined to oceanic ecologies. Up to the present, we simply have not searched sufficiently for them elsewhere. But, with the expansion of metagenomics, this situation is changing.

8.3.3.4 A VIRAL ROLE IN THE ORIGINS OF PHOTOSYNTHESIS

The evolution of photosynthesis by cyanobacteria was a major step in the evolution of complex life. Cyanobacteria are one of the earliest branching groups of organisms on Earth. They are also the only known prokaryotes to carry out oxygenic photosynthesis—in other words, to capture the energy of sunlight for metabolic purposes—meanwhile producing oxygen to enter the ambient ecology as a by-product. The complexity of the photosynthesis machinery leaves no doubt that its origin and subsequent evolution involved multiple steps under constant selection pressure. This selective pressure came from two key factors: the need for energy to feed the cell’s metabolic activities and the concomitant need to reduce the damaging effects of solar ultraviolet (UV) radiation, which was at more toxic levels than today because of the absence of an ozone shield (Mulkidjanian et al 2006). From the original photosynthetic cyanobacteria, the capacity for photosynthesis spread to other prokaryotes within the same taxonomic group and, further through a series of genetic symbiogenetic incorporations, to eukaryotic protists and beyond to the kingdom of the plants (Bonen and Doolittle 1975; Sagan 1967). Such repeated horizontal gene transfers suggest the involvement of viral transferases and ultimately phage viruses in what must have been a very complex and long-term process during the evolution of photosynthesis. The marine cyanobacterium *Prochlorococcus* is “infected by” three phage viruses from two viral families, *Mycoviridae* and *Podoviridae*. Analysis of the phage genomes reveals that the genes that encode the photosystem II core reaction center protein D1 and a

high-light-inducible protein (HLIP), *hli*, which are central to oxygenic photosynthesis, are present in the viral genomes. The mycoviruses also contain additional *hli* genes, one of which encodes the second photosystem II core reaction center protein D2 (Lindell et al. 2004). The authors conclude that the bacteriophage viruses may be mediating the expansion of the *hli* gene family by transferring these genes back into their hosts after a period of evolution within the phage virus. The authors concluded that these gene transfers were likely to play a role in the fitness landscape of hosts and bacteriophage viruses in the surface oceans.

Phylogenetic examination of the genomes of the two key organelles, chloroplasts and mitochondria—themselves of microbial symbiogenetic origins in photosynthetic eukaryotes—has revealed historic bacteriophage symbiotic interaction. For example, mitochondrial RNA polymerase, DNA polymerase, and DNA primase are likely to have been contributed by T3/T7 bacteriophages, with authors suggesting that the prophage was present in the ancestral α -proteobacterium at the very origin of mitochondria (Filée and Forterre 2005). The same authors report another T3/T7 viral-like RNA polymerase in chloroplasts, indicating that strong selection pressure has favored replacement of some cellular proteins by viral alternatives during organelle evolution. This same group extended the examination more broadly to the role played by viruses in the evolution of their hosts, concluding that such is the level of lateral gene transfers from viruses to cells and non-orthologous gene replacements of cellular genes by viral ones that viruses should be considered major players in the evolution of cellular genomes (Filée et al. 2003).

8.3.4 VIRUSES IN THE EVOLUTION AND DIVERSIFICATION OF THE EUKARYOTES

8.3.4.1 VIRAL SYMBIOSIS IN THE ORIGINS AND DIVERSIFICATION OF THE EUKARYOTES

The explosive evolution of eukaryotic life, with its complexity and diversity, was accompanied by a parallel explosion of novel viral evolution, involving all three modalities of symbiotic interaction, namely parasitism, mutualism, and commensalism and including dynamic intermediate situations (Villarreal 2005; Ryan 2009; Witzany 2012). The eukaryotic viruses are much more varied than those of prokaryotes, being grouped into many different families, subfamilies, and genera, with further subdivisions based on the degree of antigenic similarity. Classification is imprecise beyond this point, since virus families cannot readily be placed into branching taxonomic trees; although modern genomic and protein analysis has discovered interesting relationships between some that may point to common ancestries in the remote past. Nomenclature is somewhat random, with some viruses named after the diseases they cause, for example, the pox (from “pocks” or skin ulcers) viruses, while others based on acronyms, such as the papovaviruses (from *papilloma–polyoma–vacuolating agent*), and still others based on morphological features or even the places where they were first discovered (Collier and Oxford 1993). Today, viruses, and

virus-like “selfish genetic elements,” are ubiquitous to life (Forterre 2013). The same author considers viruses to have polyphyletic, if also truly ancient, origins. We argue that all through the ages, from the self-replicators through 3 billion years exclusive to the prokaryotes and the evolution of the ensuing diversity of eukaryotes, the same deep interrelationship between viruses, and virus-linked genetic entities, and life has been essential and formative. This is amply illustrated when we consider the evolution of eukaryotic viruses.

Where, in the origin of viruses and the evolution from the stage of self-replicating chemicals to that of prokaryotic life, we inevitably encounter mysteries, the further evolution from prokaryotic viruses to the present-day world of eukaryotes has the benefit of potential genomic exploration of both stages and their viruses in the present day. In contrast to the prokaryotes, where the majority of viruses are double-stranded DNA-based bacteriophages, it is both curious and interesting that the majority of eukaryotic viruses are RNA-based (Koonin et al. 2015). Phylogenetic analysis reveals “tangible clues” to the origins of positive-strand RNA viruses of eukaryotes from double-stranded RNA-based bacteriophages or from positive-strand RNA viruses. Meanwhile, the same authors suggest that different families of double-stranded DNA viruses of eukaryotes may have originated from specific groups of bacteriophages. They conclude that the evolution of all classes of eukaryotic viruses is likely to have involved the amalgamation of various structural and replicative genetic modules deriving from different sources. Such an evolution would, in part, be facilitated through prolonged and extensive virus-host interactions, resulting in holobiontic genomic unions. Indeed, it is enlightening to consider some examples of such a pattern of evolution.

8.3.4.2 A POSSIBLE VIRAL ROLE IN THE ORIGIN OF THE EUKARYOTIC NUCLEUS

In 1967, Lynn Margulis, writing under her married name of Sagan, published a now-famous article, in which she proposed the “Serial Endosymbiotic Theory” for the origin of the eukaryotic cells, including their intrinsic organelar structures, mitochondria, plastids, and flagellae (Sagan 1967). This involved a key holobiontic genomic merger of a thermo-plasma-like Archaean and Spirochaete-like eubacterium. This gave rise to an amitochondriate chimera capable of evolving to a primal eukaryotic protist, which generated the nucleus as a complex series of evolutionary steps deriving from a component of the “karyomastigont,” an intracellular complex that ensured genetic continuity of the former bacterial symbionts (Margulis et al. 2000). Margulis’s theory of endosymbiotic origins of mitochondria and plastids has withstood the test of time (López-García et al. 2017), though the same authors do not support the spirochaete origins of flagellae. The karyomastigont theory for the nucleus has also been challenged. In 2000, a viral origin was proposed for the eukaryotic replication proteins (Villarreal and DeFilippis 2000). The eukaryotic replicative DNA polymerases are dissimilar to those of eubacteria but bear similarities to the polymerases of large

DNA viruses that infect eukaryotes as well as the polymerases of T4 bacteriophages. In examining the DNA polymerase from phycodnavirus, which was chosen because it infects the primitive eukaryotes, microalgae, these authors found significant sequence similarities to the polymerases of eukaryotes and certain of their large DNA viruses. Subsequent reconstruction of a phylogenetic tree by these authors indicated that these algal viral DNA polymerases are near the root of the clade containing all eukaryotic DNA polymerase delta members and that this clade did not contain the polymerases of other DNA viruses.

In 2001, Bell put forward a hypothesis for a viral origin of the eukaryotic nucleus (Bell 2001), and the same author subsequently developed this to the “Viral Eukaryogenesis Hypothesis” (Bell 2009). A recent study supported this hypothesis with the report of the assembly of a nucleus-like structure during viral infection and replication by a *Pseudomonas chlororaphis* bacteriophage infecting a strain of *Pseudomonas* eubacterium, in which a phage-encoded tubulin-like cytoskeletal protein (PhuZ) formed a bipolar spindle that positioned the replicating viral DNA at the cell midpoint, apparently compartmentalizing and segregating phage and bacterial proteins according to function (Chaikeeratisak et al. 2017). Proteins involved in DNA replication and transcription were localized inside the compartment; meanwhile, proteins involved in translation and nucleotide synthesis were localized outside the compartment. In the words of the authors: “This subcellular compartmentalization of enzymes and DNA resembles the organization of eukaryotic cells containing a nucleus. In this, and the expanding modern scientific experience, viruses, formerly excluded from mainstream biological consideration, are now “taking centre stage in cellular evolution” (Claverie 2006).

This viral theory for the origin of the eukaryotic nucleus is challenged by López-García et al., above, who broadly support the Margulis’s theory of nuclear origin from symbiogenetic fusion of archaea and bacteria, with the nucleus most likely deriving from an archaean of an Asgard or related lineage. Meanwhile, Witzany (2008) has proposed a viral origin for the telomeres and their enzymes, the telomerases, that play an important role in the physiological health of chromosomes.

8.3.4.3 AGGRESSIVE PLAGUE DYNAMICS

Even in the case of the extreme interactions of virus and host that accompany an epidemic, or pandemic, plague virus and host can be seen to affect one another’s evolution. Aggression *per se* may thus be seen to play an important role in the origins of some persisting evolutionary partnerships. Moreover, this capacity for aggression, initially directed at the subsequent partner species, may later be directed at a rival or prey of the partner species after the co-evolutionary association evolves. The virus-host dynamics in the myxomatosis epidemic of Australian and subsequently European rabbits is an illustrative example of this. The wild European rabbit, *Oryctolagus cuniculus*, was first introduced into Australia in 1859 as a source of food for British settlers. Lacking

natural predators, the rabbit population underwent an explosive expansion, leading to widespread destruction of agricultural grassland. In 1950, in a deliberate act of biological warfare, feral rabbits in southeastern Australia were infected with a myxoma pox virus of the genus *Leporipoxvirus* (Fenner and Kerr 1994), known to infect the South American rabbit, *Sylvilagus brasiliensis*.

The myxoma virus gives rise to a persistent infection in rabbits. After initial arrival, it never abandons its new host, generation after generation, co-evolving with—a virological term that is essentially the equivalent of symbiotic with—the host species. In its evolved relationship with the Brazilian rabbit, the virus caused little in the way of illness, but some strains of this virus were known to be exceedingly lethal to the European rabbit. High lethality strains were injected into a test group of rabbits, which were released into the wild. In this way, the innate aggression of a potentially “plague virus” was employed to control a “plague of rabbits.”

Although no evolutionary experiment was planned, the methodology and outcome are now seen to provide a model with stark evolutionary implications. In retrospect, we might visualize the release of infected rabbits into the wild as creating a situation analogous to virgin contact between the two rabbit species in nature, with the Brazilian rabbit already symbiotic with its myxoma virus. Surprisingly, little happened after the first release of the infected rabbits. But the virus is spread in nature by biting insects. After proliferation of mosquitoes during a wet spring, the epidemic exploded. Within 3 months, 99.8% of the rabbits of southeast Australia, a land area the size of Western Europe, were exterminated. Had this been the result of a natural coming together of the two rabbit populations, it seems likely that viral aggression would have decimated the Brazilian rabbit’s rival, thus allowing the Brazilian rabbit-plus-virus to dominate the ecology.

In this man-induced scenario, there was no evolutionary rival to take advantage of the cull. Instead, the aggressive symbiotic evolutionary dynamics of virus and host took a different course and a pattern we shall return to in relation to the dynamics of HIV-1 in humans. We must assume, in the rabbit example, that the myxoma virus culled the most susceptible genotypes of Australian rabbit population, selecting a minority genotype capable of surviving its lethal presence. Culling was followed by co-evolution between the virus and its new host, so that, within 7 years, the lethality of what was now an endemic infection was reduced to 25%. This same evolutionary symbiosis between rabbit and virus has continued to the present, when the rabbit population, still persistently infected with the myxoma virus, is now almost completely resistant to its former lethality. Indeed, the rabbit-plus-virus holobiont now occupies the ecology in large numbers.

8.3.4.4 A SUCCESSFUL EVOLUTIONARY STRATEGY OF AGGRESSIVE VIRAL SYMBIOSIS IN INSECTS

Another exemplar of aggressive symbiosis as an efficient evolutionary strategy is that of the parasitoid wasps. These include approximately 25,000 species in symbiotic partnerships with

approximately 20,000 species of polydnnaviruses. In many instances, the wasps inject their eggs into the lepidopteran caterpillar prey. In some relationships, the virus inhabits the tissues of the wasp ovaries and the eggs are coated with virus as they emerge into the ovipositor. But in many other relationships, the viral genome has been integrated into the wasp genome (Whitfield 1990). These “unique symbiotic viruses,” with a segmented genome of circular double-stranded DNA, replicate from integrated proviral DNA in the wasp ovary (Martí et al. 2003; Wyler and Lanzrein 2003) and are injected as fully infectious viruses along with the wasp egg into the host, where they are essential for the wasp larval survival. Genetic analysis of the wasp genomes reveals major change to incorporate the genomes of the symbiotic viruses. Analysis of the polydnnaviruses has also revealed a complex reorganization of their genomes in an adaptive response to the holobiontic relationship (Espagne et al. 2004). The discovery of a conserved gene family in viruses of different wasp subfamilies led Provost et al. (2004) to propose a common phylogenetic origin of all such symbiotic partnerships. Estimations of the first establishment of the symbiosis, based on mitochondrial and nuclear sequencing, suggest a unique integration event 73.7 ± 10 million years ago (Belle et al. 2002; Whitfield 2002), illustrating powerful selection stability of the virus-wasp symbiosis over time.

It is important to grasp how such aggressive symbioses work. Selection is no longer working exclusively at rabbit or myxoma virus level, or at wasp or polydnnavirus level, but also to a significant degree at the “holobiontic” level of rabbit-plus-virus and wasp-plus-virus. The symbiosis of parasitoid wasps with their viral partners is believed to be one of the most successful survival strategies among the insects.

8.3.4.5 VIRULENCE VERSUS MUTUALISM: ACUTE AND PERSISTENT VIRAL STRATEGIES

Study of virulence in viral infections suggests that the level of virulence is predicated on the relationship between degree of virulence and evolutionary success in terms of infection rate and ultimately viral reproduction. In the case of some viruses, notoriously so in cases such as smallpox and pandemic influenza in humans, extreme virulence and high mortality would suggest that such virulence offers the most efficient route to viral reproduction. As we have seen with the Australian rabbit epidemic of myxomatosis, a similar high virulence and mortality characterized the virus-host interaction to begin with. But then, the virulence and mortality ameliorated as the virus-host relationship evolved to mutualism. It is noteworthy that both the symbiotic partnerships of the myxoma virus and rabbit and the parasitic wasp and its polydnnavirus involve persistent infections— infections that never abandon the host once virus and host become associated.

Such persistent viral infections, extending through vast numbers of generations, allow the evolutionary time necessary for a mutualistic symbiosis to develop and consolidate. But even in the acute and highly virulent phase of a lethal virus pandemic, symbiotic interactions between virus and host are

demonstrable. Thus, we find that even at the height of the AIDS pandemic, a multi-center study of the virus-host dynamics revealed a telling series of findings (Kiepiela et al. 2004). The rate of disease progression was strongly associated with the human leukocyte antigen HLA-B but not HLA-A allele expression. HLA-B is a gene coded within the major histocompatibility complex of the human genome—the part of the genome that determines “self” from foreign and governs the immune reaction to microbial invaders. The same authors concluded that substantially greater selection pressure was imposed on HIV-1 evolution by host HLA-B alleles than by HLA-A. They also concluded that HLA-B gene frequencies in the human population were those likely to be most influenced by HIV disease. In other words, at the height of the AIDS pandemic, virus and host were influencing the evolution of one another. This is quintessentially a symbiotic pattern of evolution.

8.3.4.6 VIRUSES OF PLANTS

When, approximately half a billion years ago, the liverwort-like forerunners of plants first colonized dry land, the oceans already teemed with prokaryotic life, with its aggressively interactive virosphere (Wellman et al. 2003). Photosynthesis, with its consequent oxygenation of atmosphere, had long been established in the oceans. The colonization of the land masses with plants was equally prone to interaction with viruses as was the animal kingdom. Indeed, the first virus to be discovered was the *Tobacco mosaic virus* (TMV), which was identified as a “filterable virus” by the eminent Dutch microbiologist Beijerinck in 1898. Most of the historic work on plant viruses was directed at their potential for disease in food plants, which cause billions of dollars in loss of crop yields annually. From the taxonomic perspective, plant viruses have been grouped into 49 families and further subdivided into 73 genera: genetically, these include circular double-stranded DNA viruses; circular single-stranded DNA viruses; single-stranded RNA viruses; negative single-stranded RNA viruses; double-stranded RNA viruses; and unassigned viruses, satellites, and viroid.

Plants are sedentary. To transmit from one plant to another, plant viruses must make use of environmental factors, such as wind and moving water, and vectors such as biting insects, nematodes, plasmodiophorids, browsing animals, and seed and pollen dissemination—not to mention the potential for transfer of viruses through widespread human intrusion, including all manner of farming, into hitherto wild ecologies (Zaitlin and Palukaitis 2000; Gray and Banerjee 1999; Verchot-Lubicz 2003). As with animal viruses, most of the earlier studies of plant viruses have focused on viral pathogens, where the devastation of agriculture by emerging viral epidemics in cultivated crops appears to follow similar host-pathogen evolutions as seen in animals, whether resulting from familiar pathogens evolving new virulence in the same hosts or through the arrival of a totally new pathogen arising from intrusion into, or proximity to, a reservoir virus in a wild or natural ecology (Elena et al. 2011, 2014). Deeper evolutionary and ecological studies in plants and

their viruses are largely still awaited. But we might reasonably infer that emerging plague viruses would cull the newly colonized host plant genotype, much as we have seen in animals, and, in the case of persisting viral infection, are likely to enter into long term co-evolutionary symbiosis with their hosts (Fraile and García-Arenal 2010).

8.3.4.7 EXAMPLES OF PLANT VIRUS EVOLUTION

Symbiotic partnerships sometimes include more than two partners. A well-known and ecologically important symbiosis involves viruses, bacteria, and plants intrinsic to the nitrogen cycle, in which soil-based rhizobial bacteria—also discovered by Beijerinck—provoke the development of root nodules in host plants, such as legumes. Here, the rhizobia fix atmospheric nitrogen into more complex organic nitrogenous compounds, which are then available for not only the host plants' metabolism but also uptake and digestion by browsing animals (Larenjo et al. 2014). Where the bacteria provide nitrogenous compounds to the plant, the plant also feeds the bacteria with carbon-rich organic compounds, constituting a metabolic symbiosis vital to the nitrogen cycle and thus biodiversity. However, many strains of soil-based rhizobia lack the fixation and nodulation genes necessary for this metabolic symbiosis. But they can gain this ability through a genetic symbiosis with a rhizobial strain known as *Mesorhizobium loti*, which carries the necessary genes within a 500-kb “symbiosis island” (Sullivan and Ronson 1998; Long 2001). Here, we discover a second twist to the story. The symbiosis island can only be transferred from a fixing to non-fixing strain of rhizobium through the contribution of a P4 bacteriophage integrase gene that is intrinsic to the symbiosis island. The integrase is the smoking gun that points to a preceding bacteriophage-rhizobial genetic symbiosis.

Virus colonization of hosts can also lessen the effects of environmental stress. For example, a tropical panic grass can survive the high soil temperatures of geothermal soils of the Yellowstone National Park through the triple symbiotic interplay between the plant, a fungus, and a virus within the fungus (Márquez et al. 2007). Plant viruses frequently make use of genetic recombination and re-assortment as driving forces in their evolution (Roossinck 1997). Plant RNA viruses also have highly error-prone replication mechanisms capable of giving rise to quasispecies fast-track evolution. As with animal genomes, a significant proportion of the genomes of higher plants consist of “transposable elements.” A component of these transposable elements arises from genome colonization by pararetroviruses, which, contrary to what one might expect, are not RNA-based but double-stranded DNA viruses. But, like retroviruses, plant pararetroviruses are dependent on the enzyme reverse transcriptase for viral transcription in the host, albeit in a different series of genetic processes to those of retroviruses in animals. When a retrovirus or pararetrovirus inserts its genome into the germline of its host, it is known as an ERV or pararetrovirus. Endogenous pararetroviruses in plants may sometimes confer resistance to exogenous viruses—a familiar phenomenon in animals in relation to

ERVs (Staginnus et al. 2007). Plant pararetroviruses will also enter into systematic recombination with non-autonomous viral species, involving region-specific non-coding regulatory sequences, which gives rise to a symbiotic pattern of evolutionary adaptation (Chen et al. 2017).

Liu et al. (2011) have discovered widespread gene transfer from circular single-stranded DNA viruses to a broad range of eukaryotic genomes. For example, they found evidence that the replication initiation protein (Rep)-related sequences of geminiviruses, nanoviruses, and circoviruses have been frequently transferred to plants, fungi, animals, and protists. They also identified geminivirus-like transposable elements in the genomes of fungi and parvovirus-like transposable elements in the genomes of lower animals, providing evidence that eukaryotic transposons could derive from single-stranded DNA viruses. Fukuhara has reported a new distinct taxon of RNA-based double-stranded endornaviruses in plants such as bell pepper and rice, which have no obvious effects in terms of illness or phenotype of the host plants (Fukuhara 2015). They appear to be efficiently transmitted to the next generation via pollen and ova in a manner that suggests that they are genuine symbionts.

Chu et al. (2014) have found at least eight families of endogenous non-retroviral genes in the genomes of eudicot and monocot plants. Most were derived from double-stranded DNA viruses, but some appear to have been single-stranded DNA viruses and single-stranded RNA viruses. Most of these belonged to the families of *Partitiviridae*, *Chrysoviridae*, and *Geminiviridae*. While it is possible that these play some role in resistance to exogenous viral invasion, further study will be needed to examine their potential contribution to plant metabolism, physiology, and evolution. Roossinck et al. discovered a wide range of viruses in plants that similarly showed no obvious effects in terms of disease or phenotype (Roossinck 2015). We should recall that symbioses involving viruses include a very wide range of virus-host interactions, from outright parasitism to mutualism, but we should also remember that it includes the possibility of commensalism, in which a virus might take advantage of host physiology or genetics, without contributing any advantage or causing any disease.

Viral metagenomics is the study of viruses, without preset notions of disease, in environmental samples, using next-generation sequencing that produces very large data sets. Recently, the introduction of such metagenomic analysis to different environments has revealed a remarkable hidden world of viruses, involving domestic and wild plants and some interfaces between the two (Roossinck et al. 2015). In the words of Roossinck, who has helped to pioneer such metagenomic searches: “these... show that we have barely begun to appreciate the immense diversity of viruses that occur on our planet” (Stobbe and Roossinck 2014). Such metagenomic studies are revealing a large diversity and proliferation of viruses that appear to be present without obvious signs of plant pathology; these in turn are changing our perceptions of how the majority of viruses actually interact in a variety of symbiotic associations with their plant hosts (Roossinck 2012).

8.3.4.8 GIANTS AND MINUSCULE DEPENDENTS: THE EXTREMES OF THE VIROSPHERE

When the Mimivirus, or *Acanthamoeba polyphaga mimivirus*, was first discovered inside an amoeba, it shocked the world of biology (Claverie 2006). Mimi had the typical genome of a virus, but it was much larger than usual. Indeed, it was so large that it was initially mistaken for a bacterium and was given the title of *Bradfordococcus*, hence the origin of its common name, “Mimicking Microbe.” It also proved to have a much more complex genome than most viruses, amassing more genes than some of the smallest bacteria. Mimi was the first of a growing plethora of giant viruses, or “macroviruses,” to be discovered, including *Megavirus chilensis*, *Pandoravirus salinus*, and *Cafeteria roenbergensis*. Many of these infect amoebae, but *Cafeteria roenbergensis* virus infects a small bacterivorous marine flagellate that gave the virus its name. One astonishing pandoravirus was found in an amoeba living in the contact lens of a woman in Germany (Scheid et al. 2010). Within the virus, they further discovered a “virophage,” labeled “Sputnik”—a virus parasitizing another virus. The discovery of these viral giants, which are now classed as the nucleocytoplasmic large DNA viruses, or the proposed order Megavirales, challenged many of the basic assumptions about viruses. In fact, detailed study suggests that they belong to three distinct groups that evolved from much smaller DNA virus ancestors that acquired many of their novel genes from genetic interchange with their eukaryotic hosts (Yutin et al. 2014).

At the opposite extreme, we find the family of minuscule viruses known as parvoviruses. These consist of three genera, two of which infect humans, causing gastroenteritis acquired from shellfish (Collier and Oxford 1993); meanwhile, other parvoviruses infect rodents, cats, dogs, and other animals. The parvoviruses are a mere 20 or so nanometers in diameter, and their genomes are so small that they can only replicate in the presence of another virus or helpful source of active DNA synthesis. They could be said to parasitize other viruses, and hence, they are also called dependoviruses. They are also the only DNA viruses with genomes consisting of single-stranded nucleic acid.

8.3.4.9 FROM PLAGUES TO Symbionts: THE CREATIVE RETROVIRUSES

In the early 1980s, one of the most dangerous plagues to emerge in the twentieth century arrived in America. Today, we know it as acquired immunodeficiency syndrome or AIDS. The causative virus is a retrovirus known as HIV-1. Retroviruses comprise a large and diverse family of RNA-based viruses, defined by common taxonomic denominators. HIV-1 is a member of the retrovirus subfamily known as lentiviruses, which also includes HIV-2 and the simian immunodeficiency virus, SIV-1. The first retrovirus to come to scientific attention was the avian sarcoma virus, discovered by Rous in 1911 during his research into the cause of avian sarcomas (Rous 1911). All retroviruses possess a viral envelope surrounding an icosahedral capsid,

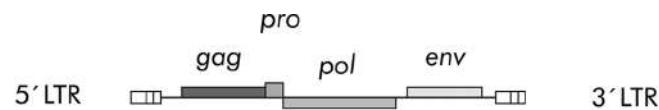

FIGURE 8.3.1 This displays the quintessential structure of a retrovirus genome, including exogenous viruses, such as HIV-1, and endogenous viral loci within the human genome. It includes the multigene domains of *gag*, *pol*, and *env* as well as the single gene, protease, flanked at both ends by the genomic regulatory regions known as the 5' and 3' long terminal repeats, or LTRs.

which in turn encloses a helical nucleocapsid (Coffin 1990; Collier and Oxford 1993). The individual viruses, or virions, are small even for viruses at 80–130 nanometers. It is likely that retroviruses infect all the known vertebrate animals. In fact, we are coming to realize that their host range extends far beyond the vertebrates.

The retroviral genome consists of two identical molecules of single-stranded RNA, bound together noncovalently (Fields and Knipe 1990). All retroviruses, including exogenous and endogenous varieties, have a similar basic genomic structure, as seen in Figure 8.3.1. The genome comprises three genetic domains, each of which codes for multiple proteins.

For example, *gag* codes for matrix and core shell proteins; *pol* codes for enzymes such as reverse transcriptase, protease, ribonuclease and integrase; and *env* codes for the surface and transmembrane glycoproteins. The flanking long terminal repeats (LTRs) are regulatory regions that control the expression of the viral genes. But once inserted as ERVs into the host genome, these same LTRs are also capable of taking over the control of neighboring host genes. The key viral enzyme, reverse transcriptase, reverses the normal direction of genetic progression by converting the viral RNA of its genome to the homologous DNA, an initial step before the viral integrase incorporates the viral DNA homologue into the chromosomes of the infected host cell (Hindmarsh and Leis 1999).

In the parasitic cycle of retroviral infection, the host cell is a specific T4 lymphocyte, the T-helper cell, which carries a CD4 receptor on its cell surface. However, some retroviruses have the capability of inserting their genome in similar fashion into the chromosomes of the host germ cells. This has remarkable potential for future genetic symbiogenesis through the creation of what is now a “holobiontic genome”—a genome comprising the former host and retroviral evolutionary lineages brought into union through genetic symbiosis. A prevailing koala retroviral epidemic in eastern Australia is providing important information on the dynamics of epidemic retrovirus behavior and, in particular, the retroviral endogenization into host germlines (Tarlinton et al. 2006; Xu and Eiden 2015). The koala epidemic began in the northeastern Australia, more than a century ago, and is working its way southward over the eastern side of the country. All of the koalas in the north are now infected, as are a third of those in the south. The virus has killed millions of animals, largely through hematological malignancies such as leukemia and lymphoma. The virus is also rapidly endogenizing into

the koala germline, with some animals already accumulating up to 46 proviral loci scattered throughout their chromosomes. Study of this extraordinary plague virus behavior is helping to throw light onto the evolution of animal genomes and, particularly, the human genome.

When, on February 12, 2001, two rival organizations announced simultaneously that they had completed the first comprehensive analysis of the human genome, there was astonishment at the fact that only some 1.5% of our DNA coded for proteins. This can be clearly seen in an updated pie chart of the DNA breakdown of the human genome shown in [Figure 8.3.2](#).

How could such a small proportion of the genome code for what was presumed to be 80,000 to 100,000 proteins involved in human metabolism? This problem was subsequently solved by the discovery of splicing. The DNA coding sequences for genes involves a number of introns and exons, with only the exons contributing to coding. The introns play a complex role, in combination with other regulatory elements, that decides what particular cluster of introns actually codes for a protein. Thus, the protein-coding portion of the human genome, which is now thought to comprise roughly 24,000 genes, can potentially code for the presumed 80,000 to 100,000 proteins (Pontén et al. 2011). There was a second surprise with the initial decipherment of the genome, which is also illustrated in [Figure 8.3.2](#). Some 9% of our human DNA is made up of sequences that are embedded endogenous retroviral loci. An additional 34% of the human DNA is made up

of sequences known as LINEs and SINEs, which are closely related to retrovirus genomic sequences and are referred to as “retrotransposons.” Meanwhile, half the total DNA, shown on the left of [Figure 8.3.2](#), remains somewhat uncertain with regard to function, though much of this would appear to be involved in so-called non-coding RNA, which is involved in regulatory and epigenetic functioning. Contrary to the earlier belief that the viral and virus-related elements of the genome were mere “junk,” making no contribution to phenotype (Orgel and Crick 1980), we now know that they have played a very important role in the evolution and function of the human genome.

8.3.4.10 THE SYMBIOTIC ROLE OF ENDOGENOUS RETROVIRUSES

If we examine the retroviral component of mammalian genomes, it consists of vast numbers of provirus genomic inserts scattered randomly throughout the chromosomes. Each insert is believed to represent an individual ancestor infected with an exogenous epidemic retrovirus (Ryan 2009). These viral genomic inserts into animal genomes are known as “endogenous retroviruses” (ERVs). Endogenous retroviruses are found in the genomes of every vertebrate on land. Indeed, they appear to have preceded the arrival of the first land vertebrates, being discovered in some varieties of farmed fish, where infection appears to cause systemic sickness and carcinogenesis. The increasing availability of fish genome sequences has allowed new insights into the diversity and host distribution of ERVs in fish, including Fugu, zebrafish, elephant shark, coelacanth, and lamprey. But the level of ERV sequences in fish genomes is generally much lower than that found in mammals, typically lower than 1% of total DNA (Naville and Volff 2016).

It is perhaps too early to speculate if fish ERVs might fulfill mutualistic functions with their hosts such as we see in mammals; however, a comprehensive recent study of 36 lineages of foamy-like retroviruses, in basal amphibians and fish, concluded that ray-finned fish foamy-like endogenous retroviruses (FLERVs) exhibited an overall co-speciation pattern with their hosts, but amphibian FLERVs might not (Aiewsakun and Katzourakis 2017). The same authors also reported several viral cross-class transmissions, involving lobe-finned fish, shark, and frog. They concluded that this major retroviral lineage and therefore retroviruses as a whole have an ancient marine origin at the time of, if not before, their jawed vertebrate hosts, more than 450 million years ago, in the Paleozoic Era.

Retroviruses suggestive of even more ancient origins have been found in the photosynthetic sea slug, *Elysia chlorotica*, where the virus floods the tissues near to the end of the slug’s life cycle (Pierce et al. 1999). The same viral manifestation, coinciding with the slug senescence or death, is seen in all *Elysia chlorotica* populations, regardless of location, including laboratory-kept specimens. Phylogenetic analysis of the *Elysia* retrovirus genome, and in particular its reverse transcriptase sequences, found sequence similarities with the reverse transcriptase of retrotransposons from the sea slug, *Aplysia californica*, and purple sea urchin, *Strongylocentrotus*

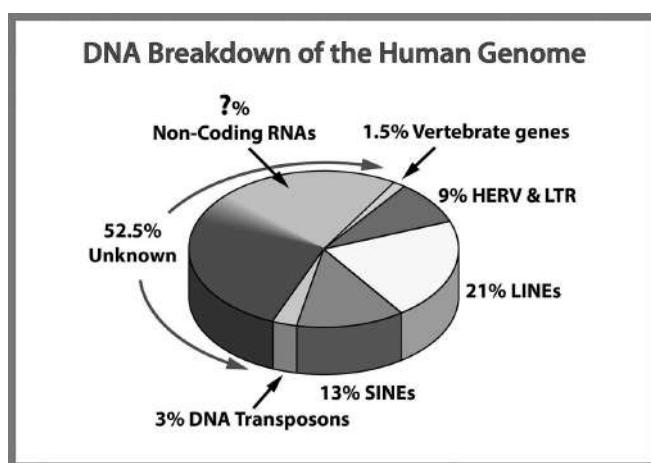

FIGURE 8.3.2 This shows an updated DNA breakdown of the human genome, showing the 1.5% that codes for proteins and the 9% comprising human endogenous retroviruses and their breakdown products, including isolated pairs of LTRs. It also shows the large sections labeled LINEs and SINEs, which are virus-related in their functions. The 3% labeled “DNA transposons” comprise relics of ancient DNA virus colonizations of the ancestral genome. The 52.5% labeled “unknown” contains sections of DNA that code for RNA molecules that are functional end products in themselves rather than messenger RNA, hence the term “non-coding” RNAs. Many of these are thought to contribute to genomic regulation in the form of long-noncoding RNAs and smaller regulatory RNAs of various sorts.

purpuratus. While the role of the retrovirus in the sea slug's life and death remains unknown (Pierce et al. 2016), the striking discovery of retroviruses in some of the earliest animals to evolve in the oceans suggests a very early origin of retroviruses; meanwhile, the very ubiquity of their presence in animals and their continuing evolutionary activity to the present day confirms their enormous importance to the evolution of the diversity of life on Earth.

When incorporated into the human genome, the retroviral inserts are referred to as "human endogenous retroviruses" (HERVs). Human endogenous retroviruses comprise between 30 and 50 families, depending on definition, and these families are further subdivided into more than 200 distinct groups and subgroups (Jurka 2000). Each of these is thought to represent an independent invasive lineage, implying that our primate ancestors have been subjected to a large series of independent HERV colonization, through exogenous retroviral epidemics. Although most of these colonizations took place more than 10 million years ago, a significant number occurred after the separation of the human lineage from that of chimpanzees. The families CERV 1 (PTERV1) and CERV 2 are unique to chimpanzees (Polavarepu et al. 2006), meanwhile at least 10 full-length HERV-K families are unique to humans (Medstrand and Mager 1998; Barbulescu et al 1999). When an ERV first enters the human genome, its loci will be suppressed by epigenetic mechanisms, such as methylation and histone modification. Over lengthy periods of time, many loci will be permanently suppressed by insertions or deletions—"indels"—or will be lost entirely from the genome during homologous sexual recombination. But epigenetic suppression is not permanent. Hence, during the lengthy period when epigenetic silencing predominates, there will opportunities for evolutionary interaction between the viral and host portions of what is now a holobiontic genome containing both mammalian and viral evolutionary lineages. Such interactions offer the potential for wide-scale genetic symbiogenesis.

Having long parasitized this same host as exogenous plague viruses, the now-endogenized viruses will have pre-evolved potentials for manipulation of host genetics, development and physiology. One important outcome would be the acquisition of new regulatory capability arising from the viral LTRs. Eukaryotic genomes are characterized more by regulatory complexity than by increase in gene numbers. Much of this complexity comes from virus-derived sequences, which, in addition to the influence of LTRs, also code for the production of small interacting regulatory RNAs, usually with stem-loop structures, which make an important contribution to the evolution and development of regulatory networks (Sundaram et al. 2014; Chuong et al. 2017).

Evolutionary biologists refer to the incorporation of viral elements into holobiontic evolution as "domestication" of viral genes and regulatory sequences. But it is important to grasp the limitations of such a term in these circumstances. The viral genes, and regulatory sequences, do not change to become similar to human genes and regulatory sequences. Indeed, their symbiotic contribution depends upon the fact that they retain those alien abilities evolved as part of their

parasitic viral lineages, in order to contribute novel interactive potential to the now-holobiontic human-viral genome and organism. We are only beginning to realize the nature and extent of this holobiontic evolutionary potential for novel innovation at the level of genetics, and whole genomics, giving rise to innovative changes in reproduction, embryological development, immunology, and cellular physiology (Villarreal 2005; Ryan 2016). This symbiogenetic pattern of evolution has undoubtedly changed the course of animal and, in particular, mammalian and human evolution.

8.3.4.11 ENDOGENOUS RETROVIRUSES IN REPRODUCTION

The first viral locus found to play a key role in human physiology was the ERVWE1 locus at chromosome 7 (7q21.2), from which the envelope gene, or *env*, was discovered to code for a viral protein, syncytin-1, which is important in human placentation (Mi et al. 2000; Mallet et al. 2004). Production of syncytin-1 is promoted by the viral locus 5'LTR, under the upstream regulatory control of a complex coordination of viral and vertebrate elements. The protein is strongly expressed in the placental trophoblasts, which fuse together to form a syncytium—a single confluent membrane studded with nuclei and with no junctional gaps between adjacent cell walls. In effect, syncytin has altered the fate of trophoblasts, converting them into syncytiotrophoblasts. This then forms the interface between the placenta and uterus, invading deep into the lining to create a very close contact between the maternal and fetal circulations, and with the syncytiotrophoblast, ensuring that all nutrients from the mother and waste from the fetus passes through cytoplasm rather than between cells. It also creates a better barrier, however fine, between the maternal and fetal circulations, helping to prevent immunological contact between maternal circulation and fetal tissues, which contain paternal antigens that would be treated as alien by the maternal immune system.

The syncytin-1 locus is common to the great apes, including gorillas, orangutans, chimpanzees, and humans and hence the ERV nomenclature rather than HERV. In an elegant study a few years later, a second fusogenic endogenous retroviral protein, dubbed syncytin-2, was discovered. Expressed by the locus FRD on chromosome 6, syncytin-2 was also found to exhibit a powerful immunosuppressant function deeper to the syncytiotrophoblast layer of the placenta (Blaise et al. 2003). Today, we know of at least 12 different endogenous retroviral loci that play significant roles in human reproduction, with at least five involved in placentation, though the precise roles of some of the others remain to be determined (Villarreal and Ryan 2011). Mice were discovered to possess two different fusogenic ERV syncytin-type genes, syncytin-A and syncytin-B, which play an important role in placentation. This led to the generation of knockout mice for syncytin-A and syncytin-B, whose embryonic placentas displayed major defects in cell-to-cell fusion, resulting in impaired embryo survival, confirming that syncytins are important for normal placental structure and function (Dupressoir et al. 2009).

Following the discovery of the human syncytins, Heidmann et al. screened a number of different mammalian clades for

related endogenous placental retroviral *syncytin* genes to confirm a variety of syncytin variants associated with a wide range of clades that included Rodentia (*syncytin-A* and -B); Lagomorpha, which include rabbits (*syncytin-Orl*); Primates (*syncytin-1* and -2); Carnivora (*syncytin-Car1*); Perissodactyls, which includes the horses; Chiroptera, which are bats; higher Ruminantia (*syncytin-Rum1*); Cetacea; Suina, which includes the pigs; Insectivora, which includes hedgehogs and shrews; Afrotheria (*syncytin-Ten1*), which include elephants, aardvarks, and sea cows; and Xenarthra, which include anteaters, sloths, and armadillos (Cornelis et al. 2012, 2013, 214). Remarkably, the same group went on to demonstrate the presence of a syncytin in the South American opossum (*syncytin-Opo1*), a marsupial that undergoes a short-lived placentation (Cornelis et al. 2015). They further demonstrated a second non-fusogenic retroviral envelope gene that had been selectively conserved for more than 80 million years among all marsupials, including the South American opossum and the Australian tammar wallaby, and that possesses an immunosuppressive domain. This latter appeared to function much as syncytin-2 in great apes, to help suppress maternal rejection of paternal and thus potentially alien antigens in the fetus.

The discovery of two retroviruses in marsupials showing transient placentation would appear to be a key finding. Up to this point, there was uncertainty whether the viruses had played a key role in the origins of placentation or whether they arrived after the evolution of a more primitive placenta and helped to make it more efficient. In the words of these researchers: “The capture of a founding syncytin by an oviparous ancestor was pivotal for the emergence of placentation more than 150 million years ago (Cornelis et al. 2014).”

It is also possible that in this wide range of retroviruses involved in placentation, and more generally in reproduction, we may be witnessing competition between groups of retroviruses, with the newer arrivals in the process of selectively displacing more ancient rivals. While this is speculative, there is some hard evidence for competition involving the Jaagsiekte sheep retrovirus (JSRV) and sheep, in this case for a fierce battle of ego versus alter-ego for the territory of the viral host. The retrovirus donating the ruminant syncytin gene, which the Heidmann group labeled *syncytin-Rum1*, is not the only retrovirus involved in placentation in sheep and goats. Where the retrovirus carrying *syncytin-Rum1* is thought to have colonized the ruminant genome approximately 30 million years ago, a second retrovirus, the JSRV, is believed to have colonized the common ancestor of sheep and goats some 5 to 7 million years ago (Palmarini et al. 2004). The name, Jaagsiekte, is a translation from the Afrikaans for the “chasing illness,” because it provokes breathlessness similar to that seen in sheep after they have been chased by a dog. The virus exists as two almost identical variants, the form endogenous to the sheep and goat genomes that contributes to placentation (Dunlap et al. 2006) and an epidemic exogenous retrovirus that causes a contagious lung cancer in sheep (Cousens et al. 2004). The two strains of the virus share 90% of their genetic sequences, so are likely to have a common origin. At some stage in history, perhaps between 400,000 and 1.3 million years ago, the JSRV endogenous virus evolved two

separate routes of blocking its “exogenous self” from gaining entry through the genital route. The exogenous virus then evolved a new route of infection through the lungs, where, unfortunately, its entire envelope gene protein has proved carcinogenic to sheep, particularly to lambs (Palmarini et al. 2004).

8.3.4.12 ENDOGENOUS RETROVIRUSES IN EMBRYONIC DEVELOPMENT

Developmental geneticists have long been aware of a strange phenomenon that takes place during the embryonic development of plants and animals. Methylation is one of the key epigenetic control regulators capable of switching off the expression of unwanted genes and other genetic sequences in the genomes of animals and plants. So, it was puzzling to discover that a major wave of genome-wide demethylation took place throughout a substantial portion of the genome of the cell during the earliest stage of embryonic development of plants and animals, including mammals (Eckardt 2006; Guo et al. 2014). This had the potential to activate normally suppressed endogenous retroviral entities and their related retrotransposons. In an experiment to explore this phenomenon, Spadafora exposed early murine embryos to the anti-reverse transcriptase drug, Nevirapine, to make the surprising discovery that it led to an irreversible arrest of development up to the four-cell stage (Spadafora 2008). Other researchers had already discovered that reverse transcriptase inhibition of early embryonic development resulted in substantial reprogramming of gene expression, involving both developmental and translational genes (Pittoggi et al. 2003). These curious findings suggested that ERVs, and/or LINE-type products, are involved in regulation and gene expression at the earliest stages of mammalian development.

The human endogenous retroviruses known as the HERV-Ks are the most recent viral lineages to colonize the primate lineage, including more than 10 groups that arrived into the human lineage after the divergence of humans and chimpanzees. These resulted in multiple HERV-K loci inserts with intact open reading frames scattered throughout the human chromosomes. Further investigation led to the discovery that DNA hypomethylation of the LTRs of the most recently acquired HERV-K integrations, accompanied by transactivation by OCT4 (a key definer of pluripotency during development), synergistically facilitates HERV-K reactivation and expression during this critical phase of human fetal development (Grow et al. 2015). Such retroviral expression appears to facilitate early embryogenesis, beginning with embryonic genome activation at the eight-cell stage, continuing through the emergence of epiblast cells in preimplantation blastocysts, and ceasing at the stage of embryonic stem cell derivation from blastocyst outgrowths.

There are roughly 1,000 loci of another endogenous virus group, the HERV-H, scattered through the human chromosomes. Some 231 of these are highly expressed in embryonic stem cells, where their LTRs, working in a coordinated way, act as a long noncoding RNA required for human embryonic stem cell identity. This causes the upregulation of *OCT4*, *SOX2*, and *NANOG*,

which maintain stem cell pluripotency. When HERV-H expression is blocked, using RNAi, the stem cells lose their pluripotency and differentiate into cells that resemble fibroblasts (Lu et al. 2014).

This arena of research is still relatively new. We have already underlined the role of endogenous viral sequences in the development of regulatory networks. It seems likely that such networks will be found to contribute to the complex regulation of embryogenesis. Indeed, given that levels of colonization of the animals with ERVs, it seems likely that, given more time and exploration, many more such intimate and important interactions with host embryonic development will be discovered.

8.3.4.13 A VIRAL CONTRIBUTION TO GENOMIC PLASTICITY AND FUNCTION

Recombination of viral loci on different chromosomes during meiosis has contributed to large-scale genetic deletions and duplications throughout our mammalian, hominid, and hominin evolution (Medstrand and Mager 1998; Hughes and Coffin 2001). Duplications of flanking endogenous retroviral loci appear to have contributed to the evolution of the extended major histocompatibility complex (Dawkins et al. 1999). A similar virally induced genomic plasticity may also have contributed to the surprising level of genetic variation, currently being observed between individual humans (Redon et al. 2006). A recent study of regulatory evolution of innate immunity showed that ERVs have shaped the evolution of a transcriptional network underlying the interferon response, which is a key element of innate immunity (Chuong et al. 2016). Meanwhile, ERVs have also contributed to many symbiotic interactions with host at post-developmental level, with implications for genetics, epigenetics, physiology, and health.

8.3.4.14 THE OPERATION OF SELECTION ON THE VIRUS-HOST HOLOBIOTIC GENOME

We have already explained that, in the holobiotic genome that arises from the symbiogenetic union of viral and host genomes, selection no longer operates solely at the level of viral or host genetic elements at individual level: for holobiotic survival, it must also operate at the level of the “holobiotic genome.” This implies selection for former host or viral genes and other genetic sequences that enhance holobiotic survival and selection against former host or viral genes and other genetic products that threaten survival. More than half of the human-specific HERV-K LTRs actively promote host DNA transcription (Buzdin et al. 2006), suggesting that viral LTRs have replaced less efficient former host promoters. For example, the LTR of ERV-9 plays a key role in transcriptional control of the β -globin gene cluster in primates, including humans (Plant et al. 2001; Routledge and Proudfoot 2002). A range of virus-derived elements is also found in a large number of human protein-coding genes, where most are inserted into introns—the non-coding regions between the coding regions,

known as exons—where they frequently effect gene function (Nekrutenko and Li 2001). Other LTRs have taken on the role of alternative promoters, or splice receptors, for example, in the control of the endothelin B receptor and apolipoprotein C-I genes and in the control of the human leptin receptor, which is involved in energy expenditure, production of sex hormones, and activation of hematopoietic cells (Kapitonov and Jurka 1999; Medstrand et al. 2001).

The observed viral roles fulfill the predictions of symbiogenetic evolution, as do the large repertoire of viral elements that code for a multiplicity of functions essential to the evolution and normal working of the genome. Even viral loci that have lost all of their protein-coding genetic elements, to be reduced to paired empty LTRs, are capable of playing a significant role in genomic regulation.

8.3.4.15 VIRAL LOCI EXPRESSING VIRAL GENES AS PROTEINS IN HUMAN TISSUES

A number of earlier studies have suggested that viral genes in the human genome might be expressed as proteins in the human tissue. We have powerful evidence for this in the viral role in placentation described previously. There is growing evidence that HERV genes may also be expressed as proteins in a variety of non-placental somatic cells, tissues, and organs. Most such studies have examined viral gene expression at messenger RNA (mRNA) level rather than the more difficult direct definition of actual protein expression within cells and tissues. However, expression of viral genes at RNA level may be an unreliable guide to protein expression because of differences in mRNA turnover, stability, and efficiency in translation. There is clearly a need to develop reliable techniques for detecting and measuring virally encoded proteins in cells, tissues, and organs. One such technique has been developed at The Rudbeck Laboratory, Uppsala University, and Uppsala University Hospital, Sweden, in an attempt to solve this problem. Focusing on the endogenous virus locus, known as ERV3, situated on chromosome 7q11.21, as a primary test system, they generated monospecific polyclonal antibodies capable of reliably detecting the expression of the ERV3-encoded Env proteins in human cells, tissues, and organs (Fei et al. 2014). This experiment found that ERV3-encoded Env proteins are expressed at substantive levels in placenta, testis, adrenal gland, corpus luteum, Fallopian tubes, sebaceous glands, astrocytes, bronchial epithelium, and the ducts of the salivary glands. Meaningful expression was also discovered in epithelial cells, fused macrophages, myocardium, and striated muscle. The authors concluded that the virus plays a significant role in human physiology and may also play a possible role in disease.

Preliminary results of a more comprehensive search for other endogenous viral gene expression as proteins in human cells, tissues, and organs look promising (personal communication). These results clearly suggest the need for more comprehensive investigation, along the lines of the former Human Genome and Human Proteome projects, to catalogue the total

HERV genome and HERV proteome expression in human reproduction, embryogenesis, and normal physiology.

8.3.5 CONCLUSION

While the origin of viruses as a whole remains uncertain, and may well be polyphyletic, we have made a case for the likely origin of RNA-based viruses in the putative RNA world. It seems likely, at the very least, that DNA-based viruses existed at the very earliest stages of prokaryotic life, and it is overwhelmingly evident that DNA- and RNA-based viruses have made a major contribution to, and have been an essential component of, the subsequent evolution to biodiversity as we find it today. We humans, like all other cellular life-forms, inhabit a ubiquitous and intensively interactive virosphere that molds our environment and ecology and interacts with life in a quintessentially symbiological fashion at every level.

8.4.1 INTRODUCTION

If I have seen further than others, it is because I was looking in the right direction.

Carl R. Woese
2010 (*personal communication*)

All of life is composed of “stardust” that came into existence with the advent of the Big Bang event billions of years ago. These celestial raw materials, relentlessly transformed and reshaped, provided molecules that are now the building blocks for the breathtaking biodiversity inhabiting our planet (Lane 2015). Yet, even this awe-inspiring display of life is but a small sampling, a modern snapshot, of the trillions upon trillions of organisms that have flourished and gone extinct during geological time on Earth and likely other planets. A more in-depth understanding of the origin and evolution of life on Earth provides an essential context with which to probe the primary mission objectives of NASA Astrobiology (Hays 2015; Domagal-Goldman et al. 2016), which include the following: How does life begin and evolve? Does life exist elsewhere in the universe? What is the future of life on Earth and beyond?

Concepts of human genealogy, established by the ancient Egyptians, Chinese, Greeks, Arabs, Romans, and all other peoples of the world, have long been the centerpiece for determining social structure, wealth distribution, royalty bloodlines, and governance. Therefore, an invaluable starting point from which to consider evolution is the idea of a family tree—an idea that is familiar and relevant to all people. Anyone can sketch a few branches of their own family and

know what they mean: your grandparents gave birth to your parents, who gave birth to you. Everyone on every branch in your tree is descended from, and connected to, everyone else. Similar diagrams of lineage and descent are pervasive in the biological sciences (Barton et al. 2007). In this case, however, the objective is to understand evolutionary relationships and gain insight regarding the shape and structure of the ultimate family tree that relates all living entities through geological time. Reproducible science that is predictive in nature, the very definition of good science, requires a robust tree of life applicable to the past, present, and future of all of life on Earth.

Remarkably, we now actually *do* know much more about the tree of life, based on the revolutionary work that began nearly 60 years ago by Carl R. Woese, who was a professor in the Department of Microbiology at the University of Illinois Urbana-Champaign (Figure 8.4.1). His research literally established a new structure for the tree of life for our planet, as well as hypothesized the sequence of events surrounding its origin (Sapp 2009). The long and winding road of Woese’s discoveries about the tree of life reached a pivotal point when classical Darwinian evolutionists, rooted in macro-level observations, were challenged by unexpected new discoveries that were driven by the advent of new micro-scale recombinant deoxyribonucleic acid (DNA) technologies. The progression of Woese’s work is also a story of how the life and physical sciences themselves were required to change and adapt as new discoveries were made. This article presents the progression of scientific inquiry that led Woese to establish a three-domain universal tree of life

FIGURE 8.4.1 Photograph of Carl R. Woese at the light table on which he painstakingly analyzed molecular patterns of microbial ribosomes that were radioactively exposed on x-ray film. These tedious and methodical measurements led to the identification the 16S rRNA gene sequence, the fundamental yardstick for measuring evolutionary relatedness. (Courtesy of Jason Lindsay, College of Liberal Arts & Sciences, University of Illinois Urbana-Champaign, Urbana, IL.)

(Bacteria, Archaea, and Eucarya; [Figure 8.4.2](#)). The result is that we now have fundamentally new integrated biological approach to better understanding the environmental sustainability, energy exploration, and production, as well as make bold new advances in medicine and space exploration.

8.4.2 REVOLUTION OF THE TREE OF LIFE

Science has long endeavored to establish a tree of life that would encompass all single-celled and multicellular life, human and otherwise ([Table 8.4.1](#)). This effort in Western science began in 1674, when Antonie van Leeuwenhoek developed the first microscope (Gest 2004). A textile merchant and self-taught scientist in Delft, The Netherlands, Leeuwenhoek is considered the father of modern-day microbiology. His revolutionary research tool was more like a powerful magnifying lens than an actual microscope, composed of a small brass plate, a hand-pulled and ground spherical glass lens, and set screws that positioned a needle point on which a microscopic sample was held. Despite its simplicity, this revolutionary device allowed Leeuwenhoek to make the first observation of microscopic life in lake water, organisms that he called “cavorting wee beasties” and published in the *Proceedings of the Royal Academy of Science*. In recognition of this fundamental contribution, one of the most prestigious awards in microbiology to this day is the Leeuwenhoek Medal—an honor bestowed on Woese in 1992.

The next major advancement toward establishing a tree of Life took place in 1735, when Carl Linnaeus, a Swedish scientist (also known as Carl von Linné), established a systematic approach (*taxonomy*) for describing and classifying living organisms in a publication he entitled *Systema Naturae* (Huneman 2007). The endeavor required many years of

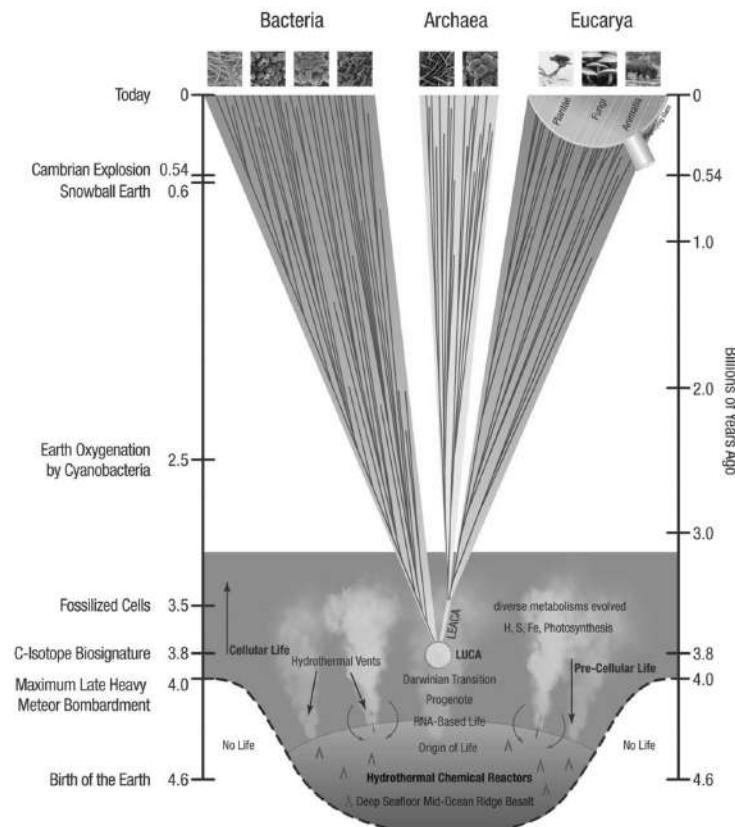

FIGURE 8.4.2 Universal tree of life, integrating the deep seafloor origin of life, geological time, and key Earth events with the three-domain (Bacteria, Archaea, and Eucarya) structure of life.

TABLE 8.4.1
Timeline of the Development of the Tree of Life (ToL) Model

Year	Scientist's Name	Tool	Historical Importance
1674	Antonie van Leeuwenhoek	First, simple microscope (no stains)	Known as the father of microbiology, he used his microscope invention to make the first discovery of microbes that were living in lake water.
1735	Carl Linnaeus	Field and lab observations	Created a taxonomic system for classifying organisms. Developed a three-kingdom model, <i>Animalia</i> , <i>Vegetable</i> , and <i>Lapideum</i> (the inanimate world). Developed the binomial nomenclature of <i>genus</i> and <i>species</i> .
1859	Charles Darwin	Field and lab observations	Darwin, inspired by the ideas of Alfred Wallace, further developed and described patterns of biodiversity. This included proposing the process of natural selection, yet it did not include microorganisms.
1866	Ernst Haeckel	Field and lab human observations	Established the first full ToL that included microbes (<i>Monera</i>) at the base of a tree that had three branches: <i>Plantae</i> , <i>Animalia</i> , and <i>Protista</i> . Also proposed that evolutionary history is recorded in developmental stages of individuals. (<i>Ontogeny recapitulates phylogeny</i>)
1938	Édouard Chatton	Sophisticated microscope with stains	Established two evolutionary “empires”: the single-celled Prokaryotes without a nucleus, which were thought to directly evolve into the single- and multi-celled Eukaryotes with a nucleus.
1959	Whittaker	Field and lab observations; biochemistry	Established a five-kingdom tree of life model, rooted by <i>Monera</i> , which branched into <i>Protista</i> , <i>Animalia</i> , <i>Plantae</i> , and <i>Fungi</i> .
1977 and 1990	Carl Woese	Ribosomal RNA molecular sequencing	Identified analysis of the ribosome (<i>molecular phylogeny</i>) as a sensitive tool for measuring the evolutionary relatedness of all living organisms. Results indicated a tree of life with three domains: <i>Bacteria</i> , <i>Archaea</i> , and <i>Eucarya</i> .

revision and development, spanning from inception of the idea during his education at the University of Leiden, The Netherlands, through his appointment as a professor at Uppsala University, Sweden. During this time, *Systema Naturae* grew from a thin pamphlet into a multi-volume treatise. Linnaeus’s taxonomy organized all living things into just two groups or kingdoms, *Animalia* and *Vegetable*. The third kingdom was that of *Lapideum*, which he conceived of as the inanimate world of rocks, minerals, and fossils. Linnaeus’s taxonomy was based on the shared traits of plants and animals, rather than the type of environment in which the organism lived, which was the widely accepted context for taxonomy in the scientific community at that time. Linnaeus originally based his taxonomy on reproductive organs, later expanding it to incorporate all morphological characteristics of an organism. Importantly, Linnaeus dramatically simplified and systematized the naming of organisms into just two words—genus and species.

The middle of the nineteenth century saw explosive developments in the quest to understand the history of life. The groundbreaking works of Alfred Russel Wallace and Charles

Darwin were the first to introduce evolutionary theory and the concepts of natural selection and fitness (Barton et al. 2007). Darwin’s 1859 publication of *Origin of Species* was the first to link the branching patterns of heredity with evolutionary process and recommended that taxonomic classifications be based on these evolutionary relationships. However, *Origin of Species* focused exclusively on animals and plants and did not include single-celled microorganisms. It was not until an 1866 publication by Ernst Haeckel, a professor at the University of Jena, Germany, included microbes for the first time into the tree of life (Richards 2008). Haeckel strongly supported evolutionary theory and is well known for his masterful illustrations of life-forms, as well as his hypothesis that “phylogeny recapitulates ontogeny”—the observation that an organism’s evolutionary history is often expressed in its early developmental stages. Haeckel constructed the first comprehensive tree of life in his publication *Generelle Morphologie der Organismen*, in which he described three great branches he called *Plantae*, *Animalia*, and *Protista*. Importantly, Haeckel included unicellular microorganisms, which he called *Monera*, at the base of the tree as part of the *Protista* kingdom.

From its first invention by Robert Hooke of the Royal Society of London in 1665, through its ever-increasing technical sophistication into the early twentieth century, the compound microscope facilitated advancement in the observation of cells (Gest 2004). This allowed Édouard Chatton, in 1938, to propose that all of life can be organized into two great “Empires”—*Eukaryotes*, plants and animals with cells that have a nucleus containing genetic material, and *Prokaryotes*, whose microbial cells have no nucleus (Woese et al. 1990). This work further fueled Haeckel’s notion of a linear tree of life in which more “complex” and larger multicellular eukaryotic life evolved directly along a single trunk from the small less complex single-celled prokaryotic life (Figure 8.4.3). Classification and ecological thinking were then fundamentally recast in the middle of the twentieth century by Robert H. Whittaker, who completed his graduate education at the University of Illinois Urbana-Champaign before eventually becoming a professor in the Department of Biology at Cornell University. Initially published in 1959 and later refined and expanded in 1969, Whittaker’s work established a five-kingdom structure for the tree of life that included the Animalia, Plantae, Fungi, Protista, and Monera (Figure 8.4.4). This followed the primary tree structure of Haeckel and his rooted separation of Monera, while also reflecting Whittaker’s inclination that “functional” kingdoms should be based on community ecosystem biochemistry and ecology (Barton et al. 2007).

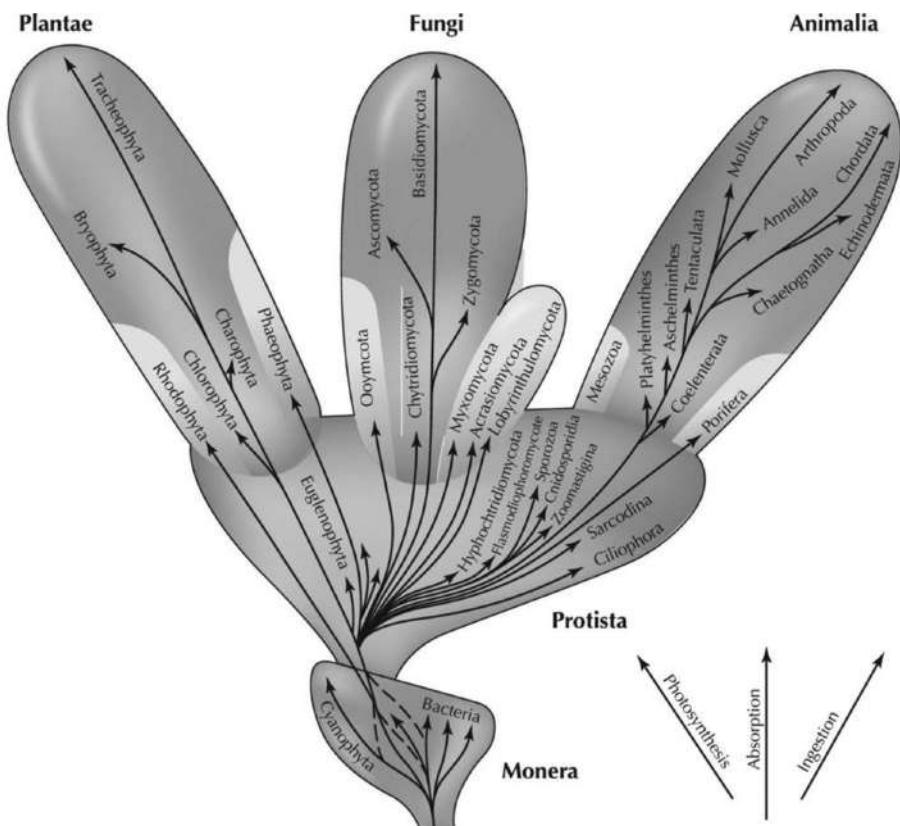

FIGURE 8.4.4 The Whittaker five-kingdom tree of life, which indicates direct lineage of the Animalia, Plantae, and Fungi from the Monera and Protista. (Modified from Barton, N.H. et al., *Evolution*, Cold Spring Harbor Laboratory Press, Cold Spring Harbor, NY, 833 p, 2007.)

8.4.3 ESTABLISHMENT OF MOLECULAR PHYLOGENY

Prior to Woese's work, the scientific community's view was predicated upon Chatton's proposal that there were just two types of life on Earth—Eukaryotes and Prokaryotes (Figure 8.4.3). At this time, microbes were sorted into one or the other of these grouping based on two criteria—their biochemical (metabolic) capabilities when grown in the laboratory (called *isolates* or *pure cultures*) and their shapes and structures when viewed under the microscope. While culturing provides invaluable information on how microorganisms function, it is estimated that less than 1% of the microbes on Earth can be cultured in the laboratory (Pace et al. 2012). Furthermore, even if cultivated, the full microbial community with which a species interacts in nature can only rarely be reproduced in the laboratory. Furthermore, microbes are generally tiny and indistinguishable spheres, rods, or filaments with similar internal physical structure. Therefore, even when the biochemical and morphological attributes of microbes were determined with microscopic analysis and culturing, they still did not provide a crisp and unambiguous measure of evolutionary relatedness. This is akin to using traits like hair color and height in people to determine their relatedness—they tell you something but not enough to be a reliable indicator of family ties.

Woese therefore began his scientific quest with the basic idea that, in order to create a universal tree of life, some kind of objective measure of evolutionary relatedness needed to be made that was guaranteed to be found in the cells of every single living creature. Born in Syracuse, New York, Woese originally studied mathematics and physics at Amherst College and then received a Ph.D. in biophysics, studying viruses under the direction of Professor Ernest Pollard at Yale University in 1953. Woese then worked in the General Electric Research Laboratory and was given an unprecedented instant-tenure faculty position in microbiology at University of Illinois Urbana-Champaign, driven in large part by Professor Sol Spiegelman. As a result of his background, Woese was a relative outsider to classical biology and had no preconceived agenda. He did not set out to overturn the foundations of modern classification, but instead simply wanted taxonomy to better reflect evolutionary relatedness (Sapp 2009).

The word phylogeny is derived from the Greek roots “*phylon*” meaning stem and “*genesis*” meaning origin. Molecular phylogenetics therefore seeks to establish evolutionary relatedness by measuring and comparing the chemical composition of key biomolecules within cells (Pace et al. 2012). The *genetic code* is the set of three-letter combinations, in which each letter represents a nitrogen-containing nucleotide base pair (A-T or adenine-thymine, G-C or guanine-cytosine), and each triplet corresponds to a specific amino acid building block. Woese believed that a universal tree of life was possible because the genetic code is universally consistent across all life-forms on Earth (Woese 1965). Humans have the same genetic code as bison, which have the same genetic code as bears, moose, eagles, rattle snakes, beetles, lodge pole pines, and all other living organisms that have been encountered. In addition, the genetic code is extremely good at minimizing errors

(Butler et al. 2009). Furthermore, if a permanent alteration is made in the nucleotide sequence of an organism's genome (a *mutation*), due to either damage or errors, the resulting amino acids are still close to the ones that should have originally been made. While the genetic code has evolved toward an optimal state, is close to being optimal, and itself has evolved somewhat, its robust stability and consistency through most of life's history permit development of an accurate and comprehensive molecular phylogeny (Woese 1965).

In 1964, just a few years after becoming a professor in microbiology at University of Illinois Urbana-Champaign, Woese began an ambitious program to construct a molecular phylogeny for all of life. This was while a major focus in the rest of the scientific world was on furthering the work of American biologist James Watson and English physicist Francis Crick on the double-helical structure of DNA and the genetic code (Sapp 2009). However, from early on, Woese clearly understood that this level of structure was not sufficient to understand biological functions. Woese went so far as to write a personal note to Crick about these ideas in 1969, but Crick responded that his goals were likely impossible to reach, that his proposed work would therefore likely offer limited results, and that it would be hard for him to receive federal funding for this work. This would be a harbinger of precisely how the rest of the scientific community would react to Woese's avant-garde work in future years.

Woese was undeterred. He continued his work by considering what cells do for a living. Cells must reproduce to make future generations, they must metabolize by extracting energy from the environment, and they must learn how to do these things from the information stored and passed along in their genetic composition. Conceptualized as the *Dogma of Molecular Biology* by Crick, the key observation is that a cell ultimately functions and survives by making proteins, which they do by implementing information represented in the chemical structure of DNA. To accomplish this, the cell first reads (*transcribes*) the DNA into messenger ribonucleic acid (mRNA), an information-carrying strand, which is then processed by a complex organic molecule (a *molecular machine*) called the ribosome—the cell's protein factory. Ribosomes interpret the genetic code echoed from DNA to mRNA and string together a corresponding sequence of amino acids (a process called *translation*) to form the proteins that are essential to life. So, Woese's reasoning was that every cell must have a ribosome in order to produce proteins and survive. Therefore, to understand the evolutionary history of the cell, Woese targeted the chemical composition (*sequence*) of the various parts of the ribosome, which was most likely to be present in every living organism on Earth. He summarized these early ideas in his 1967 book *The Genetic Code: The Molecular Basis for Genetic Expression*. Woese came to appreciate that, in order to fully derive and understand biological function (especially of microorganisms), one needed to know the structure, as well as the motions and vibrations of the molecular components of the ribosome (Sapp 2009).

The ribosome is an incredibly complicated molecular machine that has somewhat-variable amounts of protein and RNA. Just as

Darwin sought to measure what he called essential evolutionary characteristics, Woese similarly chose to measure the essential chemical composition of the ribosomal RNA (rRNA) gene sequence. The idea of molecular evolution was that the age of genes could be read like a clock, a concept first proposed by Francis Crick in 1958 and later by Linus Pauling and Emil Zuckerkandl in 1965 (Sapp 2009). The information stored in molecules of nucleic acids will, as a result of random mutations, consistently change through time, like the steady beat of a ticking clock. Study of the pattern of these changes in information molecules, whether they be amino acids or nucleic acids, is therefore like studying a permanently running evolutionary timepiece. With this in mind, Woese believed that the rRNA gene sequence molecule was the ultimate universal chronometer with which to construct the universal tree of life (Woese et al. 1990). To establish this evolutionary clock, Woese labored in relative isolation from the larger scientific community, relying on the help of just a select few graduate students, postdoctoral researchers, and colleagues. This is extremely rare today, as large laboratory groups and their collaborative networks are now conducting the majority of molecular studies.

In the early 1960s, a brand new, manually time-consuming, and, in fact, hazardous radioactive tagging technique called *molecular sequencing* became available (Sapp 2009). Originally developed by Fred Sanger for protein analysis, this technique was crucial to Crick's development of ideas about how DNA encodes for proteins and later earned Sanger the Nobel Prize in Chemistry in 1958. These cutting-edge techniques were learned and brought to the Woese's laboratory as the result of a collaboration between a graduate student mentored by Woese and a postdoctoral fellow who had formerly worked in the Sanger laboratories. Using the then state-of-the-art technique, they found that the information-packed small subunit (SSU) of the rRNA was enough to determine common ancestry. The more similar the nucleotide sequences of specific regions of the chromosome in two organisms, the more closely related they are on the tree of life; the sequences found within the SSU transcript were particularly informative. However, at the time, it took months to collect a single SSU rRNA fingerprint. When sorted according to particle size settling time during centrifugation, the SSU rRNA is called the 16S rRNA gene sequence. The S unit (10^{-13} seconds) is named after the Swedish chemist Theodor Svedberg, who was awarded a 1926 Nobel Prize for developing the techniques of quantitative centrifugation of macromolecules. The 16S rRNA gene sequence is approximately 1542-nucleotide base pairs in total length, yet Sanger sequencing measured only short 13–15 nucleic acid base-pair-long reads. Woese pushed ahead to collect and analyze these short molecular sequences from as many different living organisms as possible, after tagging them with radioactive phosphate (^{32}P) and separating them using two-dimensional gel electrophoresis. The resulting gels were exposed and measured on large sheets of photographic x-ray film and analyzed on IBM computer punch cards. Woese labored for thousands of hours in solitude, hunched over a light box in a darkened laboratory, to read the x-ray films.

By looking at these small differences in these 16S rRNA gene sequences by using statistical analyses, Woese could track the most likely evolutionary pathway that might explain their differences and similarities. Woese was eventually joined by George Fox, his postdoctoral research associate, who collaborated closely with the laboratory of Illinois Professor of Microbiology Ralph Wolfe. Wolfe's laboratory specialized in culturing and biochemically analyzing microorganisms that produce natural gas or methane in environments with no oxygen (*anaerobic methanogens*). A sample, collected in spring of 1976 on the University of Illinois Veterinary Medicine farms, was taken from a surgically implanted opening (*fistula*) into the complex four-chambered stomach (*rumen*) of a cow. It was from this rumen sample that the first 16S rRNA gene sequences of methanogens were extracted and sequenced and were used to identify a whole new branch of life—the Archaea. However, Woese and Fox needed more evidence to prove that the Archaea existed. Although classified until that time as Bacteria, methanogens lack a porous outer cell wall layer composed of peptidoglycan. Upon review of the literature, Woese and his colleagues found that a few other select prokaryotes also lacked peptidoglycan, had similar metabolisms and fats (lipids) to methanogens, and thrived in extreme environments created by salt (*halophiles* in evaporating wetlands) and heat (*thermophiles* in Yellowstone hot springs). Woese and Fox acquired samples of these organisms and soon accumulated enough data to prove their similarity in 16S rRNA gene sequence composition. Thus, the Urkaryotes, Bacteria and Archaeabacteria (the new third branch of life) were established and called “urkingdoms” (a taxonomic ranking above that of Whittaker's kingdoms; Woese and Fox 1977).

These surprising results, which contextualized the five Whittaker kingdoms and departed from the eukaryote-prokaryote dichotomy of the early twentieth century, were first published in the *Proceedings of the National Academies of Science* and reported on the front page of the New York Times on Thursday November 3, 1977. The world now knew for the first time of Woese and his universal tree of life. Yet ironically, these scientific results were much more widely embraced abroad than they were by the scientific community in the United States. The world's first scientific conference on Archaeabacteria was held in Munich, Germany, in 1981. Later, in 1990, Woese and his colleagues Otto Kandler and Mark Wheelis formally renamed the urkingdoms as the three domains of life—Archaea, Bacteria, and Eucarya (Figure 8.4.2). Studies of taxonomy, phylogeny, and evolution were now unleashed to vigorously conduct experimentation in the laboratory and in the field and objectively measure evolutionary relatedness, and thus, the direction and applicability of scientific discovery would never be the same again. Today, the debate about appropriate targets to explore relatedness among cellular life continues and can be generally reduced to information systems (such as the ribosome or other protein synthesis machinery) or physiological structures (such as subunits of the ATP synthase complex; Williams and Embley 2014). In this article, the conceptual model of the tree of life follows the informational genes of the small subunit of

the ribosome (16S rRNA gene sequences) as the organizing principle for universally determining evolutionary relatedness ([Figure 8.4.2](#)).

8.4.4 EMERGENCE OF LIFE

The next step is to consider how geological time encapsulates and frames the progressive events comprising the universal tree of life ([Figure 8.4.2](#)). A practical understanding requires acknowledgment that there are various geological “clocks” that exist in nature. These tools measure the age of the Earth by taking advantage of the decay of radioactive isotopes and cooling, changing magnetic fields in lava flows that emerge from mid-ocean ridges, layering of sedimentary rocks and soil and ice deposits, the analysis of fossils trapped within these layers, tree rings, chemical analysis of layered skeletons, and the monitoring of impact craters on the moon and other planets within our solar system (Gradstein et al. 2012). All of these approaches, taken together, make it possible to accurately quantify the age of the Earth and the universe. Within this are multiple frames of reference that link geological and biological time, ranging from billionths of a second to billions of years.

Understanding the emergence of life begins with discerning its most ancient forms. Even if all of the DNA, RNA, protein, and other molecular components of a living cell are extracted and then mixed back together, humankind remains incapable of bringing this naturally perfect cocktail of ingredients back to life (Sapp 2009; Lane 2015). Scientific experiments, famously such as those of Stanley Miller and Harold Urey at the University of Chicago in 1952, have produced amino acids as well as a host of other organic molecules. These tests added electrical energy, reactive mineral surfaces, and other ingredients to prebiotic aqueous chemical mixtures under conditions that were thought at the time (but no longer) to mimic those found on the ancient Earth. This explains why amino acids, the building blocks of proteins, are commonly found on the surface of meteors. It also resoundingly proves that simply having the right water chemistry and an input of energy is not sufficient to generate life.

Two of the most ancient “fossil” entities on modern-day planet Earth are H₂O molecules and the genetic code. Much progress has been made recently in deciphering the physical and chemical conditions in which the earliest life may have been jump-started (Lane 2015). The primordial Earth was a terrifyingly violent place of ongoing meteor impact strikes and resulting extreme environmental conditions (Knoll et al. 2012). Although still intensely debated, the window of opportunity for life to gain a foothold is thought to have spanned from the latest Hadean into the early Archean, approximately 4.3–3.8 billion years before present (BYA). This is also the time frame in which the Earth’s magnetic field had become adequately developed, so as to provide a protective shield from the arrival of deadly galactic cosmic rays and solar particles. The older age limit is based on work suggesting that the Earth and Moon, as well as our entire solar system, were hit with a barrage of massive asteroids

called the Late Heavy Bombardment, which peaked at about 4.0 BYA and declined until approximately 3 BYA (Abramov and Mojzsis 2009).

The earliest fossil evidence for life on Earth occurs no later than about 3.8 BYA in the form of chemofossils. Carbon-isotope changes preserved in ancient sedimentary rocks (metamorphosed shales) are consistent with those created by the metabolic activity of modern photosynthetic cyanobacteria (Mojzsis et al. 1996; Bell 2015). Iron ore deposits in sedimentary rock, known as banded iron formations (BIFs), are also believed to be indicative of microbial metabolic activity. These BIFs are thought to have originally been formed by marine microbes capable of anoxygenic photosynthesis, which later evolved to generate oxygenic photosynthesis carried out by aquatic cyanobacteria. The Earth’s oceans and atmosphere were then charged with oxygen derived from cyanobacterial photosynthesis by about 2.5 BYA to create the worldwide Great Oxygenation Event (GOE; Lyons et al. 2014).

The first physical fossils on Earth can be found in the form of microbial cells trapped in silica crystals (Knoll 2003). Cyanobacteria and other microbes also formed *stromatolites*, many of which are finely layered sedimentary rock deposits formed when small sedimentary grains are embedded in the sticky mucous (also called extracellular polymeric substances [EPS]) of microbial mats over time. This combination of mineral-entombed cells, carbon-isotope fractionation, extensive iron deposition, and stromatolites provides strong evidence of the presence and metabolic activity of ancient Bacteria, Archaea, and Eucarya. The evolutionary chronometer of the genetic code indicates all of life evolved from a single common ancestor called the last universal common ancestor (LUCA; Weiss et al. 2016). Following the LUCA, two forms of cellular life emerged: thermophilic bacteria and another unique organism called the Last Eucarya and Archaea Common Ancestor (LEACA) that eventually evolved into Archaea and Eucarya (Pace et al. 2012).

The Earth’s oceans and atmosphere were charged with oxygen derived from cyanobacterial photosynthesis by about 2.5 BYA to create the worldwide GOE (Knoll et al. 2012). At approximately 600 million years ago (MYA), ice covered the world’s oceans, including the equatorial zones, to create a “Snowball Earth.” A rise in greenhouse gases, primarily derived from volcanic activity, then brought the planet back to warmth. At only 542 MYA, the Cambrian Explosion took place, in which large multicellular Eucarya (metazoans) with external skeletons (invertebrates) suddenly evolved on the seafloor of oceans around the world. The fossil record generally presented in science classrooms begins with this invertebrate Cambrian Explosion and then goes on to include the first and last occurrences (radiations and extinctions) of macroscopic plants and vertebrate animals. This recent approximately half-a-billion-year stretch of geological time is the physical realm of the fossil record that has been, and continues to be, extensively studied to establish early prototypes of the tree of life (most without microorganisms).

In contrast to the shallow, warm, land-based ponds of “Primordial Soup” envisioned by Darwin, it is much more likely that life began in the more stable environments of deep seafloor crustal spreading centers, which would have been sheltered from many of the direct effects of meteor bombardments. In this sheltered deep ocean realm, microbial life would have been able to originate and evolve even during the tapering of meteor bombardment (Russell et al. 2010, 2013). Immense volumes of seawater move down and through fractures in the newly formed basaltic rock that makes up the oceanic crust at the core of the spreading ridges. These water-rock interactions create highly acidic (pH 2–3) iron-sulfide black smoker vents that are widely distributed along spreading centers in the modern ocean and reach temperatures of 350°C—too hot to sustain life. However, cooler off-ridge hydrothermal vents also occur, such as the present-day Lost City hydrothermal field west of the mid-Atlantic Ridge at about 900 m water depth. In these locations, vent water is cooler and much more alkaline (70°C–90°C, pH 9–11) after circulating through and chemically reacting with ultramafic igneous crustal rocks (low in silicon dioxide and high in manganese and iron) and their overlying thin layer of marine sediments. This produces huge volumes of diagenetically altered rock deposits called serpentine. In the process, seawater is reduced by the huge supply of iron available in the crust, releasing sulfur and the type of H₂-CO₂ redox couples thought to be essential for the origin of life.

At these Lost City vents, limestone chimneys have formed over the last 100,000 years that tower 60 m above the surrounding seafloor. They are built of aragonite and calcite crystals, as well as other minerals formed during serpentization that include double-layer hydroxides (green rust), which rapidly encrust filamentous microbial mats (Russell et al. 2010, 2013). The hot chemically charged water flows up and out of the vent to immediately react with cold deep seawater, which also drives the precipitation of iron and nickel. This creates an environment of extreme heat loss (*thermal gradients*) and rapid chemical reactions that are rapidly changing and strongly unbalanced (far from *equilibrium*). It is under these conditions of dynamic, indeed frantic, carbon and energy exchange where equilibrium is trying to be restored and where life is believed to have begun (Figure 8.4.2). The energy release and exchange in these settings is something like the whirling dervish performances of Cirque du Soleil. Here, however, instead of trapeze flyers, tightrope walkers, and contortionists, metals serve to catalyze an array of basic chemical reactions that in turn form a variety of organic biomolecules.

These coupled environments of sub-seafloor serpentization and alkaline vent travertine precipitation are the natural chemical reactor vessels in which the biomolecules of life were first synthesized (Russell et al. 2010, 2013). In the process, small crystalline mineral chambers with microscopic channels (*ram jets*) formed in the serpentine and travertine mineral deposits, where biomolecules came together from the rapidly outflowing vent water to create free-floating RNA-like molecules. This earliest *RNA-based life* created a massive collective

of genetic and biochemical material that was openly free flowing and without boundaries. Although nearly impossible for us humans to comprehend, there was no “individuality,” because there were no cellular entities and no structures to separate and distinguish distinct living things. Woese, as well as Crick and Leslie Orgel, founded this idea that nucleic acids played a central role in the origin of life, which buoyed the notion of a RNA-based life precursor to cellular life (Figure 8.4.2)—a world in which nucleic acids served as both chemical catalysts and information transmitters. This suggests that one of the most enduring and realistic definitions of life is simply “the ability to evolve.” As a result, instead of “survival of the fittest” that requires individuality, success is better defined by “survival by those who are fit the best” to the environmental conditions at hand. The origin of life was therefore all about the open and complete sharing of genetic information and the strategies for survival that resulted from the ability to evolve. Woese’s work was the first to imply that there was life, and evolution, long before there were genes and before there were cells enclosed with an outer membrane (Sapp 2009).

Woese surmised that the next evolutionary step of life occurred when membranes incrementally began to close around and capture RNA and other molecules within cells. This created primitive cell-like entities, which Woese named the *progenote*, that were radically different from modern-day living cells (Figure 8.4.2). It is thought that this progression from original deep seafloor RNA synthesis through the progenote, Darwinian Transition, and the LUCA all took place in an exceedingly short time span around approximately 4.0 BYA (Woese 1998a; Woese et al. 1990; Pace et al. 2012; Lane 2015). Among other things, the progenote did not have either a fully formed cell wall membrane or the capacity to translate RNA into proteins. Thus, the linkages between genetic composition and outward cell structure and metabolism that are essential to modern living were only just in the process of being established at this time. Only late-stage versions of the progenote proto-cells would have evolved the complex capability of translation. In addition, the progenote necessarily evolved quickly, leading Woese and Fox and later workers to reason that this was driven in large part by horizontal gene transfer—the ability to move genetic material laterally between living cells in a single generation, rather than only vertically between separate generations of cells. Since then, horizontal gene transfer has been found to operate within and between all forms of life. A profound evolutionary event then took place that Woese called the *Darwinian Transition*, when the progenote evolved into modern-type cells. The resulting cells had a fully encapsulating and well-developed cell wall, as well as all of the complicated translational molecular machinery required to synthesize proteins. The LUCA was therefore the anchor point for the genetic code and the entire tree of life, but it was not the start of life (Figure 8.4.2).

The universal tree of life (Figure 8.4.2) illustrates several key concepts that are of critical importance to understanding the structure and evolutionary history of life on earth. These were surprising and fully unexpected, given

that the phylogenetic relationships are only fully revealed on the molecular level. The first is that all three domains of life (Bacteria, Archaea, and Eucarya) evolved nearly simultaneously very early in geological time at approximately 4.0–3.8 BYA window (Figure 8.4.2). Another is that the single-celled Archaea are more closely phylogenetically related to the multicellular Eucarya than they are to their fellow single-celled Bacteria. However, Eucaryotic cells are generally 10–20 times larger than those of Bacteria and Archaea, and Eukarya have genetic material organized within a nucleus, and both bacterial and archaeal cells generally have the same shape and appearance. Only the Archaea are capable of methanogenesis, but they are also metabolically diverse. Archaea are often thought of as being able to live in environments of extreme temperature, acidity, and salinity (*extremophiles*). However, this is not always the case; they are now commonly detected in common low-temperature natural and man-made environments. In addition, archaeal cell walls do not contain the peptidoglycan found in bacterial cell walls. Furthermore, Archaea have different membrane lipid bonding and fatty acids from both Bacteria and Eucarya.

8.4.5 EVOLUTIONARY WORLDS COLLIDE

Woese was confident that his findings on the evolution of the ribosome would revolutionize the very foundations on which modern biology is built and practiced (Sapp 2009). However, the process of sharing these results with the world got off to a rocky start. This was in part because Woese had labored in anonymity for so many years and did not frequently attend conferences; thus, he was unknown to most of the scientific community. Furthermore, comparison of oligonucleotide catalogs is not as straightforward as the direct comparison of DNA and RNA sequences that can be done today. These obstacles led to a general lack of understanding and skepticism in the scientific world about the validity of Woese's approaches. In addition, and not due to anything Woese had done, the New York Times made several errors in the reporting of its 1977 front-page story—thus many scientists viewed this as a failed attempt at publicity. And finally, molecular phylogeny showed that Whittaker's five-kingdom configuration (Figure 8.4.4), on which so much of biology had been anchored, was in reality a series of branches on the top portions of the universal tree of life (Figure 8.4.2). This was not, and in some sectors still is not, well received by many practicing biologists.

The *status quo* confronting Woese is perhaps best exemplified by a remarkable and protracted discourse he had with Ernst Mayr—one of the foremost classical Darwinian evolutionists of the twentieth century. These communications were published in 1998 in the *Proceedings of the National Academy of Sciences*. The controversy centered on Mayr's belief that the great morphological diversity of the eukaryotic world would certainly overwhelm any molecular and biochemical diversity present in the microbial world. In other words, how could differences in the chemical composition of a single gene possibly compare to the immense morphological diversity of animals and plants? Thus, Mayr's argument viewed molecular

phylogeny as a competing type of taxonomy and thus represented a challenge to long-held views on the assumed primitive simplicity of the microbial world. Classical evolutionists like Mayr saw phylogenetic taxonomy as something distinct and separate from the study of evolutionary processes, which was generally thought to be the bailiwick of geneticists (Sapp 2009).

Mayr, emulating Darwin, shifted the question of evolution to the origin of species and away from the big universal tree of life (Mayr 1998). Darwin had argued that in order to have a deep evolutionary phylogeny, one had to focus exclusively on the essential characteristics of an organism. Darwin's world was one of plants and animals; the accessible way to classify these living things at the time was by choosing easily observable morphological traits. Darwin focused on embryonic characters, because those characters would evolve gradually and might in fact be stable and highly conserved in evolutionary time. The problem was that this approach was not applicable for microbes. Microbes didn't have embryos, or great morphologies, or any obvious trait that was useful for Darwinian classification.

Woese therefore viewed things differently, seeing the debate as being over methodology—Darwinian morphologists use direct human observation, while molecular phylogeneticists use unseen genes and biochemistry detected only with sensitive instruments. Mayr and the classical evolutionists wanted to maintain the prokaryotes as a single “monophyletic” group because of their visible characteristics. Woese pointed out that this meant that they did not fully understand that the 16S rRNA gene sequence had shown that the Archaea are as phylogenetically distinct from Bacteria as they are from Eucarya (Woese 1998b; Sapp 2009). Furthermore, a significant amount of microbiology research in the previous two decades had focused on one representative microbe, *Escherichia coli*, which could easily be cultured and manipulated in the laboratory. The mutual exclusion and opposed differences (*dichotomy*) set up by Mayr between the eukaryotes and prokaryotes reinforced the notion that knowing everything about *E. coli* was sufficient to understand everything about prokaryotes in general, including the Archaea. Woese's molecular phylogeny, combined with the detailed biochemical analyses of archaeal methanogens, proved that this was fully incorrect. Yet, the scientific community resisted, as evidenced when Woese and Gary Olsen at Illinois submitted a proposal to sequence an archaean but were turned down on the grounds that a sequence of *E. coli* bacteria already existed and one didn't need to sequence any more of these things. If you've seen one microorganism, you've seen them all.

Further strife later arose within the field of molecular phylogeny itself, over the potential effects of horizontal gene transfer (Woese 2004). Some believed that extensive horizontal gene transfer would obliterate generational lines of descent (*lineages*), thus believing there was no fundamental core structural phylogeny that the microbial world had followed. Conversely, Woese and his colleagues saw horizontal gene transfer as a powerful integrative force that rapidly shared and integrated genetic components (Pace et al. 2012). However,

they did not envision it as being capable of blurring the lineages that were so robustly shown by the universal tree of life. In doing so, they made a distinction between the more ancient informational genes that involved transcription and translation and the more recent operational genes that governed metabolism and were more prone to horizontal gene transfer.

The scientific persistence and dogged personal commitment of Carl R. Woese eventually succeeded. As his publications and supporting data became more and more known and widely accepted in the late 1990s, the first generations of high-throughput DNA sequencing technologies also became available. Complete archaeal genome sequences immediately substantiated them as a unique third domain of life. From this point forward, Woese's accomplishments were recognized by the most prestigious of international science organizations, including the MacArthur Fellowship, membership in the US National Academy of Sciences and the Royal Netherlands Academy of Arts and Sciences, the Leeuwenhoek Medal, the US National Medal of Science, and the Royal Swedish Academy of Sciences Crafoord Award in Biosciences. Carl R. Woese fundamentally changed the way in which we perceive life on planet Earth, and he established an irreplaceable molecular insight that is now at the forefront of scientific inquiry in all sectors of modern society.

8.4.6 MOVING FORWARD

As the technologies required for high-throughput sequencing become more rapid and provide ever-deeper sequence coverage and the cost of sequencing continues to precipitously drop in price, the pace at which new hypotheses are proposed regarding the structure of the universal tree of life will continue to accelerate. An important focus of several recent deep sequencing efforts has been to better understand the appearance of the LUCA and the origination of the Eucarya. As would be expected given the history of evolutionary biology itself, these studies have been surprising, inspiring, highly controversial, and hotly debated. As a case in point, genomic DNA from a suite of water samples collected at a mid-ocean ridge vent called Loki's Castle, located on the deep-sea floor between Norway, Greenland, and Svalbard, have been heavily sequenced (Spang et al. 2015; Zaremba-Niedzwiedzka et al. 2017). This work has resulted in the identification of a group of Archaea called the Asgard Group with genetic structures and predicted membrane remodeling capabilities that are closely related to those of Eucarya, although it is critical to note that none of these microorganisms are yet in culture. Metagenomic analyses of one of these groups, called Lokiarchaea, suggest that it was directly evolved from Eucarya at about 1 Bya later in earth history than previously thought. If correct, this would imply a two-domain structure for the tree of life (called the eocyte or merger model; Raymann et al. 2015), wherein the Eucarya are a branch of the Archaea rather than representing a separate domain.

The multicellular Eucarya, which include animals, plants, and fungi, are extremely complicated in their own right, and their origins have long been disputed. This is equally true for

the algae, yeast, and amoeba, which are single-celled versions of the Eucarya (Barton et al. 2007). The discovery of the Lokiarchaea, in addition to variations in evolutionary relationships suggested by other marker genes, has led some to believe that the Eucarya evolved from the merger of Archaea and a Bacteria via endosymbiotic fusion (Martin et al. 2015). However, these studies are controversial, because they suggest they transfer of genes between cells and across domains (horizontal gene transfer [HGT]), resulting in overprinting and resetting of a significant portion of the LUCA's original genomic composition. They also assume that viruses originated from the LUCA (Forterre 2014). Martin et al. identified only 355 genes, which are not enough to drive the biosynthesis of nucleotide and amino acids. Ribosomal proteins that underwent HGT were also omitted. Regardless, their interpretation is that the original suite of genes derived from the LUCA results in a two-domain tree of life.

Hug et al. (2016) generated an extensive new suite of genome sequences from more than 1,000 uncultivated organisms and merged these with previously published sequences. These were then aligned and concatenated with a suite of 16 ribosomal proteins from each identified organism, creating what they argue is a higher-resolution tree of life than that derived from the single 16S rRNA gene sequence. Results substantiate the dominance of bacterial diversification and identify many new evolutionary radiation events that could eventually impact the basic Woese three-domain tree of life model. However, Hug et al. do not use this data set to try to decipher the evolutionary placement of the Eucarya. Woese established a three-domain universal tree of life model (Figure 8.4.2) based on changes in the ribosome, which indicates that the deeply rooted Archaea split from the Eucarya at ~3.5 Bya (Figure 8.4.2; Woese et al. 1990). Many other subsequent studies have followed suit, stating that there is more certainty in ribosomal DNA than in concatenated genes. In addition, reevaluation of the Lokiarchaea 16S rRNA gene sequences places them into a group of environmental Crenarchaeota. Furthermore, Lokiarchaea utilize a unique membrane lipid that is different from the lipids used by Eucarya and Bacteria. Conversely, citing protein phylogeny and incorporation of RNA polymerase phylogenies, other researchers have recently concluded that Lokiarchaea and the other members of the Asgard Superphylum are a firmly rooted branch within the Archaea domain (Da Cunha et al. 2017; Zaremba-Niedzwiedzka et al. 2017).

These types of invaluable scientific discussions and controversies will continue to take place as more and more organisms are found and analyzed (both on Earth and potentially other planets). The reoccurring question will therefore be how to keep the scientific evaluations of the tree of life moving forward with each new discovery (Forterre 2016). As in the case of the Lokiarchaea, the first step toward full analysis and resulting tree of life reevaluation will be to isolate the microorganisms in question. To date, the Asgard Group has only been detected using molecular techniques. A full determination of evolutionary relatedness will require having Lokiarchaea and

the others in pure culture in the laboratory. Simply put, our ideas of evolution must continually evolve with the data being collected, but those data need to include a full determination of biogeochemistry, metabolism, ecology, and closure of complete genomes, accompanied by completion of the full suite of DNA-RNA-protein *Omics* analyses. The tree of life is not yet complete and will be a work in progress for decades to come. However, the Woese three-domain universal tree of life remains reliable, because rRNA genes are some of the most stable and conserved. This provides a consistently defendable and reproducible framework, against which new interpretations and hypotheses can be rigorously tested.

8.4.7 SUMMARY

The three-domain universal tree of life established by Carl R. Woese fundamentally reset the stage of evolutionary theory and has forever changed the face of modern biology (Woese 2004). His new vision of cells that are capable of extensive collective sharing of genetic materials, and their universal possession of partially conserved genes that can serve as a measuring stick of evolutionary relatedness, resulted in the identification of the Archaea and a fundamentally new understanding of the origin and early evolution of life. The NASA was the sole federal funding agency that made this research possible. The resulting universal tree of life is now the fundamental roadmap used to probe the most fundamental of challenges facing society regarding the environment, energy, medicine, and the search for life throughout the cosmos.

ACKNOWLEDGMENTS

Financial support for this review was provided from the National Aeronautics and Space Administration (NASA) through the NASA Astrobiology Institute Education and Public Outreach initiative under Cooperative Agreement No. NNA13AA91A issued by the Science Mission Directorate. We also thank Claudia Lutz and Isaac Cann for their invaluable editorial evaluations. Conclusions in this study are those of the authors, and they do not necessarily reflect those of the funding agency.

8.5.1 INTRODUCTION

Fossils of microorganisms that can be identified under the microscope are called microfossils. Microfossils provide invaluable information about the evolution of life, stratigraphic correlation, and reconstruction of paleoenvironments. Except for well-known Ediacaran macrofossils and a few other examples, fossil records identified from the Precambrian era older than 0.54 Ga are all microfossils. Study of Precambrian microfossils started with the discovery of morphologically diverse microfossils from the 1.9 Ga sedimentary rocks of the Gunflint Formation (Barghoorn and Tyler 1965; Cloud 1965), and since then, numerous efforts have been made to search for older microfossils and other biosignatures, such as microbial sedimentary structures (stromatolites), molecular biomarkers, bio-mineralization, and isotopic signatures. In particular, cellularly preserved microfossils that provide us with direct images of ancient life have been fascinating research targets. However, there has been great debate over the biogenicity of Archean fossil-like microstructures, including how to discriminate genuine microfossils from pseudo-microfossils. This issue is still heavily debated, and new discoveries of Archean biosignatures, including doubtful ones, are appearing in succession. Therefore, it is worth reviewing Archean microfossil records, based on previously published informative reviews (Schopf and Walter 1983; Altermann and Kazmierczak 2003; Schopf 2006; Schopf et al. 2007; Wacey 2009, 2012). In this chapter, I provide a detailed review of representative microfossils and possible microfossils from the early (Meso- and Paleo-) Archean successions in the Isua Supracrustal Belt, Greenland; Nuvvuagittuq Belt, Canada; Kaapvaal Craton, South Africa; and Pilbara Craton, Western Australia, with reference to the early Earth's surface environments, criteria for biogenicity of Archean microbe-like structures, and some examples of pseudofossils. Detailed discussions are given for problematic microfossils, characterized by their large eukaryotic size and lenticular shape, that are incomparable with extant prokaryotes. Finally, frameworks and hints for further studies are presented.

8.5.2 SURFACE ENVIRONMENT OF THE EARLY EARTH

Although the Archean surface environment has not yet been fully revealed and controversies are continuing, it was closely related to metabolisms and habitats of the contemporaneous organisms. Therefore, it is worth mentioning this topic briefly before describing microfossils.

8.5.2.1 ACTIVE VOLCANISMS

Early Archean surface environments were distinctly different to those from the modern and even the Proterozoic environments, with the presence of extensively active volcanism, as indicated by rock records, dominated by mafic to ultramafic volcanic rocks (Lowe 1999; Van Kranendonk et al. 2006). Ultramafic lava known as komatiite is indicative

of a much higher temperature of the upper mantle than today (Berry et al. 2008). Greater active volcanism in the early Archean than later periods means that hydrothermal activities were more widespread and more intense in the early Archean period. Intense hydrothermal activities likely resulted in alteration of rocks, represented by silification and carbonization, and provided nutrients essential to metabolisms of primitive life.

8.5.2.2 HIGHER TEMPERATURE

Owing to active volcanism and low rate of organic carbon burial, assumed from presumed much lower biomass, the atmospheric concentration of carbon dioxide in the Archean was much higher than today. This, together with possible higher concentrations of other greenhouse gases such as methane, compensated the lower solar luminosity and might have even kept the Earth's surface temperature higher than today. Isotopic studies of oxygen and silicon of Archean cherts (quartz) suggest that the temperatures of seawater at that time were between 55°C and 85°C (Knauth and Lowe 2003; Robert and Chaussidon 2006). Such estimate had some uncertainties due to unknown seawater oxygen isotopic compositions. More recently, however, Tartèse and co-workers (2017) demonstrated that the seawater oxygen isotopic composition did not change through time. Combined with the chert oxygen isotopes, the authors indicated that the temperature of ca. 3.5 Ga ocean bottom-water was ~50°C–60°C higher than today. Although some researchers argued a temperate climate for the Archean (Hren et al. 2009; Blake et al. 2010), it seems more likely that the Archean seawater temperature was significantly higher than today.

8.5.2.3 SEAWATER COMPOSITIONS

It is widely accepted that the Archean seawater was enriched in silica and ferrous iron. Silica and iron enrichment is evidenced by extensive deposition of cherts and banded iron formations in the Archean (Siever 1992; Sugitani 1992; Maliva et al. 2005). Silica enrichment in the Archean ocean was attributed to the absence of organisms requiring silica as a nutrient, as well as intense chemical weathering on land due to high concentrations of atmospheric CO₂ and a higher flux of dissolved silica from hydrothermal vents. It is also suggested that there was ferrous iron enrichment, at least in the bottom water of stratified oceans, which can be attributed to higher hydrothermal activities and a presumed anoxia. Shibuya and co-workers (2010), on the other hand, argued that the sub-seafloor Archean hydrothermal system produced highly alkaline, SiO₂-rich, Fe-poor fluids, contrastive to most of modern seafloor hydrothermal system along mid-ocean ridges. Concentrations of other redox-sensitive components such as sulfate could have varied significantly between the surface and bottom waters and even much more locally. However, as a whole, sulfate concentrations in the Archean ocean were likely much lower than in the present ocean (Habicht et al. 2002; Schröder et al. 2008).

8.5.2.4 ASTEROID IMPACTS

Approximately 4.1–3.8 Ga ago, extensively large numbers of asteroids collided with the Earth (the Late Heavy Bombardment [LHB]). Sedimentary records in the Paleoarchean, suggest that asteroid impacts had still occurred after the LHB more frequently than late periods (Byerly et al. 2002; Lowe et al. 2003, 2014; Glikson et al. 2016). Extensive investigations in the Barberton greenstone belt revealed that eight large (at least 20–70 km across) asteroid or meteorite impacts had occurred ~3.47–3.23 Ga (Lowe et al. 2014). It is suggested that such impacts triggered the modern-type plate tectonics, also causing tsunamis, heating of the atmosphere, and boiling and even evaporation of ocean surface water (Lowe and Byerly 2015). Such impact events plausibly influenced early evolution of life; however, details are still unknown (Lowe et al. 2003).

8.5.3 ROCKS PRESERVING FOSSILIZED MICROBES

Ancient biosignatures have been identified from a wide range of rocks, including those of relatively low metamorphic grade such as cherts and carbonates, siliciclastic rocks such as shales and sandstones, volcaniclastic rocks, and even volcanic rocks. Chert composed of microcrystalline quartz is formed by various processes, including chemical precipitation of silica, silicification of non-siliceous sediments and igneous rocks, and accumulation of siliceous tests such as those of diatoms and radiolaria. In the Archean, when silica-secreting organisms were absent, cherts were formed by chemical precipitation or replacement of non-siliceous rocks/sediments (silicification) (Duchač and Hanor 1987; Sugitani et al. 1998) (Figure 8.5.1).

Chemically precipitated chert has long been regarded as the most promising rock type for hosting ancient cellularly preserved

FIGURE 8.5.1 Marble Bar Chert in the Pilbara Craton, Western Australia, representing Archean cherts formed by chemical precipitation of silica (reddish and white band) and silicification of fine-grained clastic sediments (dark-gray band and vein). See, for example, Sugitani (1992)

microfossils. Indeed, Archean microfossils have been identified mostly in chert, as described later. Other rock types are also known to host biosignatures. For example, stromatolites, which are shallow-water sedimentary structures characterized by a complicated architecture of laminae and morphology, are perhaps the most reliable non-organic biosignatures. These forms were highly abundant in the Precambrian. Walter (1976) has provided the most comprehensive work describing these structures and their potential significance. Stromatolites are preserved almost exclusively as carbonates (Walter 1976; Allwood et al. 2006), whereas microbially induced sedimentary structures are identified mainly in siliciclastic sediments (Noffke 2010). Interestingly, volcanic rocks may preserve ancient biosignatures as traces of endolithic microbes (McLoughlin et al. 2007); however, this topic is out of the focus of this chapter. Rocks of high metamorphic grade and/or subjected to intense alteration such as metasomatism could preserve biosignatures although it should be reminded that possible biosignatures in such problematic rocks have been subjected to severe criticisms and skepticisms (Bridgwater et al. 1981; Fedo et al. 2006).

8.5.4 IDENTIFICATION OF MICROBE-LIKE STRUCTURES AS MICROFOSSILS

In this section, criteria for discriminating microfossils from non-microfossils are discussed. Controversies over Archean microfossil-like structures, represented by the *Isuasphaera* controversy (see Section 8.5.6.1), have resulted in the development of sophisticated approaches to microfossil analyses. The more stringent the criteria applied and satisfied, the more confidently the biogenicity can be claimed. However, too rigid criteria, suggested, for example, by Brasier and co-workers (2002, 2005, 2006), are undesirable. The authors claimed that Archean microfossil-like structures needed to be considered as non-biological, until the non-biological origin of the structures is refuted. This “null hypothesis” approach, however, is not constructive and should not be applied to Archean paleobiology, because it is virtually impossible to test “all possible alternatives” for biological origins of microfossil-like objects. Indeed, this approach is feared to be “playing one’s own work.” Also, the null-hypothesis approach requires substantial analyses of structures under consideration by using the most updated analytical techniques, available at only limited institutions. It is therefore believed that criteria for biogenicity should be basically tested by conventional methodologies, and it seems realistic to employ a series of prefixes such as “pseudo-,” “dubio-,” “possible-,” “probable-,” and “genuine-” in order to express the reliability of the biological origin of the object under consideration. In the following sections, the criteria integrated from those previous studies (Schopf and Walter 1983; Buick 1990; Brasier et al. 2002, 2005, 2006; Hofmann 2004; Sugitani et al. 2007; Wacey 2009) are shown, along with some new concepts.

8.5.4.1 GEOLOGICAL CONTEXT

Microstructures should occur in sedimentary rocks, preferably of low metamorphic grade from well-known early Archean

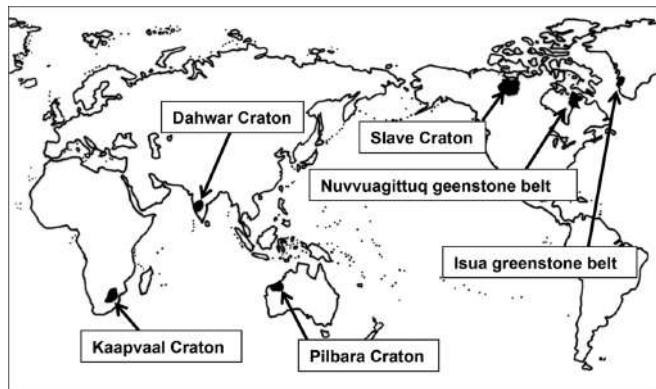

FIGURE 8.5.2 Cratons and greenstone belts containing early Archean sedimentary rocks.

terrane (Figure 8.5.2). Direct determination of the age of the host rock is desirable. This, however, can be substituted by establishing the age of the unit from which rock specimens containing the microbe-like structures were collected. It is essential to demonstrate that the host rock is definitely a part of a geographically extended Archean sedimentary succession, because duricrusts that form through modern cementation of sand and gravel by silica (silcrete) and carbonate (calcrete) could be mistaken as ancient sediments.

8.5.4.2 INGENUOUSNESS AND SYNGENECITY

Microstructures should be demonstrated to be indigenous to the host rocks. This is particularly important when microstructures are detected as objects separated by acid maceration of host rocks (extraction of organic matter by HF-HCl digestion at room temperature), during which pollens and other modern organic materials could contaminate the sample. In other words, if structures under consideration are identified within petrographic thin sections, their indigenousness is basically guaranteed. Syngenecity means that the structures are embedded within the primary mineral phase but not within significantly later-formed pores, fractures, and veins (Figure 8.5.3a). Oehler and Cady (2014) describe the importance of syngenecity in detail, along with new techniques for assessing both biogenicity and syngenecity.

8.5.4.3 BIOLOGICAL CONTEXT: SIZE AND ITS RANGE

The size of unicellular microorganisms varies greatly, from the minimum value of ~200 nm for *Mycoplasma* up to the maximum of ~20 cm for coenocytic *Xenophyophore*. In the strict sense, therefore, size criterion merely gives the minimum value. In general, microorganisms that reproduce simply by binary fission tend to have a narrow size distribution, which is expected to have a Divisional Dispersion Index (DDI) smaller than 5; such a population should also fit to a Gaussian, normal

distribution (Schopf 1976). However, a population with a wide size range does not always mean that the structure is abiogenic. Microorganisms that reproduce by multiple fissions, by asymmetric divisions, and by producing spores could result in populations characterized by a wide range of sizes. Also, it should not be overlooked that fossil populations can be composed of plural taxa, characterized by different size ranges.

8.5.4.4 BIOLOGICAL CONTEXT: SHAPE

The shape of unicellular microorganisms is very diverse; however, most prokaryotic cells are coccoid-, rod-, or filament-shaped. Abiogenic processes also can produce various morphologies, as represented by silica-witherite biomorphs (García-Ruiz et al. 2004). Thus, similarities to extant microorganisms should not be taken as weighted evidence for biogenicity. Rather than specific shapes, incompleteness is a key feature for assessing biogenicity. Cell envelopes (also called plasma membranes, cell walls, and cell capsules) are composed of polymeric materials and thus have plasticity. This means that cell shape could be deformed to various degrees. Therefore, shapes of microorganisms, particularly fossilized ones, tend to vary from complete to incomplete (i.e., being deformed) to various degrees even within a single colony. Thus, such a feature is a key part of identifying microstructures as microfossils.

Cells, if not all, display various elaborate morphologies and textures, such as an organelle, flagellum, and/or appendages. Thus, elaboration is a key criterion for biogenicity. Although delicate structures such as organelles and flagellum are difficult to preserve, protrusions and ornaments could be preserved, as evidenced by some organic-walled Proterozoic microfossils (Figure 8.5.3b) (Javaux et al. 2003; Butterfield 2005; Moczydłowska et al. 2011). Whatever their origins and functions are, the more elaborate the structures, the more likely would be their biogenicity. Morphological elaboration, assumingly related to reproduction, is strong evidence for the biogenicity of the fossil-like structure.

8.5.4.5 BIOLOGICAL CONTEXT: OCCURRENCE

Microstructures should be abundant, hopefully occurring as clusters (colonies) (Figure 8.5.3c). Unicellular microorganisms can reproduce very rapidly if environmental conditions such as temperature, pH, and concentrations of nutrients are suitable. Therefore, abundant occurrence is advantageous in assessing biogenicity, because biogenicity can be tested statistically by using the size distribution and the DDI, along with various taphonomic features, as described in the sections above and below. Additionally, a close spatial relationship of microstructures to carbonaceous laminae, which most likely represent degraded biofilms, can be presented as strong evidence for biogenicity (Figure 8.5.3d).

8.5.4.6 BIOLOGICAL CONTEXT: TAPHONOMY

Polymerized compounds that comprise cell envelopes would be degraded to smaller compounds after death of cells by hydrolysis and by heterotrophic metabolisms. Such degradation tends to progress heterogeneously, as exemplified by the different preservation status of microfossils in the same bed (Figure 8.5.3e).

8.5.4.7 BIOLOGICAL CONTEXT: CHEMICAL AND ISOTOPIC COMPOSITIONS

Carbonaceous composition is a key geochemical criterion for the biogenicity of microbe-like structures. During degradation and thermal maturation, hydrogen, oxygen, sulfur, and nitrogen, which comprise organic materials making up cell components, are eventually released, resulting in

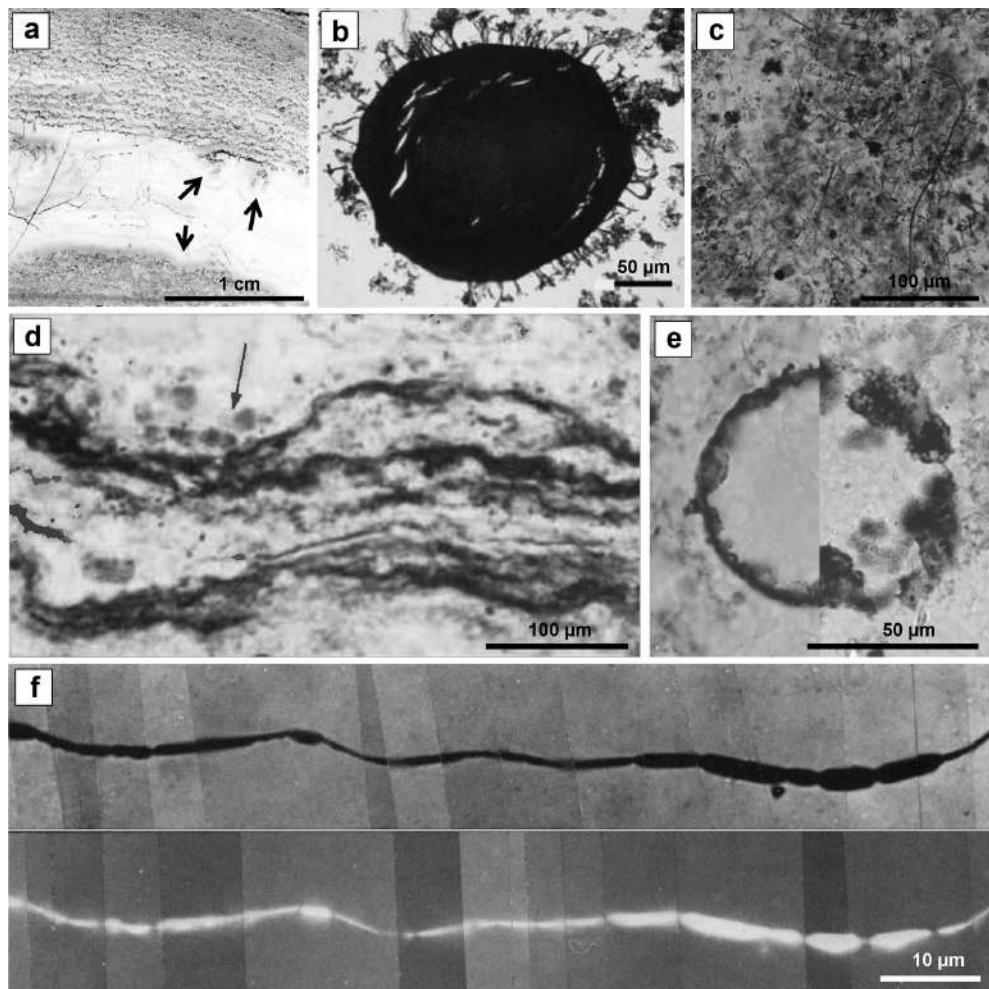

FIGURE 8.5.3 (a) Photomicrograph of vein composed of megaquartz and microquartz parallel to local lamination that locally displays coliform textures (arrows). Though probably formed during very early diagenesis, such a vein can be mistaken as a syndepositional layer. (b) Process-bearing acritarch, *Shuiyousphaeridium macroreticulatum*, from the Ruyang Group, northern China. (Javaux, E.J. et al., *Geobiology*, 2, 121–132, 2004. With permission from Blackwell publishing Ltd.) (c) Dense populations of filamentous and spheroidal microfossils comprising a Paleoproterozoic microbial colony (1.9 Ga Gunflint Chert). (d) Association of spheroidal microfossils (arrow) with irregularly wrinkled carbonaceous laminae (biofilms), from the middle Proterozoic Balbirini Dolomite (McArthur Group) of Australia. (From Oehler, D.Z., *Alcheringa*, 2, 269–309, 1978; Courtesy of D. Oehler.) (e) Composite photo of contrastively preserved walls of spheroidal microfossils from the 3.0 Ga Farrel Quartzite in the Pilbara Craton, Western Australia. The right side shows a degraded and partially granular wall, whereas the left side shows hyaline with regular dimples. (f) Filamentous bacterial microfossil replaced by pyrite, from the middle Proterozoic Barney Creek Formation (McArthur Group) of Australia. (From Oehler, J.H., *Alcheringa*, 1, 315–349, 1977.) The upper and lower photographs represent images in transmitted and reflected light, respectively. (Courtesy of D. Oehler.)

residues composed dominantly of carbon (Oberlin 1984). While an association of C, S, and N, established at the sub-micron scale with NanoSIMS, with the carbonaceous structures could be strong evidence for their biogenicity (Oehler et al. 2006, 2009, 2010), it must be cautioned that organic matter could be mobilized and redistributed in rock matrix (Marshall et al. 2012; Lepot et al. 2013), potentially producing structures that could mimic cells (Brasier et al. 2002). Though not direct evidence, detection of hydrocarbon biomarkers from host rocks could support biogenicity of microbe-like structures. It is again noteworthy that syngeneticity of biomarker molecules in Archean rocks has raised controversies and requires strictly controlled protocols from sampling through to analyses (Oehler and Cady 2014). Another note is that carbonaceous matter comprising microfossils could be replaced by other materials such as hematite and sulfide ([Figure 8.5.3f](#)) (Oehler 1977; Rasmussen 2000; Sugitani et al. 2007). Therefore, non-carbonaceous compositions of microbe-like structures do not readily discard their biogenicity.

Light (< -20 per mil Pee Dee Belemnite (PDB)) carbon isotopic compositions ($\delta^{13}\text{CPDB}$) have long been taken as a key feature in claiming the biogenicity of putative microfossils. However, this should not be taken as diagnostic, because isotopic fractionation and resultant formation of organic carbon with very light isotopic values could be produced through inorganic processes (McCollum and Seewald 2006). Yet, this is still an important feature for assessing biogenicity, particularly if carbon isotopic signatures associated with fossil-like structures are varied across micron scale and are texture-specific (Lepot et al. 2013; Williford et al. 2016; Morag et al. 2016). Carbon isotopic values of extant organisms are so diverse and depend on various factors such as the availability of inorganic carbon. Therefore, it is generally difficult to specify metabolisms based on isotopic values alone.

8.5.5 PSEUDOFOSILS

Prior to describing representative early Archean microfossils and possible microfossils, some examples of pseudofossils in Archean successions are described. To date, some well-described Archean pseudo-microfossils include pyrite trails in cherts (Knoll and Barghoorn 1974), microtubes in volcanic ashes (Lepot et al. 2011), filamentous structures composed of stacked phyllosilicates in chert (Brasier et al. 2015), volcanic vesicles (Wacey et al. 2018a, 2018b) and filamentous structures mimicked by intragranular cracks or fractures in chert (Marshall et al. 2011; Bower et al. 2016). Here, three spheroids and one filamentous

structure mimicking microfossils, identified in the author's collections, are described. All specimens are from the 3.4 Ga Strelley Pool Formation in the Pilbara Craton, Western Australia.

8.5.5.1 SILICA SPHERULITE COATED WITH MEMBRANOUS CARBONACEOUS MATTER

Some Archean cherts are thought to originate from chemically precipitated silica gel. In such cherts, micron-scale spherulitic structures (chalcedonic quartz spherulites) can form by nucleation on the surface of organic matter, as demonstrated previously (Oehler and Schopf 1971; Oehler 1976). This structure can be diagnostic for a sedimentary origin of chert, which is preferred for the assessment of biogenicity. On the other hand, this structure, which has a relatively clear carbonaceous rim, mimics fossilized spheroid cells (Buick 1990; Fig. 3). [Figure 8.5.4a](#) shows hemispheric silica bodies coated by membranous (not particulate) carbonaceous matter. Although an abiogenic origin is evident from their clearly hemispheric shape and occurrence in a vein, the presence of such objects should be reminded when considering the biogenicity of spheroids with carbonaceous wall.

8.5.5.2 SPHEROID MOLDS OF DISSOLVED SULFIDE GRAINS

Sulfide, represented by pyrite (FeS_2), is a common accessory mineral contained in Archean sedimentary rocks, particularly carbonaceous black chert. It occurs as spheroid grains, equant cubic crystals, and their aggregates. Sulfide could be oxidized and dissolved to leave molds, as shown in [Figure 8.5.4b](#) and [c](#). The molds of spheroid grains are outlined by very fine black particles, possibly carbonaceous matter, mimicking fossilized spheroid cells.

8.5.5.3 CLUSTERED FILAMENTOUS OPAQUE MATERIAL

Possibly abiogenic filamentous structures are also found ([Figure 8.5.4d](#)). Filaments are highly sinuous and comprise a cluster 50 μm across. Widths of most filaments are constant, around 1 μm , but tapering filaments are also present. These filaments are composed of opaque materials, obscuring any inner structures. Thus, hollowness and septation, key features in assessing the biogenicity of filamentous structures, cannot be identified. Their abiogenic origin is suggested from the presence of dispersed similar opaque structures of different width and lengths, without any fragmented features.

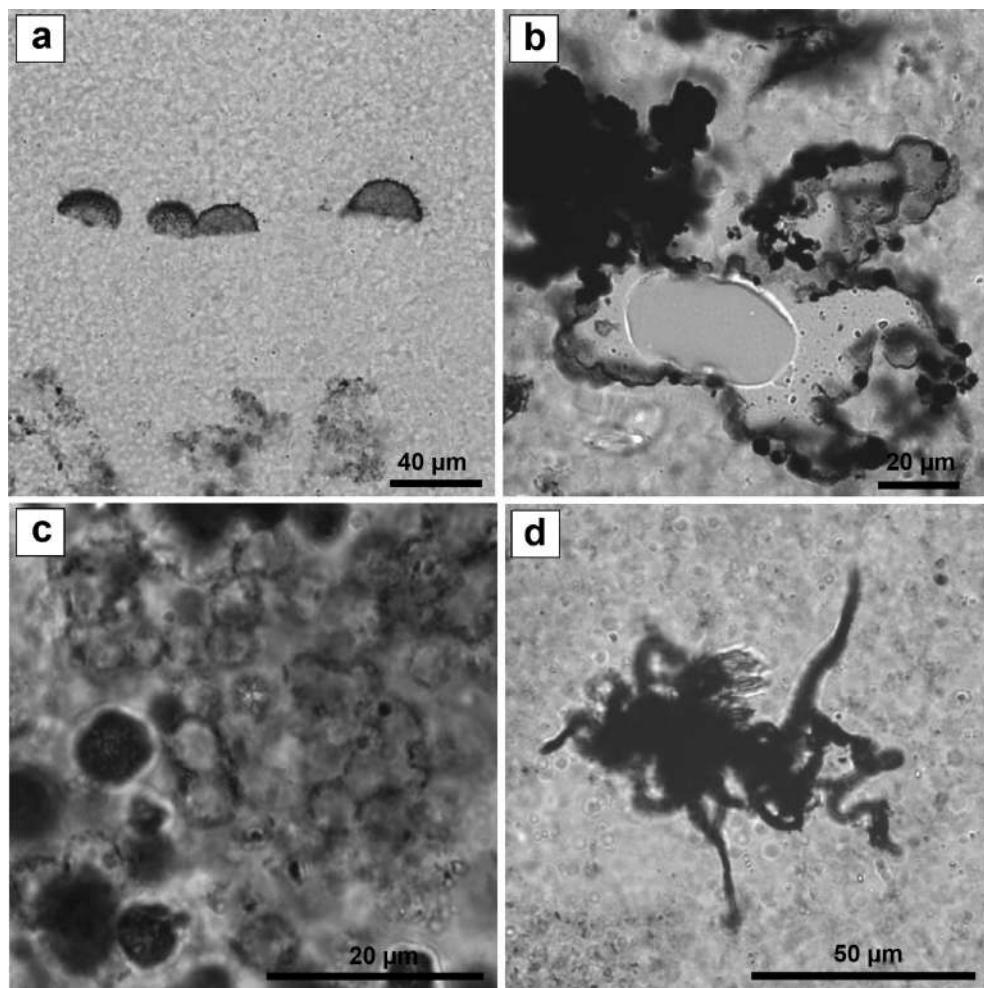

FIGURE 8.5.4 Pseudofossils from the 3.4 Ga Strelley Pool Formation in the Pilbara Craton, Western Australia. (a) Organic-walled silica hemispheres in clear chert vein. (b) Irregular spheroidal cavity formed by dissolution of sulfide cluster, walled by a thin possible organic film. (c) Spheroids probably formed by dissolution of sulfide grains (opaque areas). Remained materials are possible organic matter. (d) Cluster of sinuous filamentous opaque minerals (probably sulfide), like “Caput Medusae.”

8.5.6 EXAMPLES OF ARCHEAN MICROFOSSILS, POSSIBLE MICROFOSSILS, AND QUESTIONABLE MICROFOSSILS

8.5.6.1 ISUA SUPRACRUSTAL BELT, GREENLAND

Pflug (1978) described cell-like structures in ca. 3.8 Ga. rocks collected from the Isua Supracrustal Belt, Greenland. The ellipsoidal structures generally range from 10 to 40 µm in diameter and have hollow interiors partly filled with organic matter or pyrite (Figure 8.5.5a and b). The author claimed that the structures were biogenic and named them *Isuaspheara*. The similarity of *Isuaspheara* to yeasts was suggested. Subsequently, Pflug and Jaeschke-Boyer (1979)

performed more detailed structural and chemical analyses, including Raman microprobe analysis, where the carbonaceous compositions of walls of *Isuaspheara* specimens were demonstrated. These studies have since been subjected to criticism. Bridgwater and co-authors (1981) denied the biogenicity of *Isuaspheara* because of the context of intense geochemical alterations and high-grade (up to amphibolite-facies) metamorphism of host rocks, which were unlikely to preserve fragile microorganisms. Also, these authors suggested that limonite-stained fluid inclusions had been misinterpreted as microfossils. Roedder (1981), on the other hand, suggested that the microbe-like objects were neither limonite-stained fluid inclusions nor microfossils and reinterpreted them as limonite-stained cavities. It seems uncertain whether

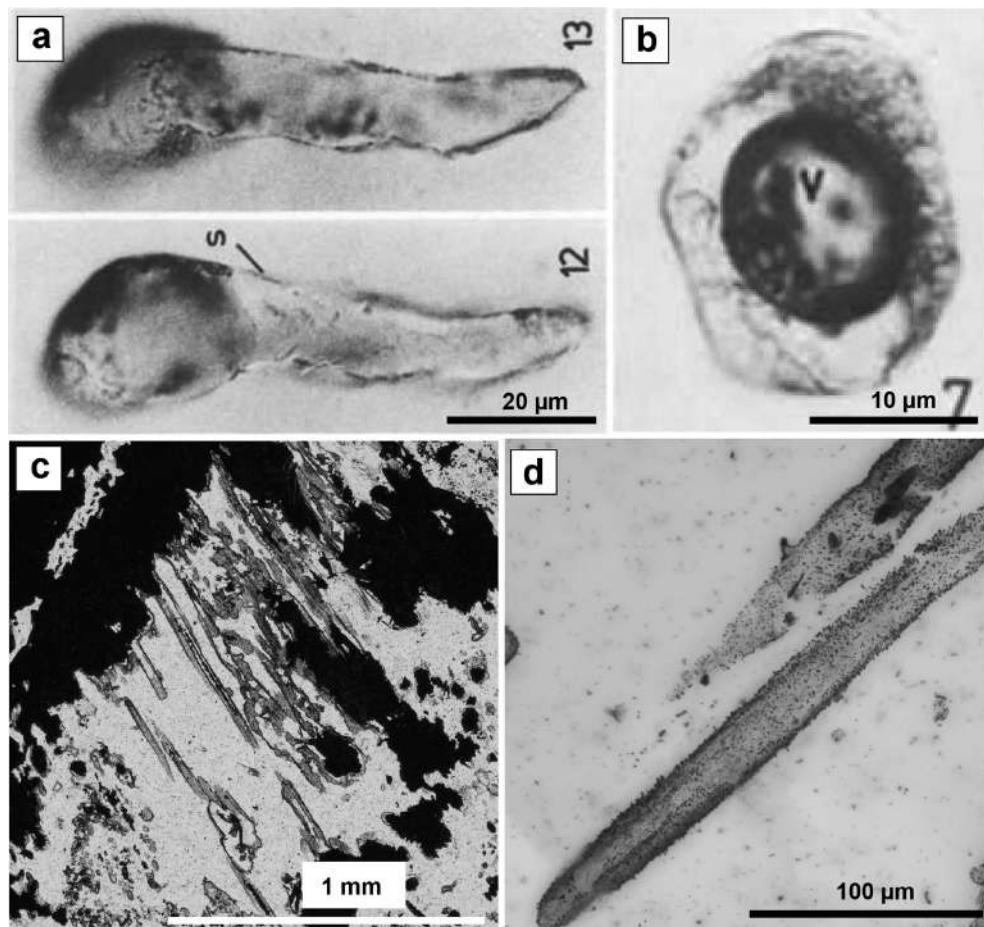

FIGURE 8.5.5 (a) Two images of *Isuasphaera isua* at different focus depths. Thin, elongated wall indicated by S is interpreted as sheath. (b) Another type of *Isuasphaera isua* with central void (v) interpreted as gas vacuole. (a and b: With kind permission from Springer Science+Business Media: *Naturwissenschaften*, Yeast-like microfossils detected in oldest sediments of the earth, 65, 1978, 611–615, Pflug, H.D.) (c and d) Hematitic filaments and tubes in early Archean (>3.8 Ga) ferruginous sedimentary rocks from the Nuvvuagittuq greenstone belt, Canada. (Courtesy of M.S. Dodd.)

these authors examined exactly the same objects (holotypes), and thus, the controversies might not have been to the point. More recently, Appel and co-workers (2003) emphasized that the host meta-chert was subjected to extreme stretching deformation, making it unlikely that syn-depositional spherical objects were preserved, and suggested that the microbe-like objects reported by Pflug (1978) probably resulted from pre-Quaternary weathering.

8.5.6.2 THE NUVVUAGITTUQ GREENSTONE BELT, CANADA

Dodd and co-workers (2017) reported filaments and tubes from at least 3,770 million and potentially 4,280 million years old rocks from the Nuvvuagittuq Belt, Canada. The structures are composed dominantly of hematite and occur in seafloor-hydrothermal-vent-related precipitates (Figure 8.5.5c and d). The authors emphasized that the structures were similar in morphology and associated materials to modern and younger equivalents (Little et al. 1999; Hein et al. 2008; Li et al. 2012). Carbon isotopic values of carbonate and carbonaceous matter are also consistent with their biogenic origin. The authors claimed that

the structures were oxidized biomass that inhabited a very ancient submarine hydrothermal environment, based on the null hypothesis. As stated earlier, the author (K.S.) does not subscribe to a “null-hypothesis approach.” Furthermore, their morphological similarity to younger and modern filamentous microfossils provides only limited evidence for biogenicity, because of their morphological simplicity. At this stage, the hematitic structures cannot be readily accepted as of a biological origin.

8.5.6.3 KAAPVAAL CRATON, SOUTH AFRICA

The Kaapvaal Craton is one of the major Archean cratons in the southern part of the African Shield. Microfossils and other biosignatures such as stromatolites and microbially induced sedimentary structures have been reported from the Barberton greenstone belt and Late-Archean sedimentary units. The Barberton greenstone belt consists of the Swaziland Supergroup, which is composed of the 3.55–3.27 Ga Onverwacht, the 3.26–3.23 Ga Fig Tree, and the 3.22–3.10 Ga Moodies Groups, from all of which microfossils and possible microfossils have been reported.

8.5.6.3.1 The Onverwacht Group

The Onverwacht Group is dominated by komatiitic and basalitic volcanic and volcanioclastic rocks, with minor amounts of dacitic volcanioclastic rocks and cherts (Lowe 1999). Microfossils and other biosignatures have been reported mostly from cherts enriched in carbonaceous matter. Fossil-like microstructures from the Onverwacht Group were reported as early as the 1960s and 1970s (Engel et al. 1968; Nagy and Nagy 1969; Brooks et al. 1973; Muir and Hall 1974). Reported structures were morphologically diverse, including spheroids and filaments, among others. However, these earlier findings were later questioned (Schopf 1976; Schopf and Walter 1983). On the other hand, carbonaceous filaments, spheroids, and

spindle-lens-shaped structures reported by other investigators (Knoll and Barghoorn 1977; Walsh 1992; Walsh and Lowe 1985; Westall et al. 2001) have been widely accepted as possible to genuine microfossils. In addition, Kremer and Kaźmierczak (2017) recently described new microfossil assemblages. Selected specimens are described in this section.

Walsh (1992) described large granular spheroids and ellipsoids around 20 µm (up to a maximum of 70 µm) and spindles around 30 µm (up to a maximum of 140 µm) in size, in addition to filaments similar to those described previously by Walsh and Lowe (1985) (Figure 8.5.6a and b). Their sizes are much larger than many prokaryotic cells, and they often have thick wall. Based on the assumed frequent large asteroid impact events in

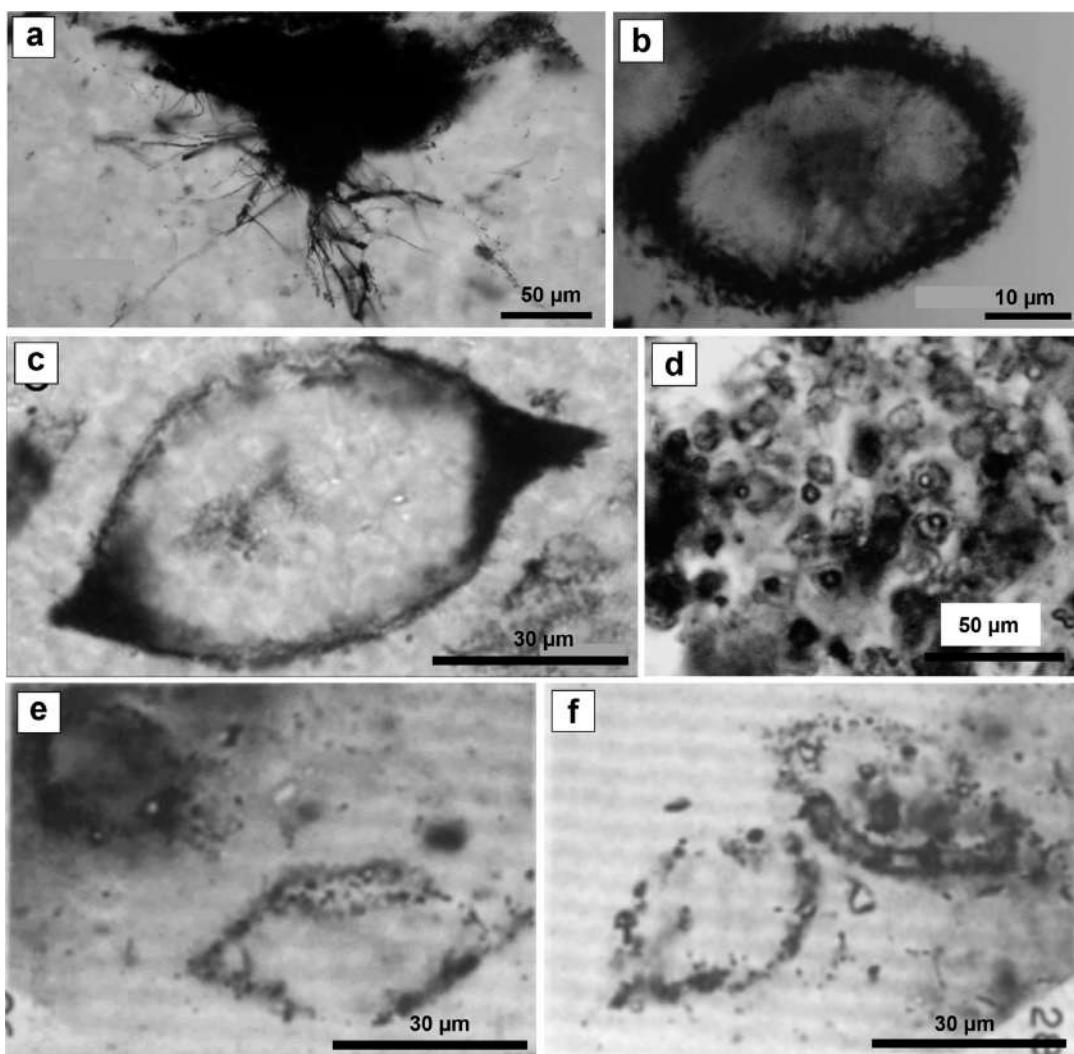

FIGURE 8.5.6 Microfossils and possible microfossils from the Onverwacht Group (a–d) and the Fig Tree Group (e, f), South Africa. (a) Filamentous microfossils from the Kromberg Formation. (From Walsh, M.M., and Lowe, D.R., *Nature*, 314, 530–532, 1985.) (b) Granular-walled large spheroid from the Kromberg Formation. (From Walsh, M.M., *Precam. Res.*, 54, 271–293, 1992.) (a and b: Courtesy of M.M. Walsh.) (c) Lenticular microfossils from the Kromberg Formation discovered independently by M.M. Walsh and K. Sugitani, respectively. (From Oehler, D.Z. et al., *Precam. Res.*, 296, 112–119, 2017.) (d) Cluster of cell-like bodies, which are interpreted as remains of variously degraded colonies of cyanobacteria-like microbes. (Reprinted from *Precam. Res.*, 295, Kremer, B., and Kaźmierczak, J., Cellularly preserved microbial fossils from ~3.4 Ga deposits of South Africa: A testimony of early appearance of oxygenic life? 117–129, Copyright 2017, with permission from Elsevier.) (e and f) Possibly poorly preserved lenticular microfossils, equivalent to that shown in (c). (Reprinted from *Rev. Palaeobot. Palynol.*, 5, Pflug, H.D., Structured organic remains from the Fig Tree Series (Precambrian) of the Barberton Mountain Land (South Africa), 9–29, Copyright 1967, with permission from Elsevier.)

the early Archean (e.g., Lowe et al. 2014), Walsh (1992) suggested the possibility that these large granular fossil-like structures represent envelopes containing endospores tolerant against the harsh environments of the early Earth. The described “spindles,” which are more likely lenticular in shape, were recently re-identified, and their biogenicity was confirmed by individual isotopic analyses (Oehler et al. 2017) (Figure 8.5.6c). Structures similar in appearance have also been reported from the 3.4 Ga Strelley Pool Formation and the 3.0 Ga Farrel Quartzite in the Pilbara Craton, Western Australia, as described later (Sugitani et al. 2007, 2010). Kremer and Kaźmierczak (2017) described large (~150–700 µm in length) clusters composed of small carbonaceous cell-like bodies in massive and weakly laminated black cherts with $\delta^{13}\text{C}_{\text{PDB}}$ values of ~−25 per mil for bulk carbonaceous matter (Figure 8.5.6d).

These cell-like bodies range in size from 3 to 12 µm, show various taphonomic features, and are associated with Al-K-Mg-Fe silicate material, known also from both modern and fossil microbial mats (Douglas 2005). The authors give an in-depth biological interpretation of their benthic-planktonic life cycle and cyanobacterial affinity, such as *Microcystis*.

8.5.6.3.2 The Fig Tree Group

The Fig Tree Group consists of terrigenous clastic rocks, with dacitic to rhyodacitic volcaniclastic and volcanic rocks. The sedimentary successions are composed of graywackes, slates, shales, chert, jasper, and banded iron formation. Possible microfossils were recorded from cherts.

Several reports of the Fig Tree microbe-like structures were published in the 1960s (Barghoorn and Schopf 1966; Pflug 1967; Schopf and Barghoorn 1967). Here, possible microfossils reported by Schopf and Barghoorn (1967) and Pflug (1967) are described.

Schopf and Barghoorn (1967) examined thin sections of carbonaceous black cherts and identified spheroidal dark-colored organic bodies ($n = 28$) that range from 15.6 to 23.3 µm in diameter. Their sizes are significantly larger than the matrix

micro-quartz. The spheroids, with walls up to 1-µm thick, were interpreted as to often exhibit a reticulate surface texture, have an irregular mass of organic matter inside, and display various taphonomic stages; however, resolutions of the photographs are not satisfactory.

Pflug (1967) examined cherts and shales of the Fig Tree Group, using both chemical and optical methods. Various morphological types of carbonaceous structures were identified, including opaque, egg-shaped bodies, ellipsoidal bodies characterized by a somewhat transparent wall, disc- or lens-shaped bodies, globular bodies, and filamentous structures. Globular-type objects ranged from 5 to 70 µm across, with the majority larger than 20 µm. Pflug (1967) described that these often occur as colonies and exhibit differentiations such as pores and internal structures. As resolutions of the photographs are not satisfactory, some of the interpretations cannot be verified. It is, however, noteworthy that the described globular objects include morphologies comparable to lenticular microfossils (Figure 8.5.6e and f) described from the older Onverwacht Group (Walsh 1992; Oehler et al. 2017) and the ca. 3.4 Ga Strelley Pool Formation and the ca. 3.0 Ga Farrel Quartzite of the Pilbara Supergroup, Western Australia (Sugitani et al. 2007, 2010; Oehler et al. 2017).

8.5.6.3.3 The Moodies Group

The Moodies Group consists dominantly of alluvial to shallow-marine sandstone with subordinate conglomerate, shale, siltstone, iron formation, and volcanic rocks and provides one of the oldest records of a tide (Heubeck and Lowe 1994; Eriksson and Simpson 2000; Heubeck et al. 2013). Microfossils were discovered from shale, siltstone and chert lenses in sandstone; two reports of microfossils are known to date (Javaux et al. 2010; Homann et al. 2016).

Javaux and co-workers (2010) reported spheroidal microfossils from the lowermost Clutha Formation (Figure 8.5.7a). These occur in gray shales and siltstones that were deposited in shallow-water environments, above the wave base. This finding is significant for the following reasons. First, the host

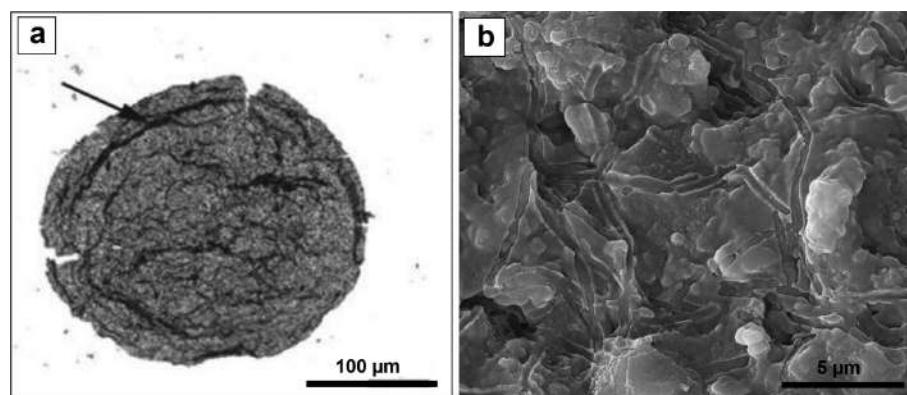

FIGURE 8.5.7 Microfossils from the Moodies Group, South Africa. (a) Organic-walled carbonaceous spheroidal microfossil extracted from siliciclastic rock (shale/siltstone). The arrow shows concentric fold. (With kind permission from Springer Science+Business Media: *Nature*, Organic-walled microfossils in 3.2-billion-year-old shallow-marine siliciclastic deposits, 463, 2010, 934–938, Javaux, E.J. et al.) (b) Meshwork of filamentous molds embedded in chert. Image obtained by secondary electron microscope. (Homann et al. 2016; Courtesy of M. Homann.)

clastic rocks have long been regarded to have low potential to preserve ancient microfossils. Second, the microfossils are large, up to 300 µm in diameter. Third, the microfossils have a recalcitrant organic wall and can be extracted by conventional acid (HF-HCl) maceration. Homann et al. (2016) identified abundant cylindrical and hollow filamentous molds from 0.3 to 0.5 µm in diameter in lens-shaped chert, with kerogenous laminae, in siliciclastic rock (Figure 8.5.7b). The filaments are bent in various directions and are regularly segmented. Carbon isotopic values of associated kerogenous laminae are significantly light ($\delta^{13}\text{C}_{\text{PDB}} = -26.5$ per mil, on average). The authors interpreted the lens-shaped chert as early-silicified cavities formed beneath microbial mats and the filamentous molds as cavity-dwelling microbes. It is suggested that the microbes protected themselves from the supposed intense ultraviolet radiation on the early Earth (Catling and Claire 2005).

8.5.6.4 THE PILBARA CRATON, WESTERN AUSTRALIA

The Pilbara Craton is composed of the East Pilbara, Regal, Karratha, Sholl, and Kurrana Terranes and the De Grey Supergroup (Van Kranendonk et al. 2002, 2006; Hickman and Van Kranendonk 2008; Hickman 2012). Most of the microfossils and possible microfossils have been reported from the Pilbara Supergroup, including the ca. 3.52–3.42 Ga Warrawoona Group, the ca. 3.4 Ga Strelley Pool Formation, the ca. 3.24 Ga Sulfur Springs Group, and the ca. 3.0 Ga Gorge Creek Group of the De Grey Supergroup. In addition, the ca. 3.2 Ga Dixon Island Formation in the Western Pilbara is known to contain possible microfossils.

8.5.6.4.1 The Warrawoona Group

The Warrawoona Group is dominated by mafic to ultramafic volcanic rocks. Subordinate components include felsic volcanic and sedimentary rocks such as chert, evaporite, carbonates, siliciclastic rocks, and volcaniclastic rocks (Van Kranendonk et al. 2006). Microfossils and possible microfossils have been reported from four different rock units, including the Dresser Formation (~3,490 Ma), the Mount Ada Basalt (~3,470 Ma), the Apex Basalt (~3,460 Ma), and the Panorama Formation (~3,450 Ma); these are described in the subsequent paragraphs.

The Dresser Formation is composed dominantly of varicolored bedded cherts, with minor carbonates and barite. Komatiitic basalt and chert veins also occur (Van Kranendonk et al. 2008). The depositional environment is somewhat controversial. Buick and Dunlop (1990) suggested deposition in a closed to semi-closed shallow coastal basin, whereas Van Kranendonk and co-workers claimed an active volcanic caldera setting (Van Kranendonk 2006; Van Kranendonk et al. 2008). Noffke and co-workers (2013) also suggested a shallow to subaerial environment, including sabkha. Others described microfossils and possible microfossils from bedded chert and chert veins (Dunlop et al. 1978; Ueno et al. 2001a, 2001b; Glikson et al. 2008).

Morphologically diverse hollow carbonaceous spheroids 1.2–12 µm in diameter were obtained by acid maceration of carbonaceous cherts (Dunlop et al. 1978). The spheroids are solitary, paired, and rarely in chains. Some show splitting and rupturing (Figure 8.5.8a and b).

Biogenicity of the Dresser spheroids was argued based on composition, variations in morphology, and DDI. Additionally,

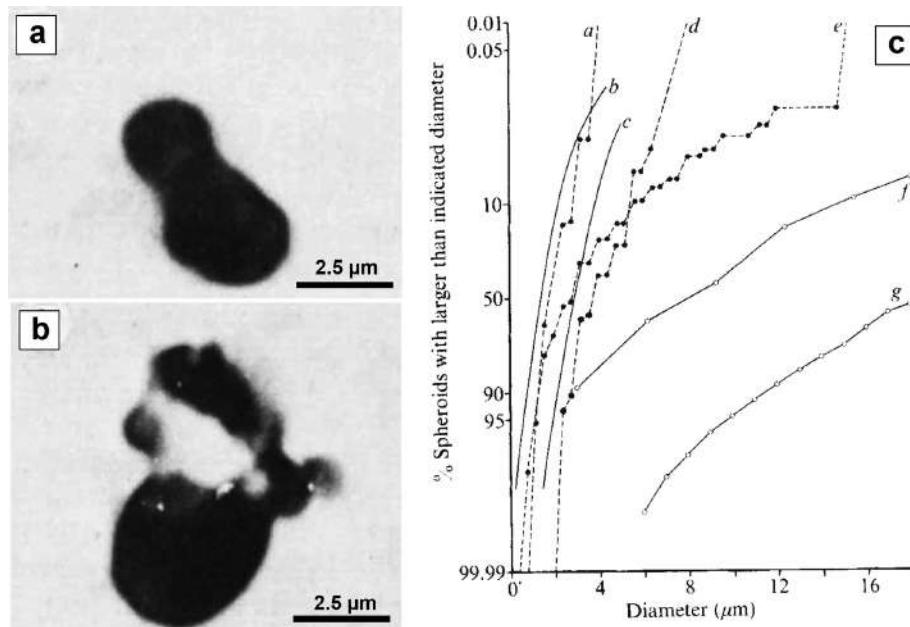

FIGURE 8.5.8 Microfossils from the Dresser Formation of the Warrawoona Group in the Pilbara Craton. (a and b) Carbonaceous spheroids extracted by acid maceration, showing paired morphology and ruptured split. (c) Probability plots of carbonaceous spheroids from the Dresser Formation and extant microalgae: a, gray-black spheroids; b, *Chlorella* sp; c, *Gloeocapsa* sp; d, spheroids with splits; e, North Pole spheroids (total); f, North Pole abiogenic spheroids; and g, synthetic quartz spheres. (With kind permission from Springer Science+Business Media: *Nature*, A new microfossil assemblage from the Archaean of Western Australia, 274, 1978, 676–678, Dunlop, J.S.R. et al.)

Dunlop and co-workers (1978) employed a size probability plot (Knoll and Barghoorn 1977) to claim their biogenicity. The results show that two distinct morphological types, separately plotted, comprise steeply inclined curves that indicate a narrow size distribution, comparative to the extant algae *Chlorella* and *Gloeocapsa* (Figure 8.5.8c). However, these structures are now generally considered to be viscous bitumen droplets or mineralic non-biological spheroids (Awramik et al. 1983; Schopf and Walter 1983; Buick 1990; Wacey 2009).

Ueno et al. (2001a, 2001b) described carbonaceous filamentous structures of several types from hydrothermal chert veins and bedded cherts of this formation. The structures include solitary spiral filaments, radiating clusters of threads, and tubular filaments ~10-μm thick (Figure 8.5.9a). Analyses of carbon isotopic values of these filaments by using secondary ion mass spectrometry (SIMS) give significantly light values ($\delta^{13}\text{C} < -30$ per mil). It is suggested that the values can be interpreted as products of the Calvin cycle or reductive acetyl-coenzyme A (CoA) pathway. Supposed habitats for these microfossils also suggest that they represent chemolithotrophs. Evidence for microbial methanogenesis in this formation was also obtained from analyses of fluid inclusions (Ueno et al. 2006). Acid maceration of bedded black chert also suggested the presence of different types of microbes in the Dresser Formation (Glikson et al. 2008). Several types of carbonaceous objects, including tiny cell-like bodies (less than 3 μm to sub-micron in diameter), were obtained; however, their biogenicity has not yet been fully demonstrated owing to the small size. It should be finally noted that organic matter extracted from the Dresser chert has some biogenic traits (long-chain aliphatic hydrocarbons characterized by an odd-over-even carbon number dominance) (Derenne et al. 2008).

In bedded chert collected from the Mount Ada Basalt in the North Pole area, Awramik and co-workers (1983) identified carbonaceous spheroids and filaments and suggested their prokaryotic affinity. One of the described filaments possesses biological elaboration and taphonomy. It is relatively thick (~5 μm), acutely folded, and regularly septate (Figure 8.5.9b), consistent with biogenicity. Buick questioned this finding, in the context of sample locality and syngenicity (Buick 1984), leading to a published debate (Awramik et al. 1988; Buick 1988). However, Grey and co-workers (2010) resolved uncertainty about the sample locality; the cherts hosting the structures were indeed in the Mount Ada Basalt.

The Apex Basalt, together with the Panorama Formation, comprises the Salgash Subgroup. This volcanic unit is composed dominantly of basalt, komatiitic basalt, and serpentinized peridotite, with local dolerite sills. Felsic volcaniclastic rocks and chert occur as minor components. Microfossil-like structures were reported from the chert collected from the Chinaman Creek locality (Schopf and Packer 1987; Schopf 1993). The structures are carbonaceous and filamentous and were classified into 11 taxa (Schopf 1993). The authors suggested the possibility of their cyanobacterial (*Oscillatoria*) affinity, based on morphological similarity, and inferred inhabitation in shallow-water environment. However, the original rock specimen was subsequently revealed to be from a

hydrothermal chert vein within the Apex Basalt. Furthermore, it was shown that the distribution of carbonaceous matter was at least partially controlled by crystal growth. The formation process of the host rock appears to be not suitable for life, and microbe-like morphologies could have been produced by abiological processes (Brasier et al. 2002, 2005, 2006; Van Kranendonk and Pirajno 2004; Van Kranendonk 2006; Sforza et al. 2014). Pinti and co-authors (2009) also demonstrated that the chert in the Apex Basalt was repeatedly hydrothermally altered. Marshall and co-workers (2012) revealed that carbonaceous matter in the Apex chert had multiple generations, clearly associated with hydrothermal processes, indicating that indigeneness of carbonaceous matter cannot always be guaranteed. Marshall and co-workers (2011) also examined segmented structures, supposedly similar to those described by Schopf (1993), but in a different Apex chert sample, and showed that they were fractures composed of a series of quartz and hematite crystals. Schopf and Kudryavtsev (2011) pointed out the many differences between the mineral veins of Marshall and co-authors (2011) and the carbonaceous structures analyzed by Schopf and colleagues in numerous publications. However, some Apex microfossil-like structures such as the *Archaeoscillatoriopsis* and *Primaevifilum* paratypes (Schopf 1993) were also revealed to be composed of vermiform phyllosilicate grains and adsorbed carbonaceous matter (Brasier et al. 2015). Bower and co-workers (2016) demonstrated that *Eoleptonema apex* (Schopf 1993) was a sheet-shaped pseudofossil composed of an intragranular crack infilled with carbon. These studies may lead readers to wonder if all of the Apex structures described by Schopf and Packer (1987) and later by Schopf (1993) are, in fact, pseudofossils. However, the analyses were not always performed on the holotype specimens (Schopf and Kudryavtsev 2011). To date, the only holotype whose biogenicity was directly rejected is *Eoleptonema apex* (Bower et al. 2016). The *Primaevifilum amoenum* are indeed cylindrical and “hollow” and are composed of a uniserial sequence of individual carbonaceous compartments, most likely biogenic in origin (Figure 8.5.9c and d) (Schopf and Kudryavtsev 2009). This has recently been demonstrated by analyses of carbon isotopic compositions of individual microstructures (Schopf et al., 2018).

Also, it should not be overlooked that organic matter extracted from the Apex chert has some biogenic traits (De Gregorio et al. 2009). Thus, the author (K.S.) suggests that it is possible that some other Apex microstructures could be biogenic. The author's observation of the genuine microfossils from the Pilbara Craton, whose biogenicity has been established by multidisciplinary studies, as discussed later, indicates that microfossils composed originally of carbonaceous matter can be replaced by other materials such as hematite (Sugitani et al. 2007) or pyrite (Figure 8.5.3f). Thus, non-carbonaceous compositions of microbe-like structures in the Apex chert demonstrated by some critics do not readily exclude their biogenicity.

From the Kitty's Gap, 50 km northeast of Marble Bar in the Pilbara Craton, fossil-like microstructures were reported from silicified volcaniclastic sediments (Westall et al. 2006, 2011). The volcanic-sedimentary succession there is thought to be

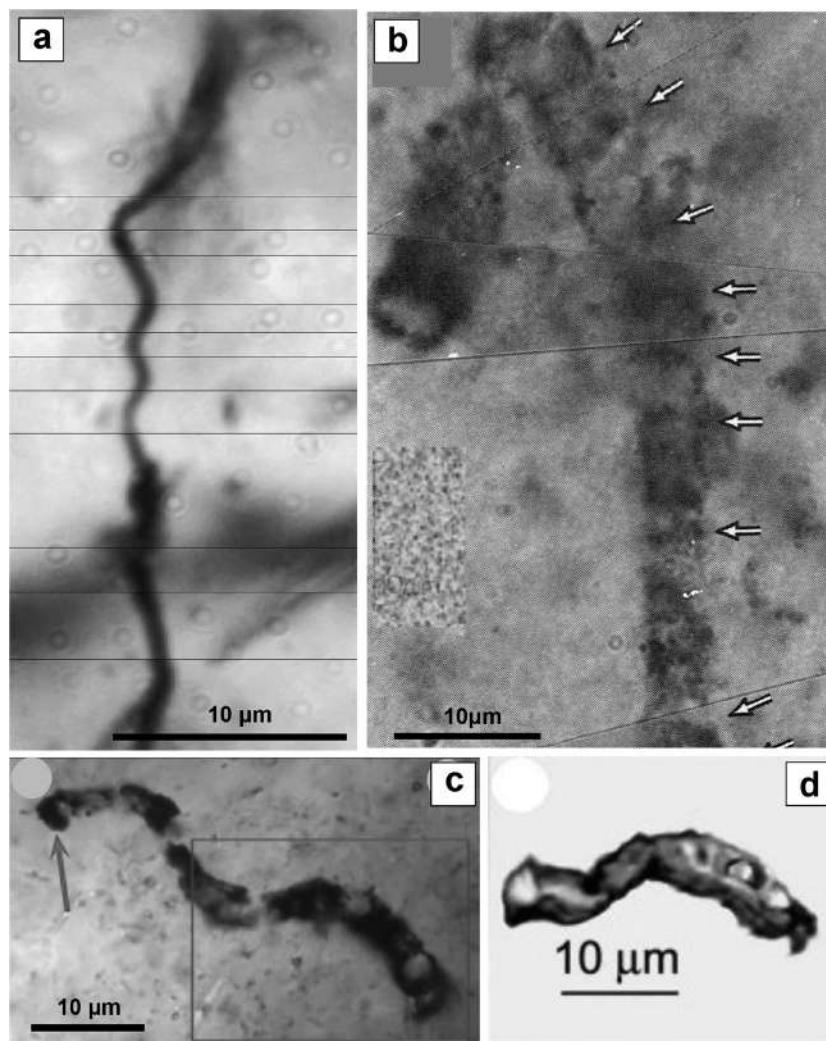

FIGURE 8.5.9 (a) Sinuous carbonaceous filament in black chert from the Dresser Formation. (From Ueno, Y. et al., *Int. Geol. Rev.*, 43, 196–212, 2001; Courtesy of Y. Ueno.) (b) Acute-folded, relative thick septate filament from chert of the Mount Ada Basalt in the North Pole area, Pilbara Craton. The arrows show septation. (Reprinted from *Precam. Res.*, 20, Awramik, S.M. et al., Filamentous fossil bacteria from the Archean of Western Australia, 357–374, Copyright 1983, with permission from Elsevier.) (c) Septate filament (*Primaevifilum amoenum*) from the Apex chert in the Pilbara Craton. The arrow points to the rounded terminus. (d) Three-dimensional Raman image indicating cylindrical morphology of the rectangular portion of (c). (Reprinted from *Precam. Res.*, 158, Schopf, J.W. et al., Evidence of Archean life: Stromatolites and microfossils, 141–155, Copyright 2007, with permission from Elsevier.)

correlative to the Panorama Formation of the Salgash Subgroup (Van Kranendonk et al. 2002). Chert at the Kitty's Gap is cut by numerous chert veins and originates from silicification of the volcaniclastic sediments. The depositional setting was closely associated with hydrothermal activities. Westall and co-workers (2006, 2011) identified microstructures on the vapor hydrofluoric acid (HF)-etched surface. Carbonaceous microstructures include filaments less than 0.3 µm in width, coccoids 0.4–0.8 µm in diameter, and rods ~1 µm in length. They occasionally comprise colony-like clusters associated with extracellular polymeric substance (EPS). Morphology (shape and size), composition, and occurrence appear to be all consistent with their biogenicity; however, some doubts can be casted on their syngenicity based on the absence of corresponding structures in petrographic thin sections (Wacey 2009).

8.5.6.4.2 The Strelley Pool Formation

The Strelley Pool Formation is an independent formation that does not belong to the higher stratigraphic unit. It has been identified widely in the East Pilbara Terrane, and its depositional area is assumed to have been at least 30,000 km² (Hickman 2008). This formation is typically 8–11 m thick, but locally, it can be up to 100 m thick. It is composed of various types of rock, including siliciclastic sedimentary rocks, carbonates (mainly bedded and stromatolitic dolomite), cherts, and volcaniclastic rocks. The environments of deposition were various but mainly shallow-water environment, such as a rocky coastal shoreline and beach environment; shallow-water marine carbonate platform; possible sabkha; and tidal flat and alluvial fan, all with or without hydrothermal inputs (Allwood et al. 2006, 2007, 2010; Hickman 2008;

Sugitani et al. 2015b). Schopf and Packer (1987) and Schopf (2006) first described microbe-like structures in carbonaceous chert from the Strelley Pool Formation. The sheathed structures are up to over 50 μm across and are composed of multiple spheroids. Such morphological elaboration appears to be consistent with the biogenicity.

Promising microbe-like structures were later reported by Sugitani and co-authors (2010), who described morphologically diverse carbonaceous microstructures in carbonaceous cherts of sedimentary origin from the Strelley Pool Formation. These were discovered from three remote localities in the Panorama, Warralang, and Goldsworthy greenstone belts. The lithostratigraphies at these localities are different to each other, meaning different depositional settings. Nevertheless, a similar morphological assemblage of microstructures, including spheroids, lenses, filaments, and films, occurs. This preliminary report for the Strelley Pool microfossils was followed by a discovery of similar structures from a new locality in the Panorama greenstone belt, which was 8 km away from the original locality (Sugitani et al. 2013). Microfossil-bearing black cherts in the Panorama greenstone belt and the Warralang greenstone belt were deposited in a shallow marine environment (intertidal to sub-tidal zone), and those in the Goldsworthy greenstone belt were possibly deposited in a terrestrial hydrothermal field near a coastal zone (Sugitani et al. 2010, 2013, 2015b).

Spheroids are mostly less than 15 μm in diameter, but rarely, large ones, >50 μm in diameter, also occur. Spheroids with intermediate sizes are also present. Small and intermediate spheroids often comprise colony-like clusters (Figure 8.5.10a and b), whereas very large ones occur solitarily (Figure 8.5.10c and d). Colonies of intermediate-sized spheroids are not common, but where they do occur, these exhibit unique habits. One example is a colony composed of several spheroids of nearly the same size (~20 μm across), with a mutual compress contact; it is further characterized by being embedded within a foam-like envelope (Figure 8.5.10e). Other interesting specimens include an elongated colony composed of spheroids of different sizes, with a budding-like attachment of smaller hemispheroids (Figure 8.5.10f).

Lenses are mostly 20–60 μm in length along the major dimension, and some can be up to 100 μm . The structures are composed of a central body and surrounding sheet-like appendage, which is called a flange (Figure 8.5.11a) (Sugitani et al. 2007). These lens-shaped structures can be extracted by acid maceration. Observation of extracted specimens, in addition to those in petrographic thin sections, revealed their minor morphological variations such as ellipticity of the polar view, transparency of the central body, and flange width and texture (Sugitani et al. 2010, 2013, 2015a) (Figure 8.5.11b–h), possible reflection of speciation (Sugitani et al. 2018). Lenses often comprise colony-like clusters of various shapes and pairs or chains (Figure 8.5.12a–c).

Biogenicity of these spheroids and lenses has been demonstrated by their carbonaceous composition; size distribution; taphonomic features; occurrences suggestive of vital activities such as reproduction, texture-specific, and significant negative carbon isotopic value; the presence of nitrogen- and oxygen-rich

molecules in lenticular structures and alveolar or hollow internal texture of the central body (Figure 8.5.12d–f) (Sugitani et al. 2010, 2013, 2015a; Lepot et al. 2013; Alleon et al. 2018).

Possible biogenic filaments are rare and occur solitarily, without any spatial relationships (Sugitani et al. 2013). They are relatively thick, up to 20 μm in width, and up to 200 μm in length. The structures are hollow, bent, and have notched edges (Figure 8.5.13a). They were likely reworked from the original site of formation. The other type of filament has been discovered from Anchor Ridge in the Panorama greenstone belt, from which lenticular microfossils were originally described (Sugitani et al. 2010). The thin (~2 μm wide), sinuous, and hollow filaments are identified within facies showing a carbonaceous cobweb structure (Figure 8.5.13b), which is inter-layered with distinct facies (characterized by fine lamination of carbonaceous matter and enrichment of sulfides) containing spheroidal and lenticular microfossils. Recently, Schopf interpreted that the cobweb structures are composed largely of degraded filaments and silicified sulfate nodules (Schopf et al. 2017). Combined with sulfur isotopic data and resemblance to younger equivalents (Schopf et al. 2015), the authors argued that the filaments represent sulfur bacteria.

In addition to the previously described chert-hosted microfossils, possible biogenic carbonaceous spheroids, ellipsoids, and tubular filaments were reported from the basal sandstone of this formation in the East Strelley greenstone belt (Figure 8.5.13c and d) (Wacey et al. 2011). The structures were described to show various taphonomic features and occur as colony-like chains and clusters, with reproduction-like habits. Carbon isotopic values of wall-comprising carbonaceous matter, associated with nitrogen, range from $-33\text{\textperthousand}$ to $-46\text{\textperthousand}$. Possible affinity to sulfur-metabolizing bacteria was suggested (Wacey et al. 2011, 2014a).

8.5.6.4.3 The Sulfur Springs Group

The Sulfur Springs Group is composed mainly of felsic to mafic-ultramafic volcanics and volcaniclastic rocks, with minor amounts of sedimentary rocks. The Kangaroo Caves Formation of this group, from which microbe-like structures were described, consists mainly of sedimentary rocks, including for example, breccia, banded iron formation, layered chert, and shale, associated with widely spaced black chert hydrothermal veins and massive sulfide deposits. The massive sulfide deposits have possibly been deposited on a deep (>1000 m) seafloor, from high (~300°C)-temperature hydrothermal solutions (Vearncombe et al. 1995). Filamentous and spheroidal possible microfossils have been reported (Rasmussen 2000; Duck et al. 2007).

These possible fossil-like microstructures include thin pyritic filaments that occur in colloform-textured microcrystalline quartz masses in massive sulfide deposits (Rasmussen 2000). The sinuous filaments, up to 300 μm long, have a uniform length-wise diameter of 0.7–0.9 μm . They also exhibit an intertwined habit and were oriented differently in different portions, suggesting behavioral variations in different microenvironments (Figure 8.5.13e). Rasmussen interpreted the filaments as probable microfossils replaced by pyrite and suggested their affinity to

hyperthermophilic chemoautotrophs (Rasmussen 2000). Later, these filaments were revealed to have internal carbon and nitrogen patches and nano-pores (Wacey et al. 2014b) (Figure 8.5.13f). Such additional evidence appears to provide convincing evidence for their biogenicity; however, Wacey and co-workers (2014b) posed some doubts, referring to their morphological simplicity.

Acid maceration of sedimentary rock overlying the massive sulfide deposit also yielded other types of possible microfossils (Duck et al. 2007). Obtained materials were bundles of filamentous, tubular carbonaceous structures and associated carbonaceous nanospheres, characterized by significantly light bulk carbon isotopic values ($\delta^{13}\text{C}_{\text{PDB}} = -26.8\text{\textperthousand}$ to $-34.0\text{\textperthousand}$).

These structures are similar to both modern and ancient microbes documented from seafloor hydrothermal systems, but the biogenicity has not yet been fully demonstrated.

8.5.6.4.4 The Dixon Island Formation

The Dixon Island Formation in the Regal Terrane of the West Pilbara comprises sedimentary succession of rhyolitic tuff, black shale, and varicolored cherts. The succession overlies basalts showing pillow structures. Basalts and overlying sediments were extensively veined by carbonaceous black cherts, suggesting that the deposition of this formation was closely related to hydrothermal activity. The paleodepth was assumed to have been ~500–2000 m (Kiyokawa et al. 2006, 2014). The Dixon Island Formation represents a Mesoarchean seafloor hydrothermal system. Identified microbe-like structures include iron-rich spheroids in stromatolite-like ferruginous beds and carbonaceous structures of five morphological types; spiral-shaped filaments, rod-shaped filaments, cell-shaped filaments, dendritically stalked filaments, and spheroids in carbonaceous black chert. Among them, hollow filaments of

50–100 μm in length and 10 μm in width, with length-wise uniformity, are likely biogenic.

8.5.6.4.5 The Gorge Creek Group

The Gorge Creek Group, contrastive to the Warrawoona Group described earlier, is dominated by sedimentary rocks, which include chert, jasper, and banded iron formation, as well as terrigenous clastic rocks such as shale, siltstone, sandstone, and conglomerate. To date, microfossils have been reported from the Farrel Quartzite (Van Kranendonk et al. 2006), which is the lowest unit of the Gorge Creek Group. The Farrel Quartzite in the Goldsworthy greenstone belt is composed dominantly of very coarse- to coarse-grained sandstone, including quartzite and minor conglomerate. Mafic to ultramafic volcaniclastic beds, evaporite beds, fine-grained clastic rock, and layers of black chert comprise minor components. This sedimentary unit varies from several to 80 m in thickness along strike (Sugitani et al. 2003, 2007) and is conformably overlain by a thick (>100 m) unit of chert and banded iron formation, which is correlative to the Cleaverville Formation.

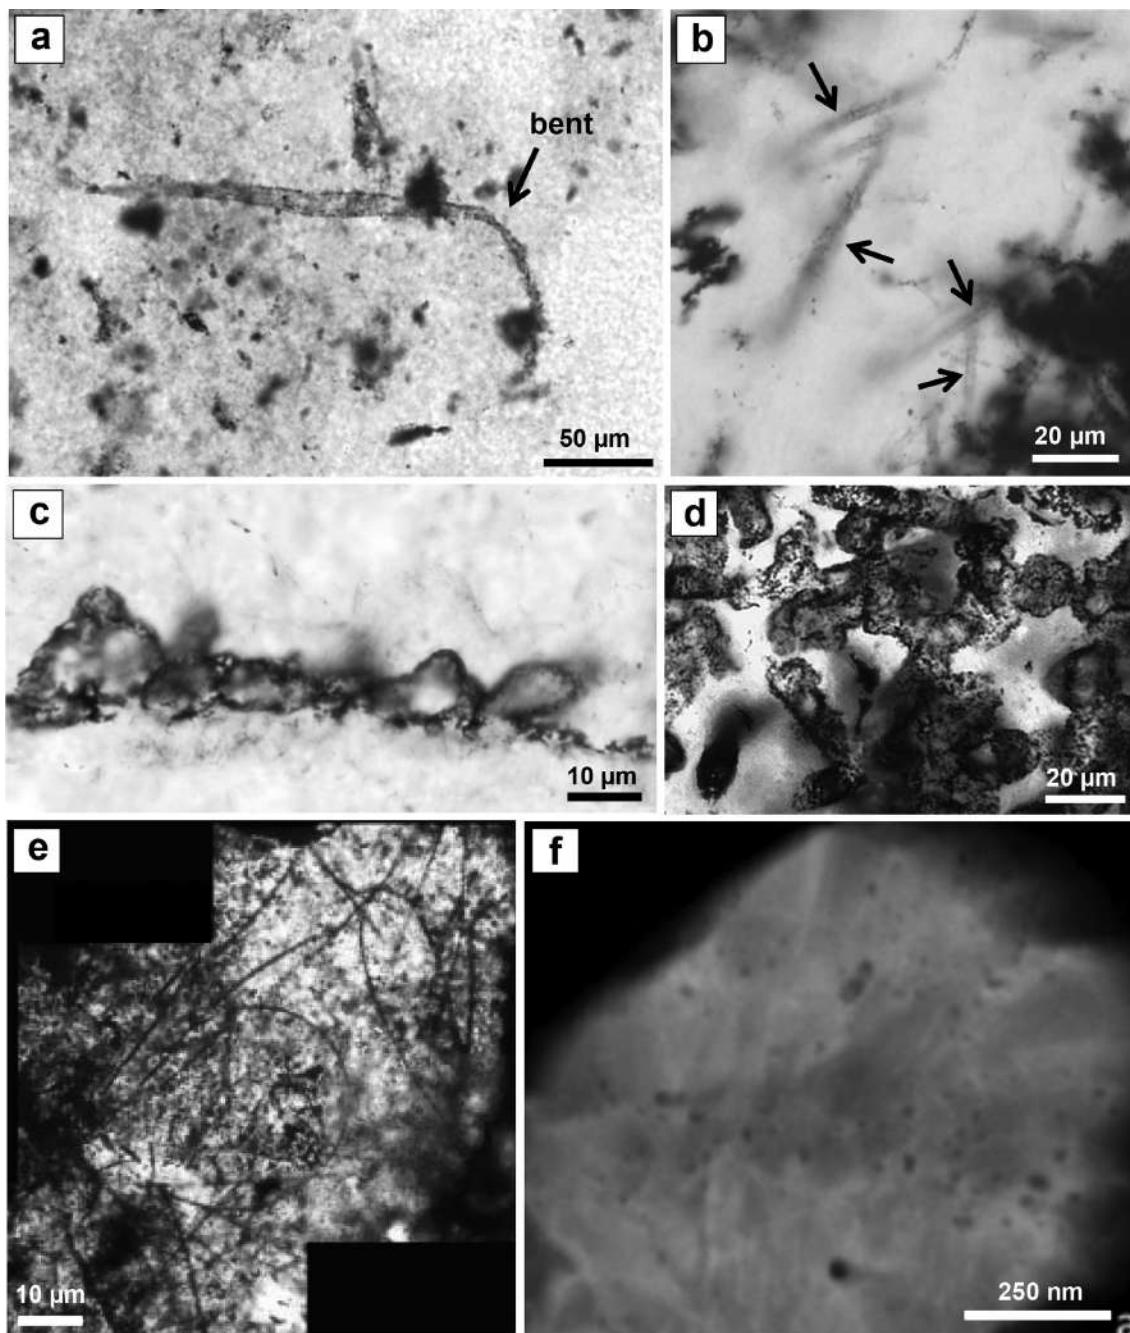

FIGURE 8.5.13 (a) Bent, tubular carbonaceous filament from the Strelley Pool Formation, in the Pilbara Craton. (From Sugitani, K. et al., *Precam. Res.*, 226, 59–74, 2013.) (b) Narrow tubular sinuous filamentous microfossils (arrows) from cobweb-like structured facies in carbonaceous black chert of the Strelley Pool Formation. (Schopf, J.W. et al., *Precam. Res.*, 299, 309–318, 2017.) (c) Spheroids and (d) tubular filaments in silica-filled pore spaces in the basal sandstone. (From Wacey, D. et al., *Nat. Geosci.*, 4, 698–702, 2011; Courtesy of D. Wacey.) (e) Variously oriented curved filaments composed of pyrite from the Sulfur Springs Group. (With kind permission from Springer Science+Business Media: *Nature*, Filamentous microfossils in a 3,235-million-year-old volcanogenic massive sulphide deposit, 405, 2000, 676–679, Rasmussen, B.) (f) TEM image of a section of the pyrite filament in (a) showing porous interior (Wacey et al. 2014b, with permission from Elsevier.)

Microfossils were discovered from black cherts at the uppermost portion of the Farrel Quartzite (Sugitani et al. 2007). The microfossil-bearing black cherts and associated evaporite beds can be traced for ca. 7 km along strike.

The microfossil-bearing black cherts exhibit micron-scale spherulitic structures and locally cross-lamination, identified

by the distribution of fine carbonaceous particles, carbonaceous clots, and microfossils. As described earlier, the spherulitic structure in cherts indicates that they originated from a silica gel, but not the silicification of non-siliceous sediments. Cross-lamination also indicates deposition under the influence of fluid flows. Aqueous deposition of the microfossil-bearing

cherts is also consistent with features of rare-earth elements and yttrium, which are best interpreted as mixing of seawater and low-temperature hydrothermal fluids, and/or as terrestrial run-off (Sugihara et al. 2010). On the other hand, Retallack and co-authors (2016) argued that the black chert originated from a paleosol and the described microfossils could be assigned to modern soil-inhabiting microbes. The authors, however, overlooked the previously described diagnostic features, and their paleosol model is unfounded (Sugitani et al. 2017).

The cellularly preserved microfossil assemblage identified in this unit is basically similar to that of the Strelley Pool Formation; spheroids and lenses were identified. Filamentous structures of equivocal origin are also present. Most spheroids are less than 15 μm in diameter and often comprise

colony-like clusters, which are rarely associated with film-like objects (Figure 8.5.14a–c). Large spheroids, from 40 μm up to 80 μm in diameter, are also present (Figure 8.5.14d–h) and occasionally comprise colonies together with smaller spheroids (Figure 8.5.14i). The walls of spheroids exhibit various taphonomic features, from granular to hyaline and from smooth to irregular wrinkles. In contrast, fluff and regular wrinkles identified in some specimens are likely primary features (Figures 8.5.3e and 8.5.14e). The Farrel Quartzite lenticular structures are similar to those from the Strelley Pool Formation; however, minor morphological and textural variations are more conspicuous in the Farrel Quartzite lenses. Flange is texturally various (translucent, hyaline, reticulated, and striated) (Sugitani et al. 2009a) (Figure 8.5.15a–c). Also,

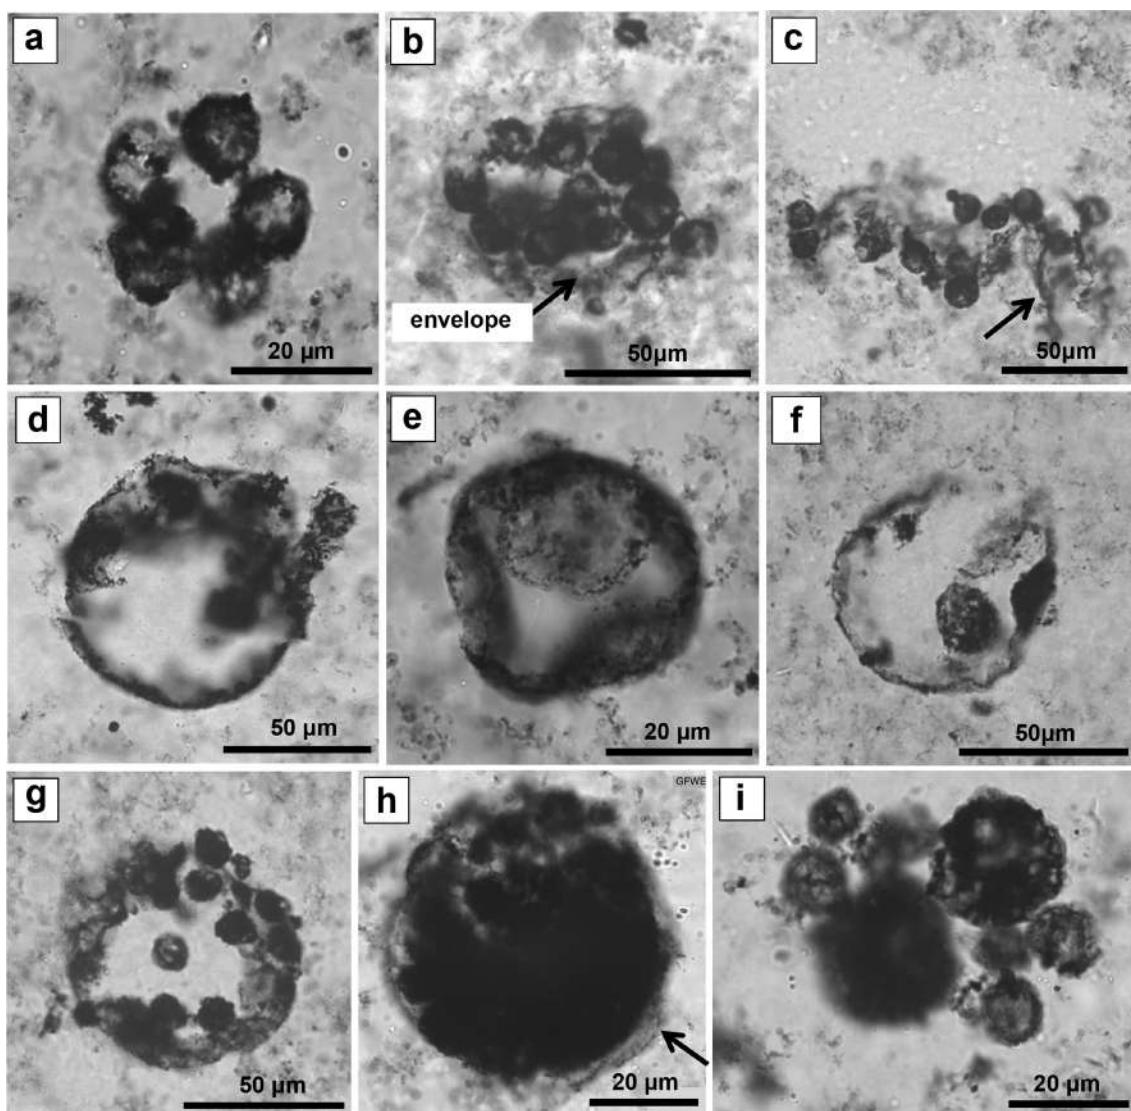

FIGURE 8.5.14 Spheroidal microfossils from the Farrel Quartzite of the Gorge Creek Group in the Pilbara Craton, Western Australia. (Sugitani, K. et al., *Precam. Res.*, 158, 228–262, 2007; Sugitani, K. et al., *Precam. Res.*, 173, 50–59, 2009.) (a) Spherical colony composed of regularly arranged small spheroids ($\sim 10 \mu\text{m}$). (b) Colony composed of small spheroids with thin envelope (arrow). (c) Small spheroids attached with hyaline film (arrow). (d) Large spheroid with smooth but partially broken wall. (e) Large spheroid with folded wall. (f) Large spheroid showing broken habit, with a smaller spheroid inside. (g) Large spheroid with wrinkled wall, associated with small spheroids inside and outside the wall. (h) Possibly partially double-walled (arrow) spheroid containing small spheroids inside. (i) Colony composed of spheroids of various sizes.

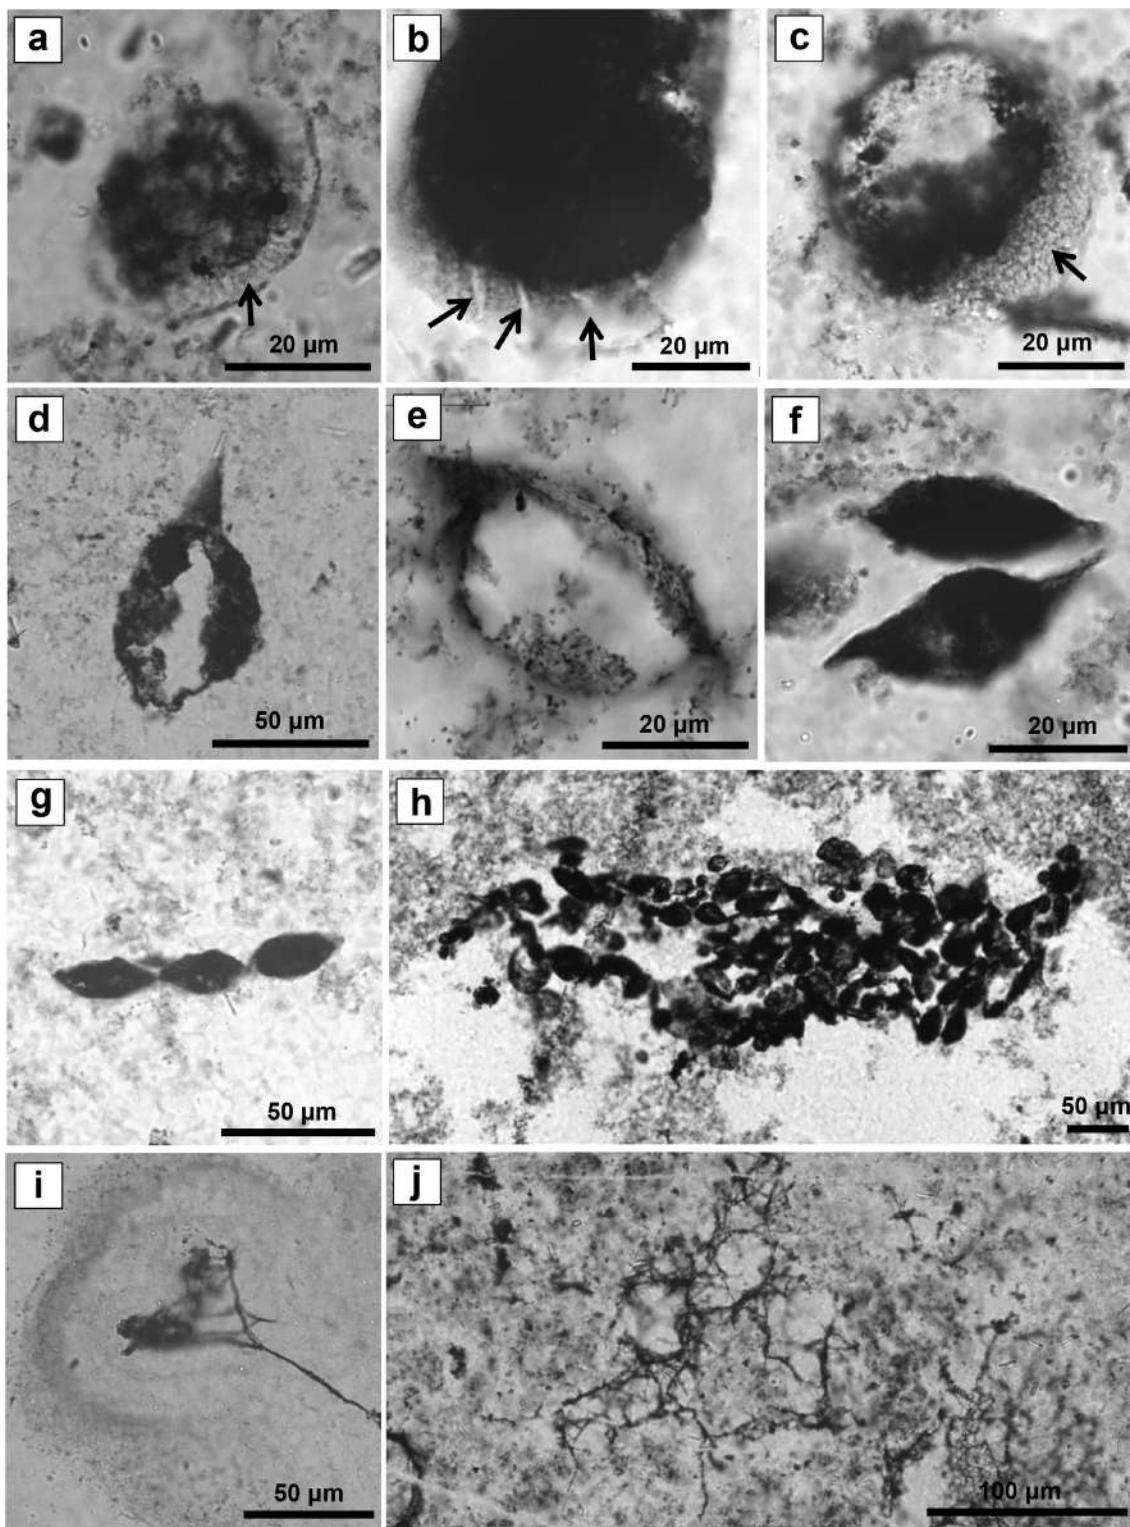

FIGURE 8.5.15 Lenticular microfossils and filaments from the Farrel Quartzite. (Sugitani, K. et al., *Precam. Res.*, 158, 228–262, 2007; Sugitani, K. et al., *Astrobiology*, 9, 603–615, 2009.) (a) Inclined polar view of lenticular microfossil with a hyaline translucent flange (arrow). (b) Inclined polar view of lenticular microfossil characterized by striated (arrows) flange. (c) Inclined polar view of lenticular microfossil with hollow (quartz-filled) central body and reticulated flange (arrow). (d) Equatorial view of lenticular microfossil with one-sided flange. (e) Three-dimensional (3D)-reconstructed image of lenticular microfossil showing asymmetric relationship between flange and central body. (f) Obliquely paired lenticular microfossils. (g) Linearly aligned triplet of lenticular microfossils. (h) Large colony composed of lenticular and spheroidal microfossils. (i) Carbonaceous filaments in colloform-textured portion in vein, such as that shown in Figure 8.5.3a. (j) Entangled, thin carbonaceous filaments observed in specific portion of the fossil-bearing chert bed.

the width is asymmetric in some specimens ([Figure 8.5.15d](#)) (Sugitani et al. 2007), while the shape of the central body is both symmetric and asymmetric (Sugitani et al. 2009a) ([Figure 8.5.15e](#)). Like the spheroids, lenses often comprise colonies, although they can occur solitarily or in pairs or chains ([Figure 8.5.15f–h](#)).

Biogenicity of the Farrel Quartzite spheroids and lenses was fully demonstrated (Sugitani et al. 2007, 2009a, 2009b; Grey and Sugitani 2009; Oehler et al. 2009, 2010; Schopf et al. 2010; House et al. 2013; Delarue et al., 2018). Their host chert is primary, deposited in an aqueous environment, which is suitable for life. The structures are composed dominantly of carbon, associated with minor amounts of N and S, which are representative organic elements. Carbon isotopic values of individual specimens are adequately negative, within the range of extant organisms, and are different from those of dispersed carbonaceous clots in the matrix. Nitrogen isotopic ratios are highly variable and morpho-specific. Walls comprising the structures are assumed to have been flexible and breakable, like cell membranes and walls. The structures are prolific: up to 100 or more, in a petrographic thin section 2.5×3.4 cm wide and $30 \mu\text{m}$ thick. Their size distributions are relatively narrow, and they often comprise pairs, chains, and colony-like clusters, likely results of reproduction. Most of the structures, if not all, are composed of membranous organic matter and can be extracted by acid maceration. To date, no such abiogenic models have been presented that could produce such complex organic-walled microstructures and their assemblages.

Filamentous microstructures from the Farrel Quartzite include solid-looking threads less than $1 \mu\text{m}$ in diameter and a hollow tube-like structure ca. $20 \mu\text{m}$ in diameter, of which only one specimen has been identified. Thus, the thread-like structures are described here. These exhibit two distinct occurrences: one occurs in colloform-textured portions composed of microcrystalline quartz in cavity fills and veins ([Figure 8.5.15i](#)), while the other consists of a dense population of threads in a specific layer that is a few millimeters thick, where the other types of microstructures (spheroids and lenses) do not occur ([Figure 8.5.15j](#)). Threads range widely from a few tens of microns to several hundred microns in length, and their length-wise thicknesses appear to be uniform. The thin filamentous microstructures are often bent and entangled. It is equivocal whether these thread-like structures, especially those in cavity fills and veins, represent fossilized microbes. Threads occurring in a dense population are more likely microfossils, but the possibility that these threads are fossilized fibrillar extracellular polymeric substances cannot be excluded.

8.5.7 IMPLICATIONS FOR HABITATS OF ARCHEAN MICROBES

As described in this chapter, the depositional environments of rocks hosting early Archean microfossils are quite diverse, including shallow to subaerial evaporitic basins, coastal hydrothermal fields, intertidal to supratidal zones, and relatively deep ocean floor with intense hydrothermal activities.

The occurrence of non-cellularly preserved biosignatures, such as stromatolites and microbially induced sedimentary structures, is mostly restricted to sediments deposited from shallow platform to supratidal and even terrestrial settings, such as a sabkha (e.g., Allwood et al. 2006; Wacey 2010; Noffke et al. 2013; Heubeck 2009). On the whole, records of habitats for Archean organisms appear to be dominantly from shallow-water environments. This, however, does not imply that deep-sea and open-ocean regions at that time were not important habitats for microbes. Sedimentary successions of deep-sea and open-ocean facies in the Precambrian are represented by banded iron formations, which may have been formed by iron-oxidizing bacteria (Kappler et al. 2005; Posth et al. 2013). It should also be reminded that morphologically preserved biosignatures may represent only a part of the Archean biosphere.

8.5.8 WHAT DO THE ARCHEAN “LARGE” MICROFOSSILS TELL?

It is now fully demonstrated that early Archean microfossil assemblages are quite diverse and include significantly large microfossils: spheroids or lenses larger than $20 \mu\text{m}$ are common and can be up to $300 \mu\text{m}$ across. Such a large size may hint of a eukaryotic affinity. In this section, the validity of this interpretation and strategies to elucidate biological affinities of large Archean microfossils are discussed. The timing of the emergence of eukaryotes is one of the most important milestones in the evolution of early life and is one of the unresolved great problems in astrobiology.

8.5.8.1 THE OLDEST RECORDS OF EUKARYOTES

In general, microbes in the Archean are considered to be prokaryotic, which is partly based on that the metabolism of eukaryotes is primarily aerobic and that the Earth's atmosphere began to be oxygenated from around 2.45 Ga (the Great Oxidation Event [GOE]). Although the oldest record of eukaryotic fossils has not yet been settled, widely accepted and reliable eukaryotic microfossils can be found in the Paleoproterozoic, such as large organic-walled spheroidal microfossils that have regular geometric ornaments and/or protrusions ([Figure 8.5.3b](#)) (Javaux et al. 2003; Knoll et al. 2006). However, Butterfield (2014) suggested that the stem group of eukaryotes could extend back to the early Archean. Fossils and possible fossils of assumed eukaryotic affinity, which are older than 2.0 Ga, have been reported. Some of these structures include 2.1 Ga megascopic coiled filaments (*Grypania spiralis*) (Han and Runnegar 1992), 2.1 Ga pyrite-replaced megascopic structures interpreted to be colonial organisms with a coordinated growth pattern (El Albani et al. 2010), and ~2.8–2.7 Ga organic-walled tubular microstructures interpreted to be equivalent to modern siphonous green or yellow-green microalgae (Kaźmierczak et al. 2016). However, a eukaryotic affinity of these older materials has not yet been widely accepted.

8.5.8.2 CRITERIA FOR EUKARYOTIC FOSSILS AND APPLICATION TO LARGE ARCHEAN MICROFOSSILS

Knoll and co-workers (2006) listed three criteria for fossilized eukaryotic cells: (1) having an acid-resistant organic wall (envelope), (2) having micron-scale ornaments and processes (Figures 8.5.3b and 8.5.16a, b), and (3) having significantly large ($>20 \mu\text{m}$) cell size. Microfossils under consideration meeting all three criteria are likely eukaryotic. These criteria are based on the following reasons. Most prokaryotic cells are smaller than $10 \mu\text{m}$, whereas those of eukaryotes are larger than $10 \mu\text{m}$. Such limited cell size of prokaryotes is considered to be a consequence of intracellular metabolism, regulated by the diffusion of nutrients, without active transportation by a cytoskeleton. Micron-scale ornaments and processes were also interpreted to be formed only under regulation by a cytoskeleton (Knoll et al. 2006). While many eukaryotic algae

can produce acid-resistance recalcitrant walls, prokaryotes cannot, except for some types of cyanobacteria. Furthermore, eukaryotic cell walls are multilayered, whereas prokaryotic cell walls are not (Javaux et al. 2004) (Figure 8.5.16c).

Spheroidal and lenticular microfossils discovered from the Kaapvaal Craton, South Africa, and the Pilbara Craton, Western Australia, are large ($>20 \mu\text{m}$ and up to $300 \mu\text{m}$) and have acid-resistant organic walls. Regularly arranged micron-scale ornamentation cannot be identified, but textures such as reticulation, striations, and regular wrinkles observed in some specimens could be related to a cytoskeleton-regulated texture; however, the primary origin of these features has yet to be fully established. Flanges, sheet-like appendages that surround the central body, are a far simpler feature compared with the protrusions of Proterozoic eukaryotic microfossils, but again, their formation was likely controlled by the cytoskeleton. Although TEM analyses revealed that envelopes

of some acid-extracted specimens of lenticular and spheroidal microfossils were single-layered (Sugitani et al. 2015b; Javaux et al. 2010), the eukaryotic affinity of large Archean microfossils, particularly flanged lenticular ones, may be worth considering. However, the reality does not allow such a straightforward interpretation, as briefly reviewed in the next section.

8.5.8.3 BIG BACTERIA AND BACTERIAL CYTOSKELETON

Large cell size is not a monopoly of eukaryotic cells. Large ($>20\text{ }\mu\text{m}$) prokaryotic spheroidal cells are known for cyanobacteria, sulfur bacteria, and gut-symbiont heterotrophic bacteria (*Epulopiscium fishelsoni*). Spheroidal cyanobacteria such as *Dermocarpea* and *Stanieria* (Waterbury and Stanier 1978; Angert 2005; Schirrmeister et al. 2016) can be $20\text{ }\mu\text{m}$ or more in diameter (Figure 8.5.16d). However, such a large size is measured for mother cells containing multiple baeocytes inside; these cells reproduce by multiple fission (Angert 2005). Large spheroidal (and ellipsoidal) cells are also found for some genera of sulfur bacteria such as *Thiomargarita*, *Achromatium*, and *Thiovulum* (Schulz et al. 1999; Schulz and Jørgensen 2001). *Thiomargarita namibiensis*, for example, can reach $750\text{ }\mu\text{m}$ in diameter and can form chains (Figure 8.5.16e); however, it should be noted that their cytoplasm exists only peripherally and their cells are volumetrically dominated by a vacuole, and in the case of *Achromatium*, cells are filled with many large calcite inclusions (Schulz et al. 1999; Schulz and Jørgensen 2001). Vacuoles and inclusions in such sulfur bacteria reduce the volume of active cytoplasm, allowing metabolisms dependent on molecular diffusion. Additionally, a newly identified taxon of sulfur bacteria (*Ca. Thiomargarita nelsonii*) includes specimens that form a colony of cells surrounded by a “rigid” envelop up to $\sim 90\text{ }\mu\text{m}$ in diameter (Salman et al. 2011, 2013).

The cytoskeleton has long been specific to eukaryotic cells, but in the last decade, homologs of elements of the eukaryotic cytoskeletal have been identified in prokaryotes (Shih and Rothfield 2006; Celler et al. 2013), and their involvement in cell growth, cell morphogenesis, cell division, DNA partitioning, and cell motility were implicated. Furthermore, new elements specific to prokaryotes have been identified. Such facts caution us against making an employment of criteria for eukaryotic affinity related to cytoskeletons described earlier; the functions of bacterial cytoskeletons have not yet been fully revealed. Obviously, these facts should be considered in discussing biological affinities of large early Archean microfossils.

8.5.8.4 FRAMEWORK FOR CONSIDERING BIOLOGICAL AFFINITY OF LARGE MICROFOSSILS

Considering the inevitable incompleteness involved in the criteria for classifying eukaryotic cells in previous sections, it is difficult at this stage to assign large Archean microfossils specifically to eukaryotes or prokaryotes. Their biological

affinities are equivocal and could be cyanobacteria, sulfur bacteria or eukaryotes, and potentially other extinct lineages. Nevertheless, the following points would be helpful for further examination of large Archean microfossils.

8.5.8.4.1 Early Evolution of Oxygenic Photosynthesis

It is evident that shallow to subaerial habitats had already been explored by microbes by 3.0 Ga. But, what are the implications of this? The most straightforward speculation is that microbes with the ability to photosynthesize had already evolved and diversified, as suggested by, for example, Tice and Lowe (2004, 2006a, 2006b). The timing of the evolution of oxygen-producing photoautotrophs is controversial, but it could be back before the Great Oxidation Event (GOE) and even to 3.0 Ga and earlier (e.g., Rosing 1999; Nisbet and Sleep 2001; Rosing and Frei 2004; Buick 2008; Crowe et al. 2013; Lyons et al., 2014; Homann et al. 2015; Schirrmeister et al. 2016; Delarue et al. 2018). The evolution of oxygen-producing photoautotrophs earlier than 3.0 Ga is not necessarily in conflict with the widely accepted scenario that atmospheric oxygen began to increase around 2.45 Ga (the GOE). Oxygen produced by photosynthesis in aquatic environments was not necessarily released to the atmosphere but could have been consumed by heterotrophs and by reductants such as Fe^{2+} . Also, for example, in a closed to semi-closed basin, where reductants could have been consumed, local enrichment in O_2 could be possible (Oxygen Oasis; e.g., Olson et al. 2013). Even in the “fully oxygenated” modern Earth, redox conditions are highly variable. As exemplified by thermally stratified water masses such as in dam reservoirs, oxygenic conditions can be closely associated with anoxygenic conditions (Bellanger et al. 2004). Plausibly, local oxygenic environments could have developed on the early Earth, which might have provided opportunities for the early evolution of eukaryotes.

8.5.8.4.2 Constraints from Life Cycle and Lifestyle

It is essential to demonstrate the stage of the life cycle at which a large microfossil is preserved. If a large microfossil represents a juvenile stage, but not aged cells with vacuoles or baeocytes, the cell size could give some constraints on the biological affinity. Sugitani and co-workers (2015a, 2018), for example, demonstrated that lenticular microfossils of the Strelley Pool Formation represent vegetative cells that reproduce simply by binary fission. This is inferred from the presence of a series of paired specimens corresponding to various stages of binary fission, from fused to point-to-point attachment, and also from that colonial clusters of lenticular microfossils do not contain other morphological types. Sugitani and co-authors (2015a) also estimated the cell volume of lenticular microfossils to be $7000\text{ }\mu\text{m}^3$, assuming that they have an ellipsoidal shape with half axes of 15, 15, and $7.5\text{ }\mu\text{m}$. This volume corresponds to a spheroid with a $\sim 23\text{ }\mu\text{m}$ diameter. Sugitani and co-workers (2009b) also suggested that some of the large spheroidal microfossils from the 3.0 Ga Farrel Quartzite might represent mother cells containing multiple daughter cells (baeocyte) inside, such as some cyanobacteria, and others might represent vesicles containing possible endospore (Figure 8.5.14f–h). It was

implied that some of the lenticular microfossils from the Farrel Quartzite reproduced by multiple fissions (Sugitani 2012). Consequently, it should not be overlooked that the significance of the size of microfossils changes, depending on the stage of life cycle preserved. Also, House and co-workers (2013) and Oehler and co-workers (2017) suggested that Meso- and Paleoarchean lenticular microfossils were planktonic, based on their stable carbon isotopic compositions (determined at the micron scale by SIMS) as well as their characteristic shape with wing-like appendages (flanges) that are thought to be advantageous, perhaps, for floating. Such an assumed life cycle could also place some constraints on the physiology of the microfossils.

8.5.8.4.3 Constraints from Ecological Niches

Assumed ecological niches could place some constraint on the biological affinity of large Archean microfossils. Javaux and co-workers (2010), for example, considered the biological affinity of organic-walled large spheroidal microfossils from the Moodies Group of South Africa, comparing these to extant large prokaryotes, the symbiont *Epulopiscium* sp., myxobacteria sporangioles, *Thiomargarita namibiensis*, and some cyanobacteria. These candidates, except cyanobacteria, were discarded, as their ecological niches are nutrient-rich gut, soil, and sulfur-rich environments, distinct from that expected for the Moodies microbes. Furthermore, they have no ability to produce a recalcitrant envelope. Javaux and co-workers (2010) suggested the possible affinity of the Moodies large spheroidal microfossils to cyanobacteria, as cyanobacteria could produce large cysts and envelopes, and the Moodies microbes were thought to have inhabited the photic zone.

8.5.8.4.4 Harsh Surface Environments of the Archean

Surface environments of the Archean Earth are presumably quite different to those of the Phanerozoic and even the Proterozoic periods. Thus, these environments are discussed in the section, related to large Archean microfossils. Walsh (1992), for example, implied large spheroids and ellipsoids discovered from the Kaapvaal Craton to be spores that had a great advantage on Archean volcanic platforms, where microbes were subjected to violent volcanisms, and would have grown within limited periods of volcanic quiescence. Additionally, the formation of spores might have been indispensable for microbes to survive through repeated asteroid impacts during the early Archean (Byerly et al. 2002; Lowe et al. 2003, 2014; Lowe and Byerly 2015). Oehler and co-workers (2017) also emphasized that Paleo- and Mesoarchean lenticular microfossils with robust walls, as shown by their thick and acid-resistant nature, had advantages for surviving on a young planet experiencing strong ultraviolet (UV) radiation (Catling and Claire 2005), as well as sudden environmental changes such as heating and even evaporation of ocean surface water, crustal fracturing, and extremely high energy waves (tsunamis) caused by large asteroid impacts (Lowe et al. 2003; Lowe 2013; Lowe and Byerly 2015).

8.5.8.4.5 Morphological Comparison with Younger Equivalents

Comparative study with morphologically similar microfossils from younger successions and even extant microbes would be an effective approach to elucidate the biological affinity and phylogeny; however, morphological similarity should not be considered diagnostically. Sugitani and co-workers (2007, 2009a, 2009b, 2015a), for example, have suggested that lenticular microfossils are morphologically similar to mature phycoma with a flange-like ala of an extant prasinophyte alga, *Pterosperma* (Parke et al. 1978; Tappan 1980). Strikingly well-preserved microfossils equivalent to phycoma of *Pterosperma* were reported from the Lower Devonian Rhynie chert (Kustatscher et al. 2014). Though biological affinities are not well known, spheroidal acritarchs with flange are also present in Meso- to Neoproterozoic successions (Samuelsson 1997; Samuelsson et al. 1999; Vorob'eva et al. 2015; Sergeev et al. 2016) (Figure 8.5.16f).

8.5.9 LESSONS FROM PREVIOUS STUDIES AND CONTROVERSIES ON ARCHEAN MICROFOSSILS

As exemplified by controversies on the biogenicity of some described microstructures from cherts in the Apex Basalt, Mount Ada Basalt, and the Isua Supracrustal Belt, studies of Archean microbe-like structures are frequently subjected to rigorous criticisms. Criticism of Archean microfossils has arisen mainly from the geologic histories of host rocks being unsuitable for preserving traces of life. Controversies are complicated when analyses are unable to be made on exactly the same material (as in the case of the Apex microstructures and possibly *IsuaspHERE*), and they can also be complicated when the three-dimensional structure of an object under study is not correctly assessed. These previous studies and controversies provide some lessons for Archean micropaleontology and the search for life on other planets:

1. Geological context is viewed as important, more than necessary. To prove the biogenicity of microbe-like objects in rocks collected from a region that has been subjected to severe deformation, metasomatism and metamorphism require tremendous lines of evidence.
2. Analyses to help determine the biogenicity of fossil-like objects should be made on exactly identical materials. Otherwise, irrelevant arguments and confusions may occur in scientific society. It should also be reminded that micro-scale objects are heterogeneously distributed in rocks, and thus, even hand specimens collected from, for example, a 30-cm-thick unit, do not always contain exactly the same objects. Also, the presence of morphologically similar well-defined pseudofossils should not be taken directly as counter-evidence for the biogenicity of the structures in question; however, it should

- also not be overlooked. Such logic may mislead scientific societies and induce barren controversies (see [Section 8.5.6.4.1](#)).
3. Criteria for biogenicity need to be applied appropriately. For example, DDI and narrow size distribution are well-defined criteria. However, these criteria require a prerequisite that microbes reproduced simply by binary fission. As described in this chapter, Archean microbes had already established various reproductive styles and complex life cycles, including multiple fissions and endospore formation. Even if a negative result is obtained from these criteria, the biogenicity of microbe-like structures under consideration should not be readily discarded.
 4. Systematic criticism and skepticism, which can be applied to one's own materials as well as others', are indispensable for studies of Archean microbe-like structures that are less-well-preserved compared with younger microfossils. The requirement of excessive analyses to confirm the biogenicity based on the "null-hypothesis approach," which in many cases can be performed only at limited institutions, also restricts sound progress of Archean paleobiology and astrobiology.

8.5.10 SUMMARY

This chapter describes representative early (Paleo- and Meso-) Archean microfossils and possible microfossils, referring in particular to surface environments of the ancient Earth, rock types potentially preserving microfossils, and various criteria for identifying Archean microbe-like structures as microfossils. To date, the oldest possible microfossils are recently reported hematite tubes and filaments from at least 3,770-million and potentially 4,280-million-year-old rocks in the Nuvvuagittuq Belt, Canada; however, their biogenicity is awaiting confirmation through further studies. In either case, it is evident from the cellularly preserved microfossils and possible microfossils that until 3.0 Ga, microbes of various morphologies and various metabolisms had already emerged and inhabited a range of environments, from deep-sea hydrothermal vent systems to shallow water and even terrestrial hydrothermal fields. Inhabitation in shallow to sub-aerial habitats provides indirect evidence for the early evolution of photosynthesis. Anoxygenic photosynthesis could have initiated as early as 3.4 Ga and oxygenic photosynthesis as early as 3.0 Ga. Thus, recent studies have provided evidence for the diversification of microbes during the first billion years since the emergence of life around 4.0 Ga and, at the same time, have revealed the presence of large, organic-walled lenticular microfossils in the Archean that appear to be out of place in an evolutionary context. However, the eukaryotic features of these lenticular microfossils should not be taken as reason for questioning their biogenicity. Discoveries of large prokaryotes with complex shapes have been accumulating. Also, there is no guarantee that evolution progressed linearly, especially in the Archean. Thus, the possibility cannot entirely

be excluded that the peculiar, large, and lenticular microbes represent extinct taxon, without phylogenetic relationship to any extant organisms. Despite the difficulties in studying Archean microfossils, in comparison with Proterozoic ones, it is worth to challenge exploring biosignatures in such deep time on Earth. As a result of controversies surrounding newly discovered materials, as well as revisions of previously reported materials, sophisticated methodologies with which we can identify cellularly preserved microfossils have been developed. These new technologies could also be applied to the search for life on other planets. Finally, the possibility cannot be eliminated that large microfossils similar to those described in detail here may be discovered in future Mars Missions, considering "..., compared to early Earth, early Mars might have had a greater supply of biologically useable energy and was perhaps, by implication, a better place for the origin of life" (Kirschvink et al. 2001).

ACKNOWLEDGMENT

I deeply acknowledge Dr. Vera Kolb for her invitation to this significant contribution and for editorial handling and Dr. Dorothy Z. Oehler for her critical and constructive comments to the earlier draft. Special thanks to Erica Barlow, who did detailed English editing and helped in finalizing the manuscript.

8.6.1 INTRODUCTION

The prime target for two forthcoming space missions, the European Space Agency (ESA)/Roscosmos' ExoMars 2020 and the National Aeronautics and Space Administration (NASA's) Mars 2020, is to acquire indisputable evidence for life signatures on another planet (Mars) and to assess whether these have arisen from extant or extinct sources. However, this simple statement generates two very important and directly relevant philosophical questions: firstly, how do we define life in the first place, and, secondly, how would we recognize its presence from chemical signatures, especially from the degraded chemical residues remaining from extinct organisms in the planetary geological record, by using remote analytical instrumentation? In this exercise, we should recognize the possibility that any extraterrestrial organism identified in future space exploration could have originated on Earth and may have been transported to our planetary neighbors in the solar system either by our own intervention, reinforcing the need for the most stringent planetary protection protocols for our spacecraft and landers, or through natural *panspermia* processes, which could include the deposition of chemical building bricks through delivery by meteorites, comets, and asteroids. The precise definition of "life" itself is actually rather elusive, and many initial attempts to do so have been eventually deemed to be not very satisfactory (Cleland and Chyba 2000; Shapiro and Schulze-Makuch 2009; Bedau 2010; Benner 2010; Tirard et al. 2010). After much debate, the NASA definition of life simply as "a self-sustaining system capable of Darwinian evolution"

incorporates a molecular genesis with replicative procedures and avoids several pitfalls of alternative definitions, which are based solely upon the perceived ability of the biological system to reproduce. Whilst the attempts to define life have been addressed comprehensively, both philosophically and scientifically, the scientific basis of the environmental requirements necessary to sustain emergent life have been summarized: the presence of an energy source, however derived; the presence of liquid water; and the presence of elements carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur (the so-called CHNOPS elements) in readily assimilable forms are all seen to be primary and necessary candidates for the successful establishment and subsequent evolution of life. However, this statement masks several factors that can conspire to restrict or defeat the establishment of the ongoing generation of life, such as the presence of extremes of temperature; desiccation; damaging insulation by low wavelength; high-energy radiation in the ultraviolet region of the electromagnetic spectrum; and environmental exposure to highly reactive chemical toxins, which can destroy bioorganic molecules, such as peroxide ions, hydroxyl radicals, and perchlorates, in addition to the compromising coordination effects of heavy metal ions.

To counter the potentially serious life-destroying scenarios of these adverse environmental conditions, terrestrial organisms such as cyanobacteria, endolithic, chasmolithic, and epilithic lichens have developed sophisticated biochemical strategies, which basically involve the harnessing of their geological substrates in niche environments where life can not only exist but multiply and evolve. The production of unique

suites of chemical protectants designed to combat a range of external stresses in hostile environments has been recognized as being critically important for the survival of cyanobacterial species in stressed terrestrial conditions (Cockell and Knowland 1999; Holder et al. 2000; Wynn-Williams and Edwards 2000a, b, 2002; Edwards 2010). This factor is actually the primary objective and the key to the analytical chemical search for life experiments that have been proposed for the first phase specialized and dedicated planetary rover Raman spectroscopic instrumentation that will be described here for the ExoMars 2020 mission (Rull et al. 2017; Vago et al. 2017). Hence, the analytical chemical perspective for a remote “search for life” astrobiological mission centres upon the ability to detect and recognize in a niche geological matrix the characteristic spectral biosignatures from these protective biomolecules, henceforth known as *biomarkers*. At this stage, we should also attempt to differentiate between scientific missions that search for evidence of life-sustaining water—however necessary that would be perceived in its astrobiological role—and those that are truly searching for extant life signals or for the residual surviving biomarkers where life has now become extinct. Where life has ceased to exist in a particularly hostile environment, the analytical detection of these surviving biosignatures is paramount, and this could be achieved primarily through the observation of signals from the preserved biomolecules and secondarily from the modifications made to the geological and mineral matrix by the biological colonies as part of their survival strategies (Wynn-Williams et al. 1999; Wynn-Williams and Edwards 2000a, b, 2002; Edwards 2010).

8.6.2 THE ROLE OF RAMAN SPECTROSCOPY IN LIFE DETECTION

Since the first reports in the literature of the successful Raman spectroscopic analyses of the biological colonization of toxic mineral pigments in Renaissance frescoes (Edwards et al. 1991a, 1991b) and that of an endolithic colonization of Beacon Sandstone from the Antarctic Peninsula (Edwards et al. 1997a, 1997b), the analytical chemical interrogation of extremophilic systems situated within a variety of geological substrates has resulted in novel information being provided about the nature of the synthetic protective chemicals and the strategies being employed for survival of the colonies in terrestrial stressed environments by using this technique. At first, the identification of the chemical complexes formed as a result of the reaction of epilithic lichen metabolic waste products upon calcareous substrates in the form of oxalates was a primary objective of the Raman spectroscopic analysis (Edwards et al. 1994, 1998, 2003a, 2003b, 2003c, 2004; Russ et al. 1995; Holder et al. 2000; Edwards 2004). It was not until much later that the characterization of the organic metabolic and protective by-products in epiliths and cryptoendoliths was accomplished through the adoption of laser excitation, using a range of wavelengths, and comparison with the spectra derived from laboratory extracted materials (Russell et al. 1998; Edwards et al. 2000, 2003d, 2003e; Jorge-Villar et al. 2003; Jorge-Villar and Edwards 2005), which had been characterised using a combination of

structural analytical techniques. As noted previously, the successful survival of extremophilic colonies in stressed terrestrial environments is dependent upon their adaptation to the prevailing conditions of high or low temperatures; extreme desiccation; high-energy ultraviolet insolation; high or low barometric pressures; extremes of pH, in the range from <1 to >12; and the presence of toxic chemicals and ions such as mercury (II), antimony (III), lead (II), barium (II), arsenic (III), and copper (II), which are found in many minerals and rocks. It was also apparent that the production of protective chemicals by extremophiles as a response to environmental stresses was supported by their ability to adapt their geological matrices and substrates, often resulting in modified biogeological signatures, which have been shown to remain in the geological record long after the extinction of the biological colonies.

The detection of the presence of life in terrestrial extreme scenarios such as oceanic vents, meteorite impact craters; glacial icefields; sabkhas; salterns; and desiccated hot and cold deserts such as the Antarctic, Atacama, Negev, and Mojave deserts, have revealed key molecular entities such as carotenoids, scytonemin, phycocyanins, and metabolic products of colonies, which are considered indubitably to be biosignatures. The key point here is that these biochemicals have been synthesized by biological organisms for their protection and survival in conditions of extreme desiccation, pressure, temperature ranges, chemical toxicity, and radiation insolation, so, indeed, they can be considered as “signs of life” for a such a forensic analytical investigation. What now needs to be considered for the transition to remote planetary studies are the following questions:

- The environmental conditions that potential life forms are going to experience on our neighbouring planets and their satellites are expected to be significantly more severe than we can find on Earth. What is the implication for the survival of biological colonies on Mars, for example?
- In the Darwinian scheme of *adaptation for survival*, would the survivors have created new molecules that represent a range of novel biosignatures, which we may not recognize from terrestrial studies undertaken hitherto?
- If life did develop extraterrestrially, would the worsening of environmental conditions result in its immediate extinction or would the adaptation for surface survival, given time, have taken a new course, such as the colonization of subsurface strata to escape surface radiation, coupled with the requisite geological host matrix modifications—and how could we then access these sites remotely?
- If life was initiated and was then extinguished, would there be a biosignature left in the planetary geological record, which could be interrogated successfully by remote investigative instrumentation?
- What would be the effect of exposure of the potential biomarkers created by now-extinct organisms to the toxic chemicals and radiation that could degrade them molecularly? And then, would such degraded

entities be recognized as descendants of their true original biomarker molecules? For example, the chemical degradation of biomolecular complex-ring systems such as polycyclic aromatic hydrocarbons and heterocyclic porphyrins to simple fused-ring aromatic hydrocarbons and purines, and eventually even to elemental carbon, might result in chemically stressed environments.

- What type of remote analytical instrumentation would be best for the securing of unambiguous evidence of molecular biomarkers in the geological record that would be recognized as being indicative of extinct or extant life on the planetary surface or subsurface?

It is in this context that we should now explore the advantages that Raman spectroscopy can offer to the interrogation of specimens of biogeological matrices in search for life experiments. Basically, these can be summarized as follows:

- Raman spectroscopy involves the focussing of a monochromatic laser beam on a sample in the ultraviolet, visible, and near-infrared regions of the electromagnetic spectrum between about 300-nm and 100-nm wavelength. Whereas most of the radiation scattered is in the form of unchanged frequency (Rayleigh scattering), the resultant Raman spectrum arises from the much weaker intensity Stokes and anti-Stokes scattered radiations, which occur with changed frequencies, shifted between about 0 cm^{-1} and 3500 cm^{-1} from the incident or Rayleigh frequency, which form a characteristic Raman spectrum comprising vibrational bands occurring in this wavenumber region. The most important analytical information arising from these frequency-shifted bands is that each chemical species (molecule or molecular ion) has a distinctive and unique Raman series of Raman spectral bands, which can be effectively utilized to identify it from a “molecular spectroscopic fingerprint.” The Raman bands arise from molecular moieties or entities found within the specimen, such as organic amide, carbonyl, aromatic rings, and aliphatic carbon-carbon unsaturation, and this applies equally well to inorganic ions found in minerals, such as sulphate, carbonate, nitrate, and metal oxide vibrations (Long 2002).
- The Raman spectrum between 0 cm^{-1} and 3500 cm^{-1} contains complementary structural information arising from mixtures of both inorganic and organic components in the same specimen, without having to effect chemical or mechanical methods of separation—making it ideal and quite specific for the interrogation of biogeological specimens that have been described earlier.
- The Raman spectroscopic examination of a specimen can be effected microscopically through the marriage of one of the oldest scientific pieces of

equipment, the microscope, and one of the newest, the laser, operating over a range of monochromatic wavelengths. In this way, depending upon the wavelength of the incident laser beam, the “footprint” at the sample can be of the order of only several microns up to about 100 microns; the high values of the incident power density (irradiance) possible for the focussed laser at the specimen should be realised for the smallest footprints, being greater than 1 MW cm^{-2} , which could be extremely damaging for sensitive materials. The practising Raman spectroscopist must therefore evaluate the desirability of using the highest level of incident laser irradiance to produce the strongest observable Raman effect, against the likely possibility of inflicting thermal damage upon the specimen. Normally, therefore, one errs on the side of safety and uses well-tried laser power levels and microscope magnifications from existing laboratory work with similar samples, and this has proved to be a trustworthy *modus operandi* for examination of biogeological specimens, even though mineral samples are found to be quite robust to higher irradiance levels of laser illumination.

- The Raman spectral data obtained from the laser illumination of samples generally comes from the surface regions, unless particular transparency to the incoming laser radiation in mineral crystals is noted, when subsurface sampling can be made to the depth of a few centimetres or more. In this way, the Raman spectra of biological colonies of cyanobacteria that exist some 5 cm below the surface of clear selenite crystals have been reported *in situ* and without fracture of the surrounding crystal matrix (Edwards et al. 2005).

8.6.3 WHY RAMAN SPECTROSCOPY?

It was appreciated at the outset that a major advantage of Raman spectroscopy as an analytical technique for the study of extremophilic colonization and survival was its ability to interrogate a system microscopically, across a horizontal or vertical transect, without any physical separation or chemical and mechanical pretreatments such as coating, grinding, and polishing (Long 2002). Hence, information about the interaction between the biological and geological components is accessible naturally, without extraction or modification of the biogeological system. This was appreciated in the analysis of works of art that had been subjected to lichen deterioration and required conservation (Edwards and Chalmers 2005).

The recognition of key definitive Raman spectral signatures in the same spectrum from the organic and inorganic components is a desirable outcome for the projected deployment of a miniaturized spectrometer unit as part of the life detection instrumentation suite on the planetary rover vehicle on the ESA/Roscosmos ExoMars mission scheduled for 2020 (Rull et al. 2017; Vago et al. 2017). In this mission,

the Raman spectrometer will be a first-pass probe of selected samples from the Martian surface and subsurface (down to a depth of 2 metres below the surface) for the detection of extremophilic spectral signatures from extinct or extant colonies in niche environments. The assimilation of Raman spectral data and signatures into a database relating to extremophiles from terrestrial Mars analogue sites is therefore of vital importance, and this has been undertaken in recent years and is still ongoing. Similarly, Raman spectroscopic analyses of other extreme terrestrial sites that have relevance to the remote exploration of other planets and their satellites in our solar system, such as glaciers, deep-sea smokers, thermal vents, hot geysers, and snowfields, have been reported. These extreme terrestrial sites have an ambience with planetary icy moons such as Europa, Titan, Io, and Enceladus, which are also noteworthy in this respect.

The purpose of the present chapter is to survey and critically examine comprehensively the existing wealth of Raman spectral data and their resultant interpretation for terrestrial extremophiles; from this analysis, the following deductions can then be made:

- The commonality of Raman spectral signatures between various sites and extreme environments (Jorge-Villar and Edwards 2005).
- The factors that affect the recording of Raman spectral signatures from the extremophilic colonization of terrestrial sites (Edwards et al. 2003a, 2003c).
- The definition of Raman data for evidence of extinct or extant life in the geological record.

8.6.4 THE ANALYTICAL CHALLENGE FOR REMOTE SPECTROSCOPY

The analytical challenge facing Martian search for life extra-terrestrial experiments involving remote spectroscopic instrumentation can be summarized as follows:

1. Can the spectral biosignatures that we recognize and have assimilated into a definitive database from terrestrial Mars analogue studies be assumed to be chemically identical? It has already been explained that the terrestrial biosignatures derive from suites of biochemical that have been synthesized by extremophilic organisms and bacterial colonies in response to external environmental conditions and stimuli. It is generally accepted that the so-called terrestrial Mars analogue sites approximate to only those conditions that can be expected on Mars itself—it can be stated categorically that nowhere on Earth do the hostile conditions pertaining on Mars match: the high insolation of ultraviolet and gamma radiations, extremely oxidising chemical toxicity in the form of perchlorates and free radicals, deficiency of nutrients, very low temperatures (about -150°C) and daily temperature range of around 170°C , and, of course, water/ice and water vapor deficiencies. Given

this apparent new range of external influences, we should expect chemical adaptation to have perhaps sought novel directions to enhance survival, with consequent new biosignatures that are not present in terrestrial extremophilic organisms. Having said this, it has been reasonably proposed that it would be impossible to expect organic molecules to survive on Mars because of the low-wavelength ionising radiation insolation and the presence of chemical species such as hydroxyl radicals, hydrogen peroxide, and perchlorates. Despite this, the recent detection of organic molecules, such as chlorobenzenes, in the Sheepbed Mudstone at Gale Crater by the NASA rover, albeit in trace concentrations, gives hope for their survival (Freissinet et al. 2015).

2. Extant *versus* extinct life: can Raman spectroscopy differentiate between the molecular signatures in living systems and those signatures from once-living systems that have not survived in their hostile environment? This argument can be reduced to a simple, rather philosophical consideration: the successful Raman spectral detection of molecules in a search for life experiment is dependent on the molecular composition of the target, which is the same for living and non-living systems. Of course, in living systems, the possible temporal degradation of molecular biomarkers is balanced by their continuous replacement, whereas the environmental destruction of the same biomarkers in an abiotic system will eventually result in their disappearance. The term “biomarkers” should not therefore be assumed to have a biotic significance—these molecules are not “living,” and therefore, their detection should not be assumed to be an unambiguous indicator of extant life.
3. A major problem facing the remote spectroscopic detection of biomarkers in a Martian niche environment is the survivability of these from long-dead colonies: this can be rephrased as: how long can reactive chemical species such as carotenoids, scytonemin, phycocyanins, sugars, and chlorophylls survive the conditions of extreme temperatures, exposure to ionising radiation, and chemical toxicity on Mars, even in protected niche environments? This will be considered in the next section.

8.6.5 THE GREAT ENIGMA: HOW WILL WE RECOGNIZE THE PRESENCE OF EXTANT OR EXTINCT LIFE USING REMOTE ANALYTICAL INSTRUMENTATION?

In our discourse, we have considered the necessity of essential adaptation of a geological niche in otherwise-hostile environments for the stabilization and survival strategy of a living organism in early planetary scenarios. For extinct life, which once comprised perhaps cyanobacterial colonies, we are faced with two problems in recognition: one of these is the detection

of unambiguous chemical signatures, which were produced during their existence, and the second is the survival of these chemical entities in recognisable quantities and forms after the death of the host colonies. We have considered the former earlier in this article, but the latter is an unknown parameter, which itself creates a further question: what is the reality of survival of the intact chemical biosignatures over periods of geological time? Current plans for search for life missions to the planet Mars, for example, represented by the NASA's Mars 2020 and ESA/Roscosmos' ExoMars 2020 missions, target geological areas and rocks from the earliest period in Martian history, known as the Noachian, extending from about 4,600 million years ago to approximately 3,500 million years ago and perhaps extending into the Hesperian period to about 3000 million years ago, when it is believed that Mars had a climate not too dissimilar from that of Earth and had significant liquid water on its surface in the form of Martian oceans. What should be appreciated is that rocks from the latest period in Martian geological history, the Amazonian, from 1800 million years ago to the present, are not considered conducive to the preservation of life signatures, because of the intense bombardment of the Martian surface by meteorites and volcanic activity and the loss of the Martian atmosphere caused by a collision with other large bodies in the solar system in the later Hesperian period. A possible location for spectral signatures for residual extant or extinct life, therefore, would be the subsurface interrogation of potential niche environments (Ellery et al. 2003, 2004). The ExoMars mission is specifically targeting this aspect with an onboard drill that will be capable of accessing and retrieving specimens from 2 metres below the Martian surface. Biosignatures in the subsurface environment, protected from the chemical toxicity present on the surface of Mars, arising from the intense ionising radiation, will be additionally preserved from deteriorative low-wavelength radiation effects owing to iron (III) oxide on the surface (Clark 1998).

We are thus faced with a very real problem in the use of remote analytical instrumentation, geared up to the detection of extraterrestrial biosignatures from extinct life, in that we need to consider how the pristine biochemical entities can be preserved in their geological environment and also how they degrade (Westall et al. 2015). Thus far, we have considered only the chemical identification of life signatures: the other possibility is the observation of residual fossilized shapes and structures in the geological record, which can be indicative of once-extant life forms, the geomorphological signature. The presence of fossilised bacterial signatures in the terrestrial geological record, along with associated minerals, such as pyrites, haematite, pyrolusite, and magnetite, gives credence to their recognition extraterrestrially by light microscopy: the first exciting release of the discovery of morphological shapes characteristic of fossilized bacteria in Martian geology came for the Martian meteorite found in 1984 in the Allen Hills in Antarctica, ALH 84001, dating from about 18 million years ago (McKay et al. 1996). After much controversial debate, this apparently conclusive evidence for life on Mars was questioned and was filed as only a possibility, as the seemingly definitive structures attributed to fossilized cellular nanobacteria some 20–100 nm or so in

length could possibly have been produced by the methodology of production of the thin sample of meteorite taken for petrological examination and its subsequent polishing process. ALH 84001, an Shergotty-Nahkla-Chassigny (SNC) class meteorite of mass 1.93 kg, was believed to have been ejected into space from the *Valles Marineris* region of Mars by meteorite impact, was captured by Earth's gravity, and was found in Antarctica on December 27, 1984. The recent announcement in *Nature* (Dodd et al. 2017) of the morphological evidence for terrestrial fossilized bacterial structures dating back to 4220 million years ago at Nuvvuagittuq in the Canadian Arctic has revived this interest. It has also moved the concept of a start-up of life on Earth some 500 million years earlier than was once thought and now to within some 400 million years of our own planet's creation. However, this still begs the question as to whether or not biological signatures would have survived this long: in this context, a specimen from the ancient Australian site at Pilbara showed evidence for chemical biosignatures, using laboratory Raman spectroscopic equipment, in 3600-million-year-old geological deposits (Pullan et al. 2008). The spectral bands for carotenoids and porphyrin key biomarkers were observed together from a small 10-micron sample footprint encased in the ancient stromatolites. Other regions of the same sample similarly gave signatures of carotenoids, scytonemin, and chlorophyll in various admixtures. A possible explanation of the appearance of these biomarkers in such an ancient specimen was that they could have resulted from later cyanobacterial colonization of the stromatolites, which, of course, challenges any idea that these biosignatures could be commensurate with the geological age of the sediments. It is clear that what is now needed is a combined analytical study of a geomorphological signature to examine the presence of chemical biosignatures, which could match the visual record; this could establish the reality of assessment of survival of such biosignatures over an extended geological timeframe appropriate to the planned survey of the Martian geological record, and similarly, their detection would inform the attribution of a biological origin to what otherwise may be doubtful structures, as in the case of ALH 84001. As Garcia-Ruiz (1999) has correctly stated:

Morphology alone cannot be used unambiguously as a tool for primitive life detection.... the interpretation of morphology is notoriously subjective.

8.6.6 KEY BIOMARKERS AND THEIR RAMAN SPECTROSCOPIC SIGNATURES

The Raman spectra of the key biomarkers and minerals relevant to Mars can be broadly classified into the following wave-number ranges: 3200–3450 cm⁻¹, containing the characteristic stretching modes of OH and NH groups; 2800–3150 cm⁻¹, containing the characteristic CH stretching modes of aromatic and aliphatic organic compounds; 1500–1650 cm⁻¹, containing the characteristic C=C stretching modes of aromatics, alkenes, and carotenoids; 1300–1400 cm⁻¹, containing the characteristic CH₂ and NH bending modes; and 1050–1200 cm⁻¹, containing the characteristic C-C stretching modes. In the

lower-wavenumber range, 100–1100 cm⁻¹, we would expect to see the vibrational modes of heavy-metal oxides, such as Fe₂O₃, and of the inorganic molecular ions sulphate, silicate, phosphate, and carbonate. It would be facile to suggest, however, that it is possible to separate organic signatures from inorganic minerals, since the Raman spectra of both contain features that occur in several of the ranges specified earlier, and the situation is exacerbated even more with biogeologically modified material; for example, metal oxalates, formed from the metabolic decomposition products of organisms in calcareous substrates, have bands near 1500, 900, and 500 cm⁻¹ and carbonates have bands near 1100, 700, and 300 cm⁻¹.

Also, there is no precise, unchanging, and defined value for any particular vibrational band in a biomarker entity, irrespective of the molecular species, since molecular structural, environmental, and crystal field effects conspire to change the wavenumbers of an identifying group significantly. Hence, calcium carbonate, CaCO_3 , has a C-O stretching band at 1086 cm^{-1} , which in dolomite, $\text{CaMg}(\text{CO}_3)_2$, occurs at 1094 cm^{-1} and in magnesite, MgCO_3 , occurs at 1115 cm^{-1} . In the potential list of organic biomarkers, carotenoids provide a key group of target molecules, and here the strongest signature, namely that of the C=C stretching vibration, can have the spectral value between 1535 cm^{-1} and 1508 cm^{-1} , dependent upon the length of conjugation in the alkene chain. Also, it is quite rational to make a molecular structural diagnosis on the basis of several cognitive

Raman bands, rather than one alone, so the selection of several wavenumber ranges for the characterization of molecular entities and functional groups is a normal procedure in Raman spectroscopy.

From comprehensive Raman spectroscopic studies, which have been reported in the scientific literature for terrestrial extremophilic systems and their colonization of geological strata in some of the most extreme environments on Earth (Jorge-Villar and Edwards 2005), it is possible to construct a working database of characteristic signatures from which it should be possible to identify analogues on Mars from remote Raman spectral data. The terrestrial data comprise laboratory experiments and, where appropriate, *in situ* experiments carried out in field expeditions to, amongst others, the Antarctic, Canadian Arctic, Svalbard, Spitsbergen, Atacama Desert, Negev Desert, Dead Sea, Mojave Desert, Death Valley, Pilbara North Pole Dome, Barberton, Kilauea, and the Dolomites (Wynn-Williams and Edwards 2000a, b; Vitek et al. 2012). The results are summarized in Table 8.6.1 (taken from Edwards et al. 2014), where the key Raman bands of some of the most important molecules are listed, with their characteristic features suitable for identification in mixtures highlighted in bold type. Naturally, this list cannot be totally inclusive, and several molecules have not been listed, but the molecules given in Table 8.6.1 represent a good cross-section for the construction of a comprehensive Raman database for biomarker detection in hostile environments.

TABLE 8.6.1
Raman Bands of Biomarkers and Associated Geomarkers in Extremophile Examples and Their Chemical Formulae

8.6.6.1 SELECTED BIOMARKERS AND THEIR RAMAN SPECTRA

From the biomarker molecules listed in Table 8.6.1 (Edwards et al. 2014), we shall select here just two for a more detailed discussion in this paper, namely, carotenoids and scytonemin. Then, a similar discussion will follow on carbon, the end-of-line result of degradative processes, which may have been operating upon these biomarkers that have been exposed to chemical change over many thousands or millions of years.

8.6.6.1.1 Carotenoids

In certain areas of the Earth's surface, the colored carotene pigments can be seen as evidence of an active biological colonisation: an example of this phenomenon is seen in Figure 8.6.1, which shows the pink colour of carotenoids in the halophilic cyanobacterial colonization of Don Juan Pond in Antarctica—the very high ionic calcareous salt content, comprising 44% by weight of salts, mainly calcium chloride and sodium chloride,

FIGURE 8.6.1 Don Juan Pond in the McMurdo Dry Valleys, Victoria Land, Antarctica, showing a pink bloom from halophilic cyanobacterial colonization. This is a hypersaline lake and is recognized as the most salt-laden liquid water on earth, containing 44% salinity and comprising almost 3.7 mol kg^{-1} and 0.5 mol kg^{-1} of CaCl_2 and NaCl , respectively, at a temperature of -51°C . (Courtesy of Dr. David Wynn-Williams, British Antarctic Survey, Cambridge, UK.)

of this location maintains one of the lowest temperatures on our planet; the water here is still in its liquid phase at approximately -50°C , yet the biology is clearly thriving!

Several biomolecules have been identified as potential biomarkers for the detection of signs of extant or extinct life in geological niches in hostile terrestrial environments, and carotenoids are recognized as a prime marker in this context: currently, some 500 members of the carotenoid family are known terrestrially, each possessing a conjugated chain of $\text{C}=\text{C}$ and $\text{C}-\text{C}$ linkages with pendant methyl groups and aliphatic or aromatic end units, which can be cyclic, as in the case of beta-carotene, or can comprise complex groups based on sugars, such as spiroxanthin. Their Raman spectroscopic detection is based upon key molecular signatures centred on the conjugated $\text{C}=\text{C}$ moieties, which give rise to two characteristic Raman vibrations due to $\text{C}=\text{C}$ stretching at about 1520 cm^{-1} and $\text{C}-\text{C}$ stretching at about 1150 cm^{-1} , both of strong intensity, and a weaker feature at about 1005 cm^{-1} , which arises from a $\text{C}=\text{C}-\text{H}$ bending mode. The presence of these bands in a biogeological system is well established as a diagnostic confirmation of the presence of carotenoids even in complex specimens, which can exhibit other bands due to accessory light-harvesting pigment, chlorophyll, and low-wavelength radiation protectants such as scytonemin (Edwards et al. 2014).

The importance of the Raman spectroscopic diagnostic analysis of biomarkers such as carotenoids in a variety of geological, biogeological, and biological systems on ExoMars 2020 rests upon their unambiguous identification and attribution to chemical species, and this depends upon several factors, including the Raman cross-section or molecular scattering coefficient, which results in a relatively high-band intensity from even small amounts of relevant material in the specimen; the placement of the characteristic bands in regions that are not subject to potential interference from other molecular species present, so minimising the risk of their escaping detection; and the spectroscopic interpretation of their molecular origins upon which the reliable band assignments are based (Marshall and Marshall 2010). All of these points are generally applicable to carotenoids, and indeed, their detectability is singularly and specifically enhanced by several orders of magnitude by using laser excitation in the green region of the spectrum through the operation of a resonance Raman effect, which is a critical factor in the 532-nm laser excitation used on ExoMars 2020 and an appropriate advantage for the detection of carotenoids through the resonance Raman enhancement of the scattered Raman signals. Figure 8.6.2 shows the Raman spectra of two distinct carotenes from an extremophilic cyanobacterial colony inside a basaltic lava vacuole (Jorge-Villar and Edwards 2010).

These spectra have been obtained with green laser excitation and are an example of the operation of resonance Raman scattering enhancement upon carotenoids. In this resonance experiment, no chlorophyll was detected, but in contrast, using near-infrared 785-nm excitation in an out-of-resonance condition, the presence of these carotenoids was recorded

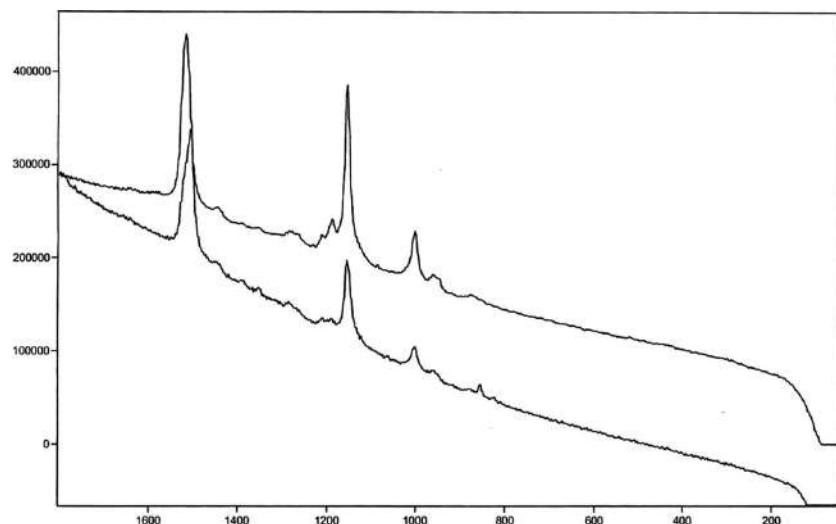

FIGURE 8.6.2 Raman spectra of two distinct carotenoids, beta-carotene and astaxanthin, from cyanobacterial colonization inside a vacuole in basalt found in Svalbard, Arctic Norway.

less strongly but along with other biomarkers such as chlorophyll and scytonemin. The detection of the three main characteristic bands of a generic carotenoid will be undoubtedly critical for the successful deployment of the Raman instruments on Mars; however, it is equally important scientifically to be able to match the signals received remotely from Mars to the molecular structure of the carotenoid concerned. This is not such a routine task, as several factors need to be considered before an unequivocal conclusion about the species of carotenoid can be deduced from the wavenumber positions of the characteristic bands, since these are dependent upon the molecular environment. Hence, one cannot assign precisely the characteristic wavenumbers of the Raman bands in beta-carotene, for example, based upon a standard specimen, since these are changed by its admixture with other molecules—so, the C=C stretching band of beta-carotene cannot be assigned a single wavenumber, but this can lie within the range 1511–1523 cm⁻¹. A further problem arises when two or more carotenoids are present in the same target specimen—both C=C stretching wavenumbers can lie within this narrow range and may not be fully resolved under the operational spectrometer conditions. In laboratory instrumentation, where the spectral resolution may be 1 cm⁻¹ or smaller, this may not be a problem, but most miniaturized Raman spectrometers have defined spectral resolutions, which are cited as high as 10 cm⁻¹, and this clearly could potentially compromise the identification of the individual molecular species. A possible marker as to the presence of more than one carotenoid in a system under study would be given by the relative intensities of the three characteristic C=C, C–C, and CCH features described earlier: for a range of carotenoids, the wavenumber positions of these features lie approximately in the narrow regions 1532–1500, 1160–1152, and 1008–1004 cm⁻¹, respectively, and the relative intensities are approximately 1.5:1:0.2. However, depending upon the spectral resolution and relative proportions of two or more carotenoids in admixture in a system, these relative intensities are changed and could also

involve peak wavenumbers sensibly different from the analogous values observed in each individual component (Jehlicka et al. 2014).

8.6.6.1.2 Scytonemin

Scytonemin is a sunscreen pigment secreted as part of the outer protective sheath of cyanobacteria; it absorbs ultraviolet B (UVB) (280–320 nm) and ultraviolet C (UVC) (190–280 nm) radiations, is resistant to degradation, and has been adopted as a distinct and selectively exclusive biomarker for cyanobacteria (Edwards et al. 2000, 2003a; Varnali et al. 2009; Varnali and Edwards 2014a, b). Scytonemin is the parent of a growing number of potential substituted biomarker derivatives (Varnali and Edwards 2010, 2013, 2014a, b), based on this unique dimeric structure, including an interesting and novel range of iron complexes (Varnali and Edwards 2010, 2013). Cyanobacterial organisms within Arctic and Antarctic rocks illustrate the capacity of life to survive under intensely cold and dry conditions, and an example of a cyanobacterial halotrophic colonization of *Nostoc* and *Gloeocapsa*, some 5 mm inside a selenite (gypsum) crystal from breccia deposits at the rim of the Haughton meteorite crater in Devon Island, Arctic Canada, was analysed using confocal Raman microscopy and 785-nm excitation (Edwards et al. 2005). The Raman spectrum of scytonemin is shown in Figure 8.6.3.

8.6.6.1.3 Carbon

The degradation of biomolecules in hostile geological environments eventually produces carbon, whose signatures in the Raman spectrum have been well described. The idea that it is possible to differentiate between biotic and abiotic carbon formation from the shape of the so-called D and G Raman bands, characteristic of sp³ and sp² hybridized carbons, effectively represented by structures typical of diamond and graphite, respectively, has had a long and rather controversial history in the literature, which is still raging today (Kudryavtsev et al. 2001; Brasier et al. 2002; Pasteris and Wopenka 2002, 2003;

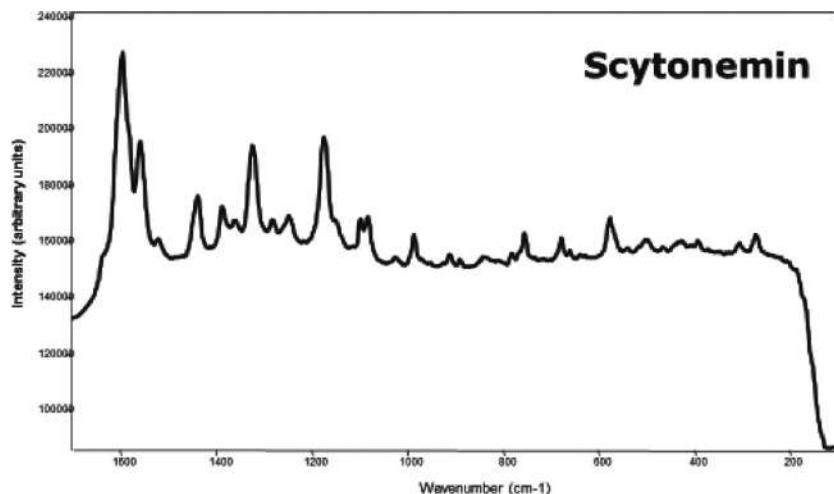

FIGURE 8.6.3 Raman spectrum of cyanobacterial colony inside a selenite crystal from breccia at edge of Haughton Crater, Devon Island, Canadian Arctic, with the characteristic bands of scytonemin.

Schopf et al. 2002; Schopf and Kudryatsev 2005); a summary of the extensive literature on this subject is provided by Marshall et al. (2010) and Marshall and Marshall (2010, 2014), who have defined a methodology for rigorously discriminating between these different carbon sources. However, if we consider the requirements of such fine spectroscopic work that has to be undertaken in the field by using portable miniaturized instrumentation, with all the sacrifices that have had to be made from laboratory versions, additionally performed under extremely hostile conditions that are mirrored nowhere else terrestrially, then one must pose the question: is it possible with current instrumentation to be able to differentiate between abiotic and biotic carbon, especially with portable devices? The result then is that the observation of characteristic carbon signatures does not constitute the presence of extinct life. So, in our definition, carbon cannot be a true biomarker. The same analogy applies to other biochemicals, which have been synthesised abiotically in the laboratory, such as amino acids, sugars, porphyrins, and proteins. This is the reason that these molecules are not presented as true biomarkers in Table 8.6.1.

8.7.1 INTRODUCTION

Microorganisms (herein the term “bacteria” *sensu lato* is used generically for microorganisms, including viruses) are the most common organisms on the surface of the Earth and the only organisms to live at depth in the subsurface. They are also the organisms that can survive the most extreme environmental conditions known today, including (to a certain extent) the space environment. Despite their generally simple morphologies, small size, and lack of hard parts, bacteria can nevertheless be themselves fossilized or leave a variety of traces in the rock record that are capable of withstanding geological processing, thereby providing direct evidence for life as far back in time as the Paleoarchean (~3.7–3.3 billion years ago, Ga). Generally, these traces are preserved in microcrystalline silica (chert), which has the ability to contemporaneously encapsulate organic material. However, the range of environments that could preserve biosignatures, particularly in deep time, include a full traverse of stratiform bedded cherts and siliciclastic settings, shallow-water sandstones and carbonates, volcanogenic edifices and deposits such as pillow basalts, hydrothermal vent

deposits and chemical sediments, and terrestrial riverine and lacustrine environments (Nisbet, 2000; Brasier et al. 2011; Westall 2016). The often-very-great ages of these traces mean that they have survived the many geological complications of Earth’s history, enduring physical, hydraulic, tectonic, and metamorphic events that, at times, could have completely obliterated them. Despite their great age, a small number of Paleoarchean terranes have survived relatively unscathed. For studies of early life, these include notably the East Pilbara terrane of Western Australia and the Barberton greenstone belt of South Africa, and more are appearing, as global warming removes protective glacial shields in certain locations, such as Greenland (indeed, there is a peculiar benefit in global warming for geologists), but this chapter will focus mostly on well-preserved and definitive morphological biosignatures.

Archean (~4.0–2.5 Ga) terranes host all the known types of biosignatures, be they morphological fossils of cells, colonies, biofilms, or other biological constructions, such as microbial mats and stromatolites; the degraded chemical traces of organic components of the original microbial communities (biomarkers); or even geochemical metabolic

by-products, such as biominerals, records of specific isotopic fractionation, and trace or rare-earth element enrichments (Westall and Cavalazzi 2011; Mustard et al. 2013). These biosignatures document a time period when the Earth was, in itself, an extreme environment: without oxygen, with high ultraviolet (UV) radiation flux, warmer oceans, slightly acidic seas, highly active in terms of volcanism and hydrothermalism, and subject to frequent impacts of extraterrestrial bolides (Hofmann 2011; Arndt and Nisbet 2012; Westall et al. 2018). Life on the early Earth was therefore what we would today consider extremophilic. This concept should, perhaps, be taken with a pinch of salt, since life, as we know it, could not have appeared on the modern Earth because of the presence of oxygen and, because these anaerobic microorganisms are most likely among the most frequent life forms in the universe, it is we, modern-day terrans, who are the true extremophiles!

Notwithstanding, the very fact that early life on Earth was anaerobic, extremophilic, and relatively simple means that it provides ideal analogues for understanding the potential distribution of life on other planets and satellites, such as Mars (Westall et al. 2015a). Early life can inform us about what we might find on the Red Planet, how it might be preserved, how to search for it, and how to confirm its biogenic origin. In determining biogenicity, Precambrian paleontology provides the perfect philosophical analogue and has set a benchmark of stringency against which potential extraterrestrial biosignatures will need to be tested. Furthermore, we will not only be searching for fossilized traces of life on Mars. Tantalizing trace amounts of methane in the Martian atmosphere, observed from the Earth (Mumma et al. 2009), from Martian orbit (Formisano et al. 2004), and *in situ* by the Mars Science Laboratory *Curiosity* rover (Webster et al. 2015), may have been, and may still be, produced by Martian microorganisms; however, of course, there are also abiotic crustal processes that could account for this methane. Thus, extant life could have found a habitable niche and refuge in the upper crust of Mars and could, under particular circumstances, be brought back up to the surface. Therefore, missions to Mars need to search for both fossil and extant traces of life, the biosignatures of which are similar but not identical and for which the means of detection and analysis are different.

8.7.2 THE FOSSILIZATION OF BACTERIA

Living microorganisms are composed of three major organic components: a replication molecule, for example, DNA; molecules for doing work in the cell and allowing it to conduct its essential functions, for example, proteins; and molecules that provide a confined and controlled environment for metabolic and replication activity, such as lipids forming a semi-permeable membrane. The identification of unknown living organisms is largely based on a battery of techniques, including lab on a chip, various -omics approaches (genomics, proteomics, or metabolomics), and polymerase chain reaction (PCR) to study small segments of DNA, all of which allow classification of organisms according to their individual molecular

signatures. Direct cell cultivation is a further method by which microbial biosignatures can be understood; however, to date, less than 2% of all microorganisms have been successfully cultivated (Wade 2002).

For the fossil record, this same suite of approaches cannot be used normally. DNA, for instance, is estimated to have a maximum longevity of 0.4–1.5 Ma under even exceptional preservational conditions while retaining sufficient signatures for analysis by sequencing technology (Willerslev et al. 2004). As a result, the range of techniques with which ancient life is studied differs greatly from (micro)-biological approaches. For many decades, direct observation was the only method by which traces of early life could be studied. Limited macroscopic to microscopic observations of cells, colonies, biofilms, microbial mats, and other morphological manifestations of microbes, including microbial constructs, such as stromatolites, organo-sedimentary structures, and microbially induced sedimentary structures (MISS; cf. Noffke 2010), nonetheless, yielded an impressive array of identified structures, the validities of some of which have survived even recent criticism (e.g., Knoll and Barghoorn 1977; Walsh 1992). However, advancements in our understanding of biogeochemistry and the application of techniques capable of estimating Earth-Life interactions in ancient rocks have significantly widened the range of possible biological indicators. We are thus able to delineate biological indicators, both living and fossil, into three classes: morphological, organic, and metabolic. The latter includes the precipitation of minerals as a side effect of changes in the immediate environment of the microbes by their metabolic activity, together with the dissolution of minerals; the leaching of minerals to obtain necessary nutrients or elements; and the concomitant patterns of enrichments and depletion that result from these processes and that are probably biological. Manifestations of microbial presence are therefore manifold (Summons et al. 2011; Westall and Cavalazzi 2011). To some degree, all of these features can be preserved in fossilized form in the rock record, with, necessarily, a certain quota of alteration after natural degradation and transformation into fossil status, as well as post-diagenetic and post-taphonomic alterations by geological processes and the effects of geological time.

8.7.2.1 THE PROCESS OF FOSSILIZATION

The series of processes affecting microorganisms upon death and their potential preservation in the rock record is termed *taphonomy*. Upon cell death, the release of enzymes breaks down the cell wall, allowing the internal contents to escape into the environment. In general, most dead cellular material is immediately degraded and taken up by heterotrophic organisms that oxidize the organic molecules as a source of energy. It is estimated that less than 10% of cellular organic matter is preserved in the rock record. Thus, in order for organisms to be preserved at the cellular level, they generally need to be (1) rapidly encapsulated or replaced by a mineral that replicates cell shape (permineralization) or (2) rapidly entombed by

anoxic sediments, permafrost, or ice, which essentially “mummifies” the cells. In both cases, stabilization of the cell wall by the chelation of metals, such as Fe (Ferris et al. 1988; Orange et al. 2011), can prolong the “life time” of the cell walls, thus allowing more time for the formal fossilization process. Most frequently, a third means of preservation occurs, whereby (3) their degraded organic components become trapped within a mineral matrix.

Finally, in order to pass into the rock record and be preserved for significantly long geological timescales, the mineralized or mummified microbial matter or their degraded components need to be lithified into sediments. With increasing age, there is more likelihood of a particular geological formation being destroyed by tectonic, mass wasting, or weathering processes. Indeed, there remain only a few enclaves of rocks dating from the early Earth, and none of these are older than 4 Ga. The preserved early Earth rocks dating from the Early Archean (subdivided into the Eoarchean and Paleoarchean) stretch the geological record to about 3.9 Ga. All have been subjected to varying degrees of metamorphism. The oldest (Eoarchean) sedimentary formations occur in Canada and Greenland. These rocks have witnessed up to amphibolite or granulite facies metamorphism and are therefore significantly altered. Understanding their protoliths and the geochemical signatures preserved within is challenging. Nevertheless, carbon in the form of graphite exhibiting isotopic signatures consistent with those produced by microbial fractionation occurs in a number of these highly metamorphosed formations (e.g., Rosing 1999; Tashiro et al. 2017). Once fossilized, biosignatures do not automatically enter into the rock record to be preserved in deep time. For example, even though microbial mats can be calcified, calcification can also be reversed depending on diurnal cycles (Dupraz et al. 2009). Indeed, modern stromatolites form largely from sediment trapping within their sticky extracellular polymeric substance (EPS), as opposed to calcification.

Also, among these ancient metamorphosed terranes are two that are significantly better preserved, having generally undergone no greater than lower greenschist metamorphic grade. These two terranes are the Kaapvaal craton in South Africa and the East Pilbara craton in Australia, both dating back to ~3.5 Ga. Sedimentary successions within greenstone belts in these cratons contain a large variety of well-preserved traces of life, including those fossilized by mineral encapsulation and mummification, together with more generic, degraded organic matter. The fossilized microbial matter therein is well preserved because of the very early (almost immediate) encapsulation by silica, which, by virtue of widespread hydrothermal activity, was present at elevated concentrations in the already-Si-rich seas. The early Earth was hydrothermally very active, and microbial materials provided a suitable substrate for mineral precipitation. Thus, the cells, colonies, biofilms, mats, and generic degraded organic matter were rapidly fixed in a mineral matrix. This pervasive silicification affected not only the layers of sediments but also the underlying volcanic rocks (Hofmann 2011), thus further stabilizing the sediment pile. Finally, the terranes onto which the

sediments were deposited were themselves tectonically stabilized by an underlying keel (Van Kranendonk et al. 2015).

In the case of Mars, on the other hand, the small size of the planet (approximately half the diameter of the Earth) vastly reduces the potential temperatures and pressures encountered in typical burial metamorphism on Earth. As a result, Martian sediments of Noachian age (>3.8 Ga), that is, almost the time equivalent of the Early Archean, are far less metamorphosed than Archean sediments. An estimated metamorphic grade of prehnite-pumpellyite (the lowest grade of burial metamorphism) is common for surface rocks on Mars and is largely due to heat from hydrothermal activity generated by impacts (McSween et al. 2015). Noachian biosignatures, especially organic biosignatures, are thus likely to be little altered on Mars.

8.7.2 MINERAL ENCAPSULATION

During encapsulation by a mineral—a process defined as biologically influenced fossilization (Li et al. 2013)—ions in the immediate environment of the cell or other microbial products, such as extracellular polymeric substances that co-occur with the degraded products of dead organisms, are passively fixed (chelated) to functional groups, such as carboxyls, hydroxyls, and phosphoryls, in the organic material. Fixation can also occur by means of cation bridging, whereby the cation, for instance, Fe, acts as a link between the organic functional group and the fossilizing mineral. Initial fixation occurs immediately, within the first 24 hours of exposure to the fossilizing medium (Orange et al. 2009). After initial templating by the organic substrate, polymerization of the fossilizing mineral results in complete encapsulation of the organic substrate, cell, or EPS (Figure 8.7.1a and b). Interestingly, EPS is more readily “fossilizable” than most individual cells because of the greater abundance of organic molecules with functional groups (Westall et al. 2000). Cyanobacterial sheaths and Gram-positive bacteria are also rich in functional groups and, therefore, relatively more fossilizable than bacteria with a different cell wall construction and composition, such as Gram-negative bacteria and Archaea. For example, it has been shown that fossilization of the Gram-positive *Bacillus laterosporus* (with a peptidoglycan-rich outer cell envelope) by silica produced a thick, robust crust around the organism, compared with a thin, delicate crust around the Gram-negative *Pseudomonas fluorescens*, *P. vesicularis*, and *P. acidovorans*, suggesting that microorganisms with a peptidoglycan-rich cell wall were more likely to enter into the rock record than more delicately encrusted forms (Westall 1997).

Even among microorganisms with similar cell wall characteristics, there are differing reactions to mineral encapsulation. The thermophilic Archaea *Pyrococcus abyssi* has been fossilized by silica, with delicate reproduction of its cell wall structure (Figure 8.7.1a), whereas another thermophile from the Archaea, *Methanocaldococcus jannaschii*, lysed almost immediately in the presence of silica (Orange et al. 2009). No cellular remains of the latter were preserved, but the EPS with which it was associated (that also included the degraded

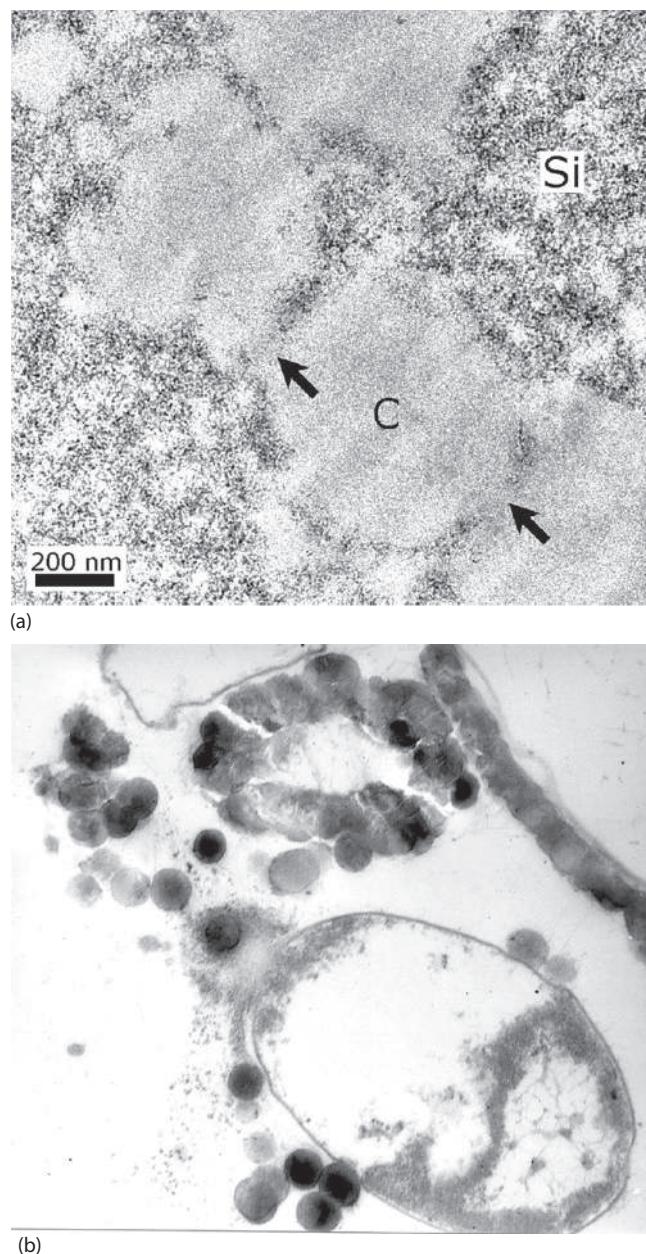

FIGURE 8.7.1 Examples of mineral-encapsulated microbial fossils. (a) *Pyrococcus abyssi*, a member of the domain Archaea, after 4 months of experimental fossilization in silica (Si), showing a chain of cells (C) whose cell walls have been silicified (and are still visible at the boundaries of juxtaposed cells (arrows). (Courtesy of F. Orange, 2008.) (b) Four months of experimental silicification of a cocktail of marine microorganisms from the domain bacteria showing the differential aspect of mineral encapsulation. The upper cell exhibits robust silica encapsulation in the form of spherical silica crystallites, while still conserving some degraded organic components inside. The lower cell has resisted encapsulation; almost all of its wall is clear of the silica spheroids; and the degraded remnants of its cytoplasm are preserved within the cell. Field of view = 3 μ m. (Courtesy of F. Westall, 1993.)

breakdown products of the lysed organisms) was faithfully encrusted by silica. Interestingly, it was shown that exposure of the *M. jannaschii* cells to metal cations prior to exposure to the fossilizing solution conferred sufficient stability of the cell wall as to permit the fossilization of this organism, with Fe^{3+} being more effective than Ca^{2+} , Pb^{2+} , Zn^{2+} , or Cu^{2+} (Orange et al. 2011).

A further artificial fossilization study—in the case of a Mars-analogue microorganism, the *Yersinia intermedia*

MASE-LG-1 strain, isolated from the basalt-hosted, cold, acidic Lake Graenavatn in Iceland—produced interesting results of relevance to fossilization in astrobiology (Gaboyer et al. 2017). *Yersinia intermedia* MASE-LG-1, a Proteobacterium, was stressed under a combination of Mars-like environmental conditions, namely desiccation, UV radiation, and exposure to perchlorates, and both stressed and unstressed cells were fossilized using silica or the calcium sulfate mineral gypsum. Both minerals have relevance for Mars

since silica is a typical product of hydrothermal fluids and was the agent of fossilization on the early Earth under conditions similar to those of the Noachian Mars, whereas sulfates are a common mineral phase on Mars from Hesperian time onward. In the experiment, prior environmental stress made no difference to the fossilization potential of *Yersinia*, but there was a difference in the rate and manner with which the two minerals fossilized the microorganism. While silica rapidly fixed to the cell wall and embedded cells in a thick, mineral precipitate, fossilization by gypsum occurred much more slowly. On the other hand, it appears that gypsum precipitation occurred both inside and outside the cells, while silica remained only on the outside of the cell. This is in contrast to earlier observations documenting the permeation of microbial cells by silica, often with silica precipitating around collapsed cytoplasm within the cells (Westall et al. 1995).

Fossilization or mineral encapsulation of microbial communities in the natural environment is a common phenomenon and can be considered a natural stress. Microorganisms can change the expression of their genome during mineralization, for example, silicification, to control membrane exchange (Iwai et al. 2010). Moreover, in artificial fossilization experiments, there are always some cells that appear to survive for significant periods of time. Approximately 10% of the cells could still be alive after several months of exposure to a silica solution (Gaboyer et al. 2017); however, this of course depends upon the rapidity of mineralization. There are thus strategies that microorganisms use to adapt to survive stressful situations. While the majority of cells do not survive beyond initial exposure to the agent of mineralization, some do.

8.7.2.3 THE ORGANIC COMPONENT

What happens to the organic matter of microorganisms that have been encapsulated by a mineral? In an aerobic environment, the organics are oxidized, leaving a mineral cast, but in an anaerobic environment, such as on the early Earth or Mars (and many euxinic environments on Earth today), the organic component would be preserved but undergo gradual degradation over time. Investigations of the first stages of degradation show a breakdown a rapid change in the composition of the organic components during fossilization. Changes in the composition and quantity of amino acids, monosaccharides, and fatty acids of silicified *M. jannaschii* (that lyses rapidly on exposure to silica; Orange et al. 2009) were monitored over a 1-year period (Figure 8.7.2) (Orange et al. 2012). Although lysed, the cell components of *M. jannaschii* formed part of the silicified EPS. After 1 year, of these components, the amino and fatty acids were relatively well preserved, while the monosaccharides broke down into smaller fragments, in the process, thus increasing the amino acid fraction. In this way, organic matter either directly associated with a fossilized cell or colonies/biofilms of cells can be preserved in degraded form, together with the degraded breakdown products of lysed cells trapped in a mineral cement.

The alteration and maturation of biogenic organic matter with time have been well-studied in the oil industry. Going

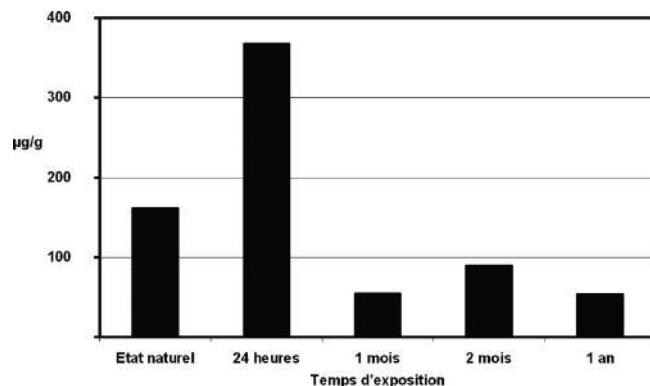

FIGURE 8.7.2 Change in the quantity of sugars present in a fossilized mixture of *Methanocaldococcus jannaschii* over the period of 1 year of fossilization with silica (the X-axis shows variation with time: temps d'exposition—exposure time [to silica], Etat naturel—natural state, 24 heures—24 hours, 1 mois—1 month, 2 mois—2 months, 1 an—1 year). The initial increase is due to the fact that *M. jannaschii* rapidly lyzes upon exposure to silica, with the degraded components joining the cellular extracellular polymeric substances (EPS). Continued fossilization leads to the breakdown of sugars with time.

through various breakdown stages related to thermal maturation and the effects of burial pressure or higher pressures related to tectonic transport into the crust and mantle, biogenic organic matter becomes increasing mature. The structure and composition of the molecules change with the loss of H, O, N, S, and functional groups, until they become refractory, aromatic molecules, generically termed kerogen. Finally, under high degrees of metamorphism, kerogen becomes graphite or even diamond, as surface sediments containing organic matter are transported into the mantle by plate tectonics (e.g., Nemchin et al. 2008). Despite the degree of degradation, it is still sometimes possible to distinguish a specific biomolecule precursor in ancient kerogen (which, in this case, is termed a biomarker). The oldest confirmed eukaryotic biomarker comes from 1.6-Ga-old Barney Creek sediments in Australia (Summons et al. 1988). Biomarker study is notoriously difficult because of the problem of contamination, not just during sampling and handling but also during transport of younger kerogen through porous horizons to older strata. This has been suggested to be the case with purported biomarkers, 2-methylhopanoids, documented in 2.7 Ga rocks (Brocks et al. 1999; Summons et al. 1999), that have been shown to originate from biomarker contaminants in mature hydrocarbons (French et al. 2015). Indeed, it is possible that no known Archean strata is within the window of thermal maturity for syngenetic biomarker preservation (French et al. 2015).

Although organic molecules can be preserved in deep time, they occur as highly degraded fragments of the former biological macromolecules. Nevertheless, certain biological characteristics can still be identified, such as isomeric, molecular weight, and isotopic fractionations of carbon, and used for determining the biogenic origin of the remnant carbon (Summons et al. 2011; Vago et al. 2017).

8.7.2.4 “MUMMIFIED” MICROORGANISMS

Some of the most spectacular microfossils of, especially, the Proterozoic era are acritarchs. These are organic-walled cells preserved without mineral encrustation, simply by entombment in fine-grained anaerobic sediments. It is clear that the kinds of cells that could be thus preserved need to have a robust outer cell envelope, and, in fact, acritarchs are believed to be the remains of protists, eukaryotic organisms (Knoll et al. 2006). They were deposited as a component of fine-grained sediments in anaerobic sedimentary basins. Of course, with time and geological processing, the organic components will degrade to become refractory molecules, as described earlier. While being relatively common in the Proterozoic Era, small acritarchs of as-yet-unknown affinity have also been described from 3.2 Ga sediments in the Barberton greenstone belt (Javaux et al. 2010, Figure 8.7.3), which we will revisit later in this chapter.

8.7.2.5 FOSSILIZED COMMUNITIES

Most of the artificial fossilization experiments described earlier concern single strains of microbes; however, in the natural environment, a wide range of microbes coexist in communities, either free floating in the water column or attached to a substrate. Experimental silicification of a natural cocktail of marine microorganisms has documented that they exhibit a wide range of responses to fossilization that corroborate some of the experiments described earlier: certain spirochetes resisted fossilization for many months, some microorganisms exhibited delicate silica crusts, while others were thickly encrusted (Westall et al. 1995). The differential responses of microorganisms to fossilization is important, because it tells

us that what we find in the rock record is only a fraction of the original communities. What is preserved in the rock record, whether it be mineral casts alone or morphologically preserved organisms complete with their degraded and preserved organic components, can be considered a bulk signature in terms of analysis in a rock.

Another aspect of the fossilization of microbial communities is that the composition of the communities evolves with time. Taking a modern phototrophic microbial mat as an example, while the primary producers are phototrophs (primarily oxygenic but also anoxygenic photosynthesizers), the mat is host to a cohort of different species that occupy microscopic ecological niches and whose niche can change on a diurnal timescale, from day to night (Bolhuis et al. 2014). Phototrophic mats can be fossilized, and stromatolites and microbial mats are the striking evidence of this. However, cellular microfossils or the traces of their former presence (palimpsest microstructures) are seldom preserved, while the mats are often characterized as layers of trapped detrital particles and bio-precipitated minerals. In rare cases, organic matter associated with the mats (or biofilms) can be investigated, but this organic matter must be appraised as a degraded bulk sample of all the microbial components of the original mat or biofilm—phototrophs and heterotrophs—and cannot be related back to one specific type of microorganism.

8.7.2.6 FOSSILIZED VIRUSES

It has been estimated that there are far more viral particles on Earth than bacterial cells, and viruses are considered to be as ancient as bacteria (Moelling 2017). Since bacteria are naturally fossilized in the environment, it is not inconceivable that viruses would also be fossilized in a similar fashion. Indeed, in the natural environment, the iron mineralization of viruses has been observed in the acid waters of Rio Tinto, Spain (Kyle et al. 2008). One of the first fossilization experiments on viruses showed precipitation of silica on the bacteriophage T4 after a few days in simulated hot spring conditions (Laidler and Stedman 2010). Furthermore, experimental silicification of viruses from extremophilic Archaea *Sulfolobus islandicus* rod-shaped virus 2 (SIRV2), *Thermococcus prieurii* virus 1 (TPV1), and *Pyrococcus abyssi* virus 1 (PAV1) over a period of several months showed that silica precipitation on DNA proteins and some cell envelopes occurred in a species-dependent manner (Orange et al. 2011); however, the resultant fossils did not reliably reproduce any particularly identifiable morphology. Moreover, the silicified parts were extremely small. It is therefore likely that fossil viruses would be very difficult to identify, even though they may be as common as fossil bacteria in the rock record.

The cell wall was sufficiently robust to resist mechanical breakdown in these sediments. Scale bar = 50 μm . (Reproduced from Javaux, E.J. et al., *Nature*, 463, 934–938, 2010. With permission.)

8.7.2.7 OTHER BIOSIGNATURES

A priori it is not expected that processes as ephemeral as microbial metabolism could be preserved. However, the effects of microbial metabolic activities on their

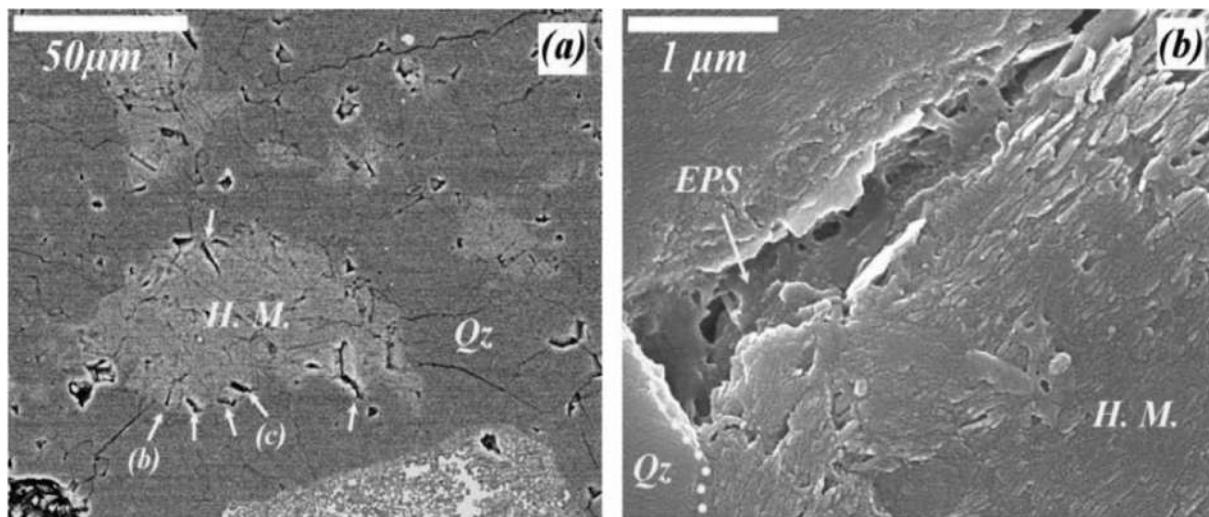

FIGURE 8.7.4 Fossilized evidence of microbial corrosion. (a) Silicified, volcanic particle (light gray) altered to hydromuscovite (H.M.), embedded within a lithifying silica cement (Qz). The arrows point to tunnels within the volcanic particle (backscattered scanning electron micrograph). (b) Close-up view of a corrosion tunnel tapering from the outer edge of the grain inward. Note the infilling of silicified amorphous material interpreted as extracellular polymeric substances (EPS). Qz: quartz; H.M.: hydromuscovite. immediate surroundings can be encapsulated into the rock record. For example, enzymes emanating from chemolithotrophs can corrode the underlying substrate to liberate elements essential for life (Figure 8.7.4). Microbial corrosion of metals is of particular interest to ships and the oil industry, costing industry large sums. Microorganisms using oxidation or reduction of sulfur play a large role in these processes (Iverson 1987). Microorganisms are also implicated in the weathering of silicate minerals on the surface and in the upper crust. The mechanisms of mineral corrosion include physical disaggregation and the effects of inorganic and organic acids, such as oxalate, as well as siderophores and proteins (Barker et al. 1997).

Minerals can be precipitated either directly by microorganisms or indirectly because of the presence of biological organic matter. Magnetite (Fe_3O_4), for example, can be indirectly precipitated extracellularly by biologically mediated mineralization (Bazylinski and Moskowitz 1997), while greigite (Fe_3S_4) can be formed through biologically controlled mineralization, that is, specifically synthesized and deposited in a particular location in the cell. Another example of relevance to astrobiology and, in particular, biosignatures, is the precipitation of carbonate. Biologically controlled precipitation of carbonate is known from hard-shelled mollusks, but biologically (in this case, microbially) mediated carbonate precipitation can lead to the encapsulation of microbial cells or the precipitation of calcium carbonate crystals within microbial EPS. Precambrian stromatolites were largely formed through the calcification of the EPS associated with the mat layers formed by phototrophic microorganisms (e.g., Pentecost 1990; Hofmann et al. 1999).

8.7.3 IMPLICATIONS FOR THE SEARCH FOR FOSSIL TRACES OF LIFE ON THE EARLY EARTH

8.7.3.1 THE EARLY MICROBIAL ENVIRONMENT

Microorganisms are vital components of many surface and subsurface environments, and the study of their traces in deep time needs, accordingly, to take into account the paleoenvironmental and geological characteristics of the biome that they inhabited. Indeed, understanding environmental context is an essential part of interpretation of fossilized traces of life. Consequently, study of early life requires an understanding of the regional and local environments prevalent on the early Earth. This has been described in greater detail in other works (Nisbet and Sleep 2001; Arndt and Nisbet 2012; Pearce et al. 2018; Westall et al. 2018), but it is useful to briefly review the salient characteristics here. The early Earth was a truly alien world: an anoxic planet characterized by high heat flow from the mantle—the result of some combination of the latent heat of accretion, the decay of now-extinct radioactive nucleides, and the unique (proto)tectonic system—that resulted in vigorous volcanic activity and pervasive hydrothermal circulation within the crust (Westall et al. 2018). pH values in the early oceans were likely variable: while the ocean would have been largely acidic as a result of its interaction with a volcanically derived CO_2 atmosphere, smaller-scale alkaline conditions occurred in sediment pore spaces due to alteration of (ultra) mafic minerals and in locations where alkaline hydrothermal fluids effused at the surface. In some oceanographic regimes, it is likewise possible that the alteration of mafic strata and sediments would have allowed the precipitation of veneers of carbonate sediments, as espoused in the “soda lake” model

(Kempe and Degens 1985). As noted earlier, only a very small portion of the sedimentary record of the early Earth has been preserved, and this represents almost exclusively shallow water basins and the platformal surrounds of sub-aerial volcanic systems. The CO₂-rich atmosphere and lack of ozone imply that UV radiation flux to the surface of the Earth was high, up to 1000 W/m² (DNA weighted, cf. Cockell and Raven 2004) in the worst-case scenario and ~54 W/m² in more clement cases, compared with 1 W/m² at present. Thus, at a global scale, the early Earth can be considered an extreme environment, and, necessarily, its microbial inhabitants were extremophiles. Infinitely small amounts of oxygen were produced by abiotic processes, this oxygen being poison to strict anaerobes.

While the earlier brief description may suggest that the early Earth was a homogeneously hostile world, that description pertains to the global environment. At the microbial scale, that is, in the sediments and on the sediment/rock surfaces, around hydrothermal vents and springs, and, possibly, even in the water column, there seems to have lived a wide variety of thermophiles, acidophiles, alkaliphiles, halophiles, and other extremophilic and extremotolerant microorganisms. Although only a small fraction of the microbial community in any habitat is preserved in the rock record, and despite the many effects of degradation during geological processing, the record of early life is nonetheless surprisingly rich. This is partly due to the lack of reworking of sediments by bioturbation prior to the Cambrian Explosion of animal life (Brasier 2009). More significantly, however, this biotic richness is due to the fact that most well-preserved Archean sediments were very rapidly silicified, silica being one of the most stable minerals at the surface of the Earth. Once silicified, it is difficult to chemically alter the lithified rock; for this reason, cherts provide high-fidelity archives of geochemistry that can endure over billions of years (van Zuilen et al. 2007; Ledevin et al. 2014; Gourcerol et al. 2016). Silica is certainly the *nec plus ultra* mineral for microbial fossilization. There is, nonetheless, a slight shortcoming in silicification and that is the dilution factor. The sometimes-significant dilution of the organic and elemental components of biosignatures mean that, while well-preserved, quite sophisticated methods and instrumentation are needed for their characterization.

Although a wide variety of minerals are known to encapsulate microbial matter, including ice, halite, sulfates, carbonates, phyllosilicates, silica, hematite, and phosphates (Summons et al. 2011), certain minerals are evidently metastable under changing conditions and alter over geological time. Ice is an excellent preserver of organic matter—as documented by the famous mummified fossil Ötzi, preserved in an alpine glacier (Müller et al. 2003), or the mammoths preserved in Siberian permafrost—but, unless on a cold or icy planet or satellite, such as Mars, Enceladus, or Europa, ice is not long-lasting. Salt has been used through historical (and possibly prehistorical) time to preserve foodstuffs, but halite is metastable and hygroscopic. It is subject to contamination, as demonstrated by the debate surrounding the discovery of bacteria in 250-Ma-old salt deposits (Vreeland et al. 2000),

and now is considered to be the result of contamination (Graur and Pupko 2001). Notwithstanding, a recent review concluded that halite can be stable on geological timescales (hundreds of My) and could, with reasonable fidelity, conserve microorganisms (Jaakkola et al. 2016). In terms of deep geological time and the search for traces of life from the early Earth, halite as such is not preserved, but halide crystals coating a fossilized microbial biofilm, both impregnated and pseudomorphed by hydrothermal silica, have been described in 3.33 Ga sediments from the Barberton greenstone belt in South Africa (Westall et al. 2006a, 2011a). With respect to sulfates, it has been claimed that DNA fragments were recovered from fossilized cyanobacteria in Miocene-age gypsum (Panieri et al. 2010), although gene sequencing from ancient strata is fraught with contamination issues. Irrespective of whether the identified DNA fragments are syngenetic with the gypsum, the morphological remains of the cyanobacteria are certainly preserved and authentic. As with halite, gypsum, as such, has not survived into deep time; however, silica-pseudomorphed gypsum has been noted in ancient rocks, for example, associated with ancient biofilms (Westall et al. 2006a).

8.7.3.2 CASE STUDIES FROM EARLY LIFE ON EARTH

In what follows, we present a small selection of some cases of exceptional preservation of microbial biosignatures from the early Earth, emphasizing the positive and negative aspects of their processes of fossilization on the eventual biosignature, and how the record of natural fossilization gives credence to the experimental approaches and findings of fossilization studies outlined earlier. The interested reader could also seek more thorough overviews of the full range of biosignatures from the ancient Earth (e.g., Wacey 2009; Westall and Cavalazzi 2011) and their relationships with the environment of early life (Nisbet and Sleep 2001; Westall 2016; Pearce et al. 2018).

Carbonates: Carbonates are common preservers of microbial material, going back into deep time. Although also often pseudomorphed by silica, carbonate in the form of dolomite occurs associated with phototrophic microbial structures in Proterozoic and Early Archean rocks (Lowe 1980; Beukes and Lowe 1989; Hofmann et al. 1999; Allwood et al. 2006). The most iconic Archean stromatolites are certainly those of the Strelley Pool Formation of the East Pilbara terrane ([Figure 8.7.5](#)), from which well-described, morphologically varied stromatolites of almost universally accepted biological significance (Hofmann et al. 1999; Van Kranendonk et al. 2003; Allwood et al. 2006, 2007; Wacey 2010) are known from at least two major localities in the East Strelley greenstone belt (the “Trendall locality” and “McPhee Creek”—the latter formerly “Strelley West”—as reported in the literature) and from the Panorama greenstone belt. REE+Y signals from well-preserved stromatoidal carbonates (Van Kranendonk

FIGURE 8.7.5 Cross-section view of silicified stromatolites from the Trendall locality of the 3.43 Ga Strelley Pool Chert, Western Australia. Fieldwork hammer (~30 cm) for scale. (Courtesy of F. Westall, 2000.)

et al. 2003), together with the multiple morphologies of stromatolite-like structures present in a single carbonate unit (Allwood et al. 2006, 2007; Wacey 2010), are highly persuasive of a biogenic origin for these structures and of a plausible geochemical environment for the development of a stromatolitic ecosystem. In addition to biologically driven carbonate (now dolomite) sedimentation during stromatolite growth, chemical precipitation certainly played a significant role in the preservation of these stromatolites, given the widespread evaporite crystal pseudomorphs in intimate association with stromatolitic laminae, which may have formed mineral crusts, aiding the preservation of the laminae (Allwood et al. 2007). The inclusion of alloigenic (detrital) and authigenic mineral phases within laminations also suggests that the microbial biostabilization helped to preserve the original organo-sedimentary structure (Allwood et al. 2007). This “trapping and binding” behavior is a widely acknowledged mechanism by which otherwise-fragile organo-sedimentary constructs may leave visible traces in the fossil record (Noffke et al. 2006, 2013; Noffke 2010; Hickman-Lewis et al. 2016, 2018). The fossilization of stromatolites of biogenic origin in carbonates of the Strelley Pool Formation can be conclusively summed up as a multi-mechanism procedure, involving biome-diated chemical precipitation and mechanical sedimentation in an environment where the propensity for the precipitation of carbonate and associated evaporite phases was enhanced. For this reason, comparison with younger forms (e.g., *Conophyton*, *Jacutophyton*, and *Thyssagates*, dependent upon morphology) in better-preserved Proterozoic and Phanerozoic sediments has enabled and justified a deeper understanding of the development and fossilization of organo-sedimentary structures such as these.

Silica: As noted earlier, silica presents an unprecedented agent of preservation when considering biosignatures from deep time. The elevated Si concentrations of ocean water throughout the Precambrian (Siever 1992; Maliva et al. 2005) enhanced the predisposition both to siliceous chemical sedimentation and to the incorporation of silica within sediments to chertify them rapidly, no doubt, in large part, due to the considerably elevated influx of Si-rich hydrothermal waters into Precambrian seas (Westall et al. 2018). Even the carbonate-preserved organo-sedimentary structures of the East Strelley greenstone belt were preserved due to synsedimentary or later silicification that pseudomorphed the carbonate mineralogy (Allwood et al. 2007; Wacey 2010). In deep time, however, chertified sediments are the typical repository for biosignatures. The following three examples from the Paleoarchean showcase the superb preservation that can be afforded by silica and explain the key mechanistic aspects ensuring this preservation:

First, within the 3.22 Ga Moodies Group, a diverse ecosystem has been reported that likely occupied multiple trophic levels. In now-silica-filled cavities beneath kerogenous microbial mat laminae, well-preserved chains of moulds with cell-like dimensions, morphologies, and habits have been reported (Homann et al. 2016; Figure 8.7.6). Transverse cross-sections of these features show tubular morphologies encapsulated by silica and are testament to the preservational potential of silica at even the micron scale. Second, in the 3.33 Ga Kromberg Formation, an exceptionally preserved microbial biofilm coated with a thin layer of silica is inferred to have been preserved by Si-rich fluids emanating from a proximal hydrothermal system (Westall et al. 2011a). Synchrotron Micro X-ray adsorption near edge studies (μ XANES) mapping and spot analyses demonstrated concentrations of sulfur in kerogenous material, within which the S-bearing molecule thiophene was identified. Together with preserved nanoscale domains of aragonite crystallites that are syngenetic with the formation of the biofilm, it was argued that such a suite of high-resolution geochemical data—faithfully preserved over long geological timescales—supports an originally diverse consortium of mat-building organisms, including sulfate-reducing bacteria. Third, silicified microclastic cherts from the 3.46 Ga stratiform “Apex chert” preserve low-relief, wrinkle-like structures that, when imaged by high-resolution three-dimensional X-ray tomographic techniques, depict preserved filament-like structures on the micron scale (Hickman-Lewis et al. 2017). These structures are directly comparable to the filament-like constructs, indicating the former presence of bacteria in both modern and fossil microbial mats (e.g., Noffke 2010), and were

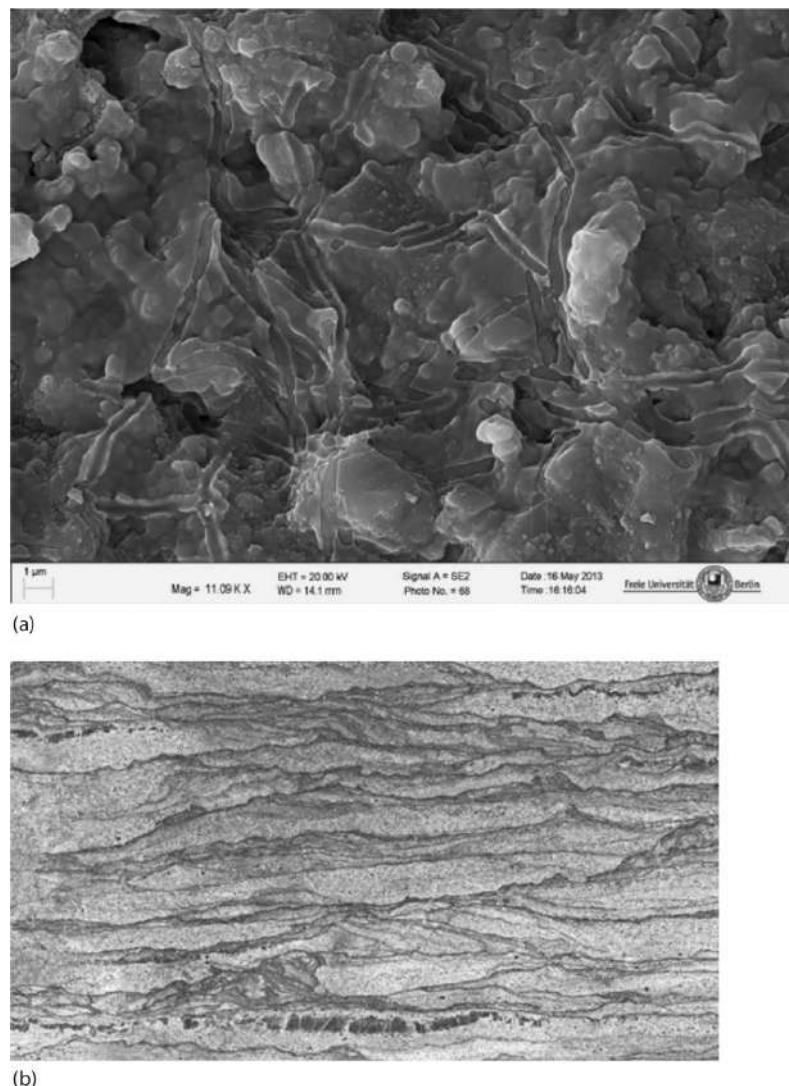

FIGURE 8.7.6 Silicified microscopic and macroscopic biosignatures from the 3.22 Ga Moodies Group clastic sediments, Barberton greenstone belt, South Africa. (a) Moulds of chains of rod-shaped microorganisms in the silica infill of a subaerial vadose cavity in the Moodies Group sediments. Here, silica has encapsulated the organisms whose organic remains were subsequently completely degraded. (b) Slab of rock cut transversally to the sediment bedding planes, in which the microbial mat-stabilized sedimentary surfaces are evidenced by the dark (organic-rich), wrinkly layering. Field of view = ~25 cm. (Reproduced from Homann, M. et al., *Geology*, 44, 51–54, 2016. With permission.)

therefore presented as a type of MISS within laminae that pass many other necessary morphological biogenicity criteria, again demonstrating the preservation potentials of silica at the finest scales.

The cavities in which the Moodies Group microfossils occur resemble gas-filled, fenestral hollows in tidal environments, which, forming through some combination of tidally driven hydraulic pumping and biologically driven gas accumulation (Homann et al. 2016), were certainly dynamic environments on short timescales. That vestiges of their microbial inhabitants are conserved is therefore a clear indication of the rapidity of the silicification in these coelobiontic microbiomes. Microbial remains from the Kromberg Formation, exhibiting both the volume preservation of a biofilm and syngenetic

metastable mineral phases (e.g., aragonite) within, support that silicification was initiated rapidly while the biofilm was still alive and metabolizing (Westall et al. 2011a). The ancient MISS-like structures in the stratiform “Apex chert” being preserved in volume and including turgid, three-dimensional fabric elements (Hickman-Lewis et al. 2017) strongly suggest that the silicification of this putative microbial system occurred penecontemporaneously with its growth and that particularly rapid silicification can indeed circumvent the morphological alteration caused to biosignatures by compression during diagenetic processes. These three examples of exceptional biosignature preservation demonstrate the fine-scale fidelity of preservation afforded thereby ensuring rapid entry of morphological and

geochemical biosignatures into the fossil record, and consequently the status of microcrystalline silica as an exceptional mineralization medium for the most ancient rock record.

This siliceous entombment is similarly beautifully exhibited by the microfossil communities of the Kitty's Gap Chert. Coccoidal microfossils occurring in monolayer coatings surrounding volcanic particles (Figure 8.7.7), together with microbial corrosion features (Figure 8.7.4), have been well-documented in terms of their morphological and geochemical characteristics (Westall et al. 2006b, 2011b; Foucher et al. 2010). The preservation of these coccoidal microfossils is such that they have been captured in multiple life modes: cell division, cell lysis, and at presumably multiple growth stages (Westall et al. 2011b). Further high-resolution scanning electron microscopy (SEM) imaging of corroded volcanic clasts has shown tunnels approximately 0.5–1 µm in diameter and up to ~20 µm in length that taper inward into their host clasts and are filled with a silicified amorphous material, interpreted as extracellular polymeric substance (Foucher et al. 2010). Fossils such as these, preserved from oligotrophic conditions, provide apposite analogue organisms for consideration in the search for life on other celestial bodies, where nutrient-rich conditions may not have prevailed. We will return to this idea later in the chapter.

Phosphate: A further means of high-fidelity preservation of organic fossils is cryptocrystalline phosphate,

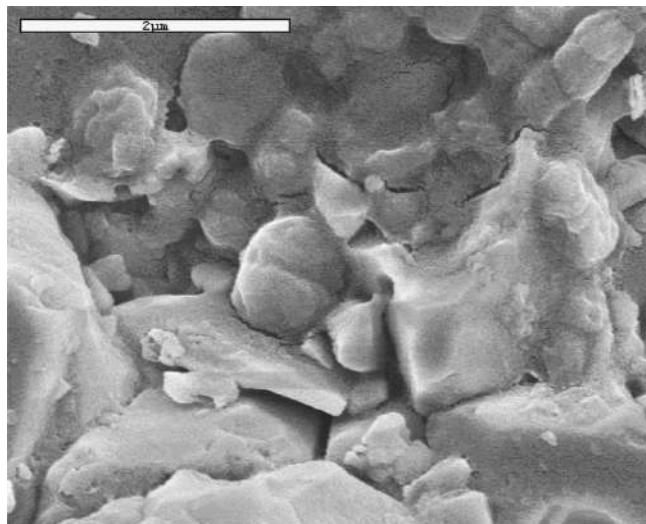

FIGURE 8.7.7 Variable preservation of a colony of silicified microbial cells from the 3.446 Ga Kitty's Gap Chert, Western Australia. The large cell in the center of the image was undergoing cell division at the time of fossilization, while those above it were already lysed and partially degraded at the moment of fossilization. The crystals surrounding and embedding the cells are now quartz but would originally have been amorphous, hydrothermal silica gel. (Courtesy of F. Westall, 2002.)

which is, as with chert, a means of preserving fossils in three dimensions. Within the scope of the current study—the harmonization between our understanding of the fossilization processes on the early Earth of relevance to potentially fossilized organisms on Mars—there is regrettably little judicial sense to discussing phosphatization. Phosphate-preserved microfossils on Earth date back no further than around 1 Ga (the lacustrine Torridon biota of Scotland), by which time any planetary (and likely microbial) similarity between Earth and Mars had necessarily ceased to exist. The preserved organisms are eukaryotic and parts of a broad and diverse ecosystem, the likes of which would not be predicted for Mars. Furthermore, P-rich deposits on Mars are often linked more to magmatic origins than to sedimentary origins and therefore not with environments clement to life. The interested reader may wish to read further into phosphate fossilization on Earth, for which a wealth of literature exists (e.g., Wilby and Briggs 1997; Strother et al. 2011; Strother and Wellman 2016).

“Mummified” fossils: Apart from the fine-scale preservation afforded by silica and phosphate, one instance of interpreted “mummified” biogenic features with morphological preservation at the nano-scale has been recorded from the Archean in the form of acritarchs in the Moodies Group (Javaux et al. 2010; Figure 8.7.3). These acritarchs are preserved in layered, laminated, silicified shales, and siltstones, which entombed and compressed them parallel to bedding planes. The highly wrinkled appearance of the preserved cell wall-like structures has been attributed to taphonomic degradation and collapse of the carbonaceous material through loss of turgor pressure (Javaux et al. 2010).

Sulfides: It is worthwhile concluding this section by examining two further, but less well-recognized, preservational media from the ancient rock record. In traverses of environmental settings conducive to the preservation of microbial biosignatures, deep-sea, black smoker settings and pillow-basalt hosted fluid-rock systems have frequently been noted as possible biosignature-rich deposits (Brasier et al. 2011; Westall and Cavalazzi 2011) but are hindered by their rare occurrence in the rock record and the simplicity and ambiguity of the biosignatures preserved therein.

Only one convincing example of biosignatures in a black smoker-type deposit is reported from the Archean rock record: the Sulphur Springs volcanogenic massive sulfide ore deposit (Rasmussen 2000). Although ore-forming fluids in this locality may have reached 300°C (beyond the known thermotolerant capacities of life), lower temperatures would have characterized the distal locations from which the putative microfossils were found. Pyritic filaments of up to 300 µm length and 0.5–2 µm constant

diameter occur in early silica generations; are of unbranched morphology, intertwine and curve; and are densely distributed in the rock. These characters are consistent with a biological origin. A fossilization model was proposed: filaments were engulfed by hydrothermal silica from proximal vent systems, after which increasing fluid temperatures due to a nearby intruding granitic body led to the replacement of the silica by pyrite (Rasmussen 2000). Unfortunately, this preservational model is somewhat incomplete in terms of geochemistry, and, to our knowledge, no experimental replication of the proposed model has been conducted. Furthermore, the abiogenic null hypothesis that these features are instead abiotic mineral growths has not been disproven. Despite later recollection of material from Sulphur Springs and advocacy for the biologically promising character of these putative microfossils (Wacey 2009; Brasier et al. 2011), no further data has been presented, and thus, the fossilization and preservational processes of bacteria in black smoker-type systems remain understudied.

Microbial corrosion: Finally, in a suite of studies, microbial trace fossils have been proposed from the rims of pillow basalts in the Archean rock records of South Africa and Western Australia (Furnes et al. 2004, 2007; Banerjee et al. 2006, 2010). These microtubular structures, of up to 10 µm in diameter and 200 µm in length, bear resemblance to modern microbial etching features in seafloor basalts, for example, in terms of their irregular growth patterns, carbon isotope fractionations, and petrological contexts. The ancient examples are preserved by titanite, which is often a metamorphic phase; however, enrichments in carbon, nitrogen, and phosphorus have also been reported in the microtubules themselves. The titanite preservation has been ascribed to water cycling through cavities, enhancing the growth and excretion processes of the chasmolithic inhabitants while simultaneously replacing and sealing the tubules (Furnes et al. 2007). Although modern etching structures in basalt and hyaloclastite rims are doubtless of biological origin, a set of geochemical-geochronological studies has cast doubt on the syn-genicity of the ancient examples (e.g., Grosch and McLoughlin 2014, 2015). In the absence of detailed experimental work to understand the preservation of these kinds of biosignatures, these structures remain enigmatic, and their relevance to the preservation of biotic processes on the early Earth remains unconfirmed.

In contrast, two recent studies have documented biocorrosion in the ancient volcanic sediments. The Kitty's Gap Chert example mentioned earlier reveals tunnels running from the rims of clasts inward and infilled with what is interpreted to be silicified EPS, and this

is a sample within which silicified microbial colonies have been observed on the surfaces of the volcanic particles (Foucher et al. 2010). Another recent study of tubular structures in volcanic glass showed the co-occurrence of organic material and titanium (Wacey et al., 2017), i.e. the kind of signature needed in the Furnes et al. (2007) study.

Implications of early biosignature study for the search for life on Mars: In this section, we have attempted to outline, through several relevant examples, the links between processes known from artificial fossilization experiments and the representation of these reactions in the ancient fossil record. Despite great ages of more than 3 Ga in some cases, the appearance and nature of preservation of some exceptional biosignatures corroborate experimental procedures. This correlative understanding is important for understanding the links between organisms, their environments, and their diagenesis and taphonomy. In turn, the recognition of these processes is of fundamental importance to assessing the biogenicity of potentially controversial microfossils and microbial constructs. The relevance of the understanding of early life to astrobiology is axiomatic: Archean life records the early, and perhaps initial, stages of evolution following the emergence of life on Earth and preserves a record of biotas and their paleoenvironments, which needs to be interpreted through use of multiple appropriate techniques.

Before advancing to the discussion of the search for life on Mars, one final consideration should be raised in terms of biosignature detection. Although we have herein recapitulated a series of widely accepted, well-described, and comprehensively understood biosignatures for early life, these represent “exceptions,” not the “rule.” Biosignatures from the Archean provide both a paleontological analogue for potential Martian life and a philosophical analogue, which incorporates aspects of both epistemology and semiotics, and thus, the scrutiny that we apply to Archean biosignatures should provide a baseline for the scrutiny applied to putative Martian biosignatures. Many Early Archean biosignatures have been proposed and analyzed on weak geological and geochemical foundations, and yet, many more have been misinterpreted, despite having been subjected to the efforts of the finest terrestrial laboratories, by virtue of their enigmatic, ambiguous, and obfuscated geological-geochemical signals. The assessment of biosignatures *in situ* on Mars will present new, and even greater, challenges. The lessons from the Allan Hills 84001 meteorite (McKay et al. 1996), in which Martian bacterial fossils were proposed and subsequently disproven, underline the challenges involved in assessing the biosignatures, even in terrestrial laboratories, with the most sophisticated instrumentation. Some researchers have already

started to postulate comparisons between sedimentary fabrics on Earth and Mars—strata resembling microbially induced sedimentary structures in the Gillespie Lake Member (Noffke 2015) and digitate structures resembling biogenic hot spring deposits in Columbia Hills (Ruff and Farmer 2016)—and thus the lessons of caution, consideration, multidisciplinary consensus, correlative multi-scalar approaches, and conscious, prudent circumspection in biosignature interpretation have never been more important.

8.7.4 ASTROBIOLOGY MISSIONS TO MARS

8.7.4.1 HABITABILITY ON MARS

Water on Mars: Understanding early life on Earth, including the environmental parameters of its habitat, the nature of early life, its preservation, and, finally, the methods used to detect it, is an essential aid to the search for life on Mars. Unlike Earth, Mars has not been permanently habitable, and there is considerable question as to the degree of habitability on the planet throughout its geological history. There is evidence for a significant amount of water on the surface of

the planet during its early history (Figure 8.7.8) but not a global ocean, while the later history of Mars is characterized by an overall gradual decrease in habitability, punctuated by sporadic and localized peaks in aqueous activity during the Hesperian (e.g., the catastrophic outflow channels), before reaching essentially dry desert conditions from the Late Hesperian through the Amazonian (Carr and Head 2010). The habitability of Mars has thus changed drastically through geological time, however. Mars is half the size of the Earth and, on a global scale, would have lost its habitable conditions at the surface at around 3.8 Ga owing to the demise of the internal dynamo that created a radiation shield protecting the atmosphere and volatiles from erosion by the solar wind and specific solar events (Jakosky et al. 2015). The degradation in habitable conditions on Mars was further punctuated by events with more local effects, such as the large-scale volcanism associated with the growth of the Tharsis Massif, impacts and catastrophic outflow events, and potential tsunami.

At the present day, much water is believed to reside on Mars in a thick subsurface cryosphere, beneath which liquid water may be trapped. Breaching of

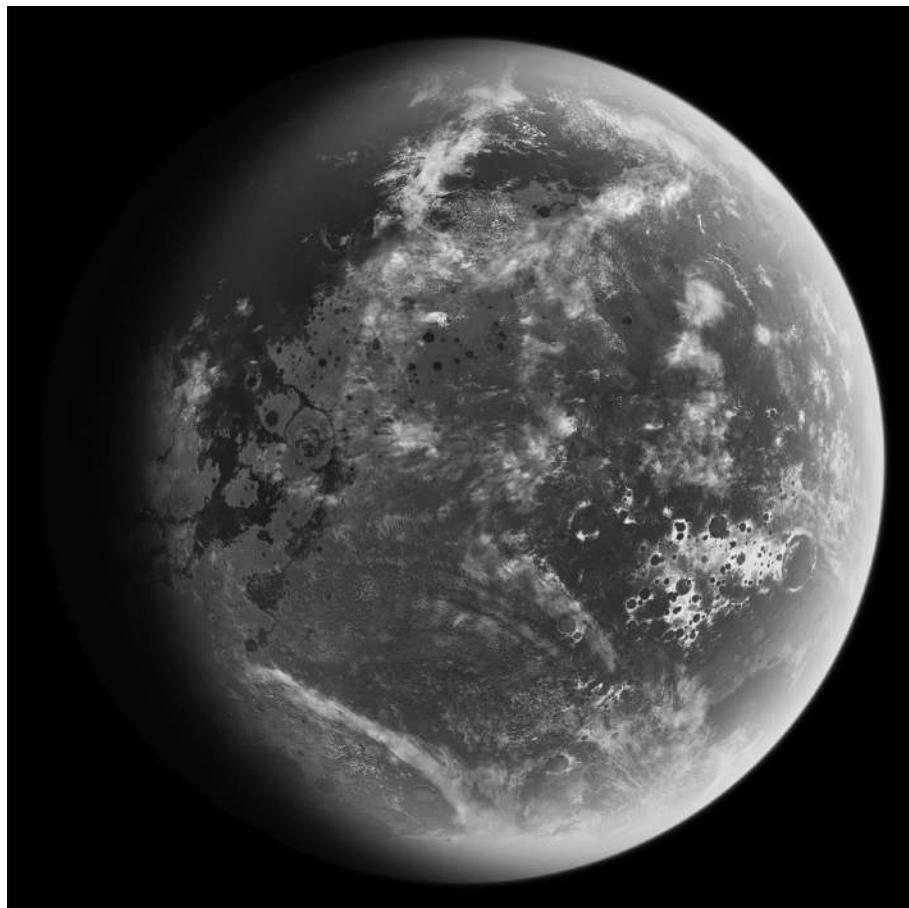

FIGURE 8.7.8 Artist's depiction of early Mars, with water at the surface. (Courtesy of Ittiz, Own work, <https://commons.wikimedia.org/w/index.php?curid=7861829>.)

the cryosphere, for example, by impacts, could lead to the catastrophic outflow events that characterized the Hesperian (Carr and Head 2010). There have also been many theories concerning the existence of major ocean in the Northern Plains (e.g., Clifford and Parker 2001), as well as large bodies of water accumulating in topographic lows, such as the giant Hellas impact basin; however, debate concerns the timing of their existence. During the Noachian, when atmospheric pressure was higher, the surface water inventory was likely to have been higher (Figure 8.7.8), whereas later, during the Hesperian, catastrophic outflows were perhaps more likely. Even after these events, as the planet was becoming increasingly dry, Amazonian Mars saw occasional liquid water at the surface. Even today, runnels formed by possibly briny water appear on south-facing slopes at the equator (recurring slope lineae, McEwen et al. 2015) and layers of water ice mixed with CO₂ ice occur at the poles (Carr and Head 2010; Orosei et al. 2018). Unlike the Earth, Mars undergoes large changes in obliquity because it lacks the stabilizing influence of a large moon. Thus, the higher latitudes can be periodically warmed by sunlight, and frozen subsurface water can be released.

The evidence for water on Mars is found not only in the abundant geomorphological features, for example, rivers, run-off channels, catastrophic channels, lakes, deltas feeding into lakes, and possibly even oceans and seas, but also in abundant mineralogical evidence. A recent review (Bishop et al. 2018) summarized the evidence for surface aqueous alteration of mostly volcanic lithologies, as well as subsurface alteration by hydrothermal solutions. Distinct clay facies suggest, for instance, that the thick and widespread sequences of Fe/Mg clays overlain by Al species with Si in a number of locations on Mars, for example, Mawrth Vallis, were the result of an event or events, such as an impact, that led to increased water vapor in the atmosphere and slight, regional warming culminating in intense chemical weathering. The *in situ* measurements by the Mars Exploration Rovers (MER) and Curiosity rover have also detected evidence for hydrous minerals (Grotzinger et al. 2005, 2014). In addition, orbital radar mapping of the planet has documented ice (in the form of hydrogen detection) (Plaut et al. 2000), whereas groundwater ice was detected by the Phoenix lander near the northern ice cap.

The history of Mars is therefore vastly different to that of the permanently habitable Earth. Nevertheless, although there are significant differences in the global-scale habitability of the two planets throughout geological time to the present day, on a microbial scale, the environment of early Mars (pre-Noachian, Noachian, and early Hesperian, i.e., >~3.6 Ga) can be considered to have been somewhat similar to that of the early Earth (Westall et al. 2013, 2015a, b).

The presence of liquid water at various times during the history of Mars, even up to the present day, means that it could have been potentially habitable, if the presence of water was co-located with a source of carbon and a source of energy. Even the small and ephemeral recurring slope lineae are considered to be potentially habitable for the purposes of planetary protection (Rettberg et al. 2016). This variation in habitability in terms of spatial and temporal scales has been termed “punctuated habitability” (Westall et al. 2015b).

An important consideration to keep in mind with respect to the concept of habitability is that its definition changes depending upon whether one is considering the emergence of life, the development of already-established and viable cells, or situations in which life can simply survive (but not flourish), that is, either in a state of dormancy or life when growing very slowly. In addition, another valid concept for Mars is that of uninhabited habitats (Cockell et al. 2012), which refer to environments that hosted the requirements for life (carbon, water, energy, and other essential elements) but remained uninhabited because viable microorganisms were unable to reach that habitat. For example, the recurring slope lineae on Mars today are most likely uninhabited habitats.

Habitability and the emergence of life: With respect to the appearance or origin of life, we have no idea of the length of time necessary to go from abiotic ingredients to the first living species on Earth. Moreover, we also do not know exactly where the first cells could have emerged. The various scenarios proposed, from hydrothermal vents, pumice rafts, coastal volcanic splash pools, and hydrothermally flushed sediments to subaerial springs, have been recently reviewed, with the conclusion that the interface between hot to warm hydrothermal fluids and reactive volcanic minerals and rock fragments would have been a favorable location for prebiotic chemical reactions, leading to the emergence of the first cells (Westall et al. 2018). Importantly, the role of mineral surfaces in prebiotic chemistry has become increasingly appreciated (e.g., Hazen and Sverjensky 2010; Dass et al. 2016; Westall et al. 2018). Mineral surfaces can concentrate organic molecules and contribute to their structural organization and configuration as well as to their confinement (Dass et al. 2018). It is thought that the prebiotic chemical reactions that culminated in the first living organisms must have occurred over short timescales, otherwise the reactions may reverse and the increasing complexification of the molecules may become inviable. The definition of “short timescales” in that context has yet to be extensively discussed; on the early, largely oceanic Earth, upon which the ingredients for life were, compared with Mars, unlimited, the question could be considered academic. Various estimates have been proposed, from tens or hundreds of thousands of years

to even a several million years (Westall et al. 2018). On Mars, however, this question is of critical importance because the emergence of life depends upon whether a particular environment hosted the ingredients of life for sufficient time to allow prebiotic chemistry to work. It has been suggested that an impact crater about 100 km in diameter could have contained water and could have been host to hydrothermal activity for up to a few million years, long enough for life to emerge, because the other essential ingredients, that is, carbon molecules, the life essential elements (H, N, O, P, S, and transition elements), and reactive mineral surfaces would have been available (Westall et al. 2015a, b). It is probable that the major source of carbon molecules would have been exogenous, likely carbonaceous meteorites and micrometeorites, together with a minor endogenous source from the crust and possibly atmosphere. The kinds of volcanic materials on early Mars, namely iron and magnesium-rich mafic and ultramafic basalts (*sensu lato*), were similar to those on the early Earth and were sources of bioelements as well as of energy from redox reactions at their surfaces. Thus, life could have emerged on Mars, possibly in multiple, isolated locations and at different points in time, as long as the ingredients of life (organic molecules, water, energy sources, hydrothermal activity, other nutrients, and physico-chemical gradients) were co-located for the length of time required for prebiotic chemistry to achieve protocellular complexity. An established cellular community can then rapidly colonize niches that are ephemerally habitable for a brief period of time (hours to week) or restricted in small spaces (centimeters to kilometers).

Punctuated habitability and its consequences: It is becoming increasingly clear that, even though early Mars had water, it was likely either generally cold and wet or cold and dry (Bishop et al. 2018). The more clement conditions of the early Earth did not exist on the Red Planet. The emergence of life on Mars might therefore be likened to a start-and-stop process. Under these conditions, it is unlikely that life could ever have evolved into complex organisms with sophisticated metabolic strategies, and putative Martian life would likely not have evolved beyond “primitive” chemosynthesis, that is, organisms obtaining their energy from the oxidation of either carbon or inorganic sources. Comparison with the early Earth shows us that the highest microbial biomass occurs in the vicinity of nutrient-rich hydrothermal sources, while oligotrophic environments away from these sources are host only to chemolithoautotrophs, whose biomass is correspondingly feeble (Westall et al. 2011b, 2015a, 2015b). In the latter case, the more limited supply of nutrients (organic or inorganic substrates that could be oxidized as an energy source) meant that organisms were required to obtain energy from sources that were not exclusively hydrothermal, for example, redox reactions at the surfaces of

volcanic detrital particles constituting the sediments. The limited potential for biomass development and the distribution of biosignatures has important notable implications for the promise of life on Mars.

Phototrophs, on the other hand, obtain their energy from a more or less inexhaustible source, sunlight, and are therefore able to reproduce more rapidly, produce cells that are larger, and, thus, provide more varied and more readily identifiable biosignatures. The only limitations to the development of phototrophs are access to sunlight and substrates. It is interesting to note that, on the early Earth, even though there was no ozone layer and the calculated flux of UV radiation (DNA-weighted) was between 54 and 1000 times greater than that reaching the surface today, phototrophs were common at least by ~3.5 Ga, when the fossil record is sufficiently well-preserved to identify them (Buick et al. 1981; Hofmann et al. 1999; Westall et al. 2006a, 2011a; Noffke et al. 2013; Hickman-Lewis et al. 2018).

Restricted habitability and cell development: What would happen to organisms when the spatially restricted habitable environment on Mars becomes uninhabitable? This is where our understanding of the limits of terrestrial life and the strategies that microbes adopt to flourish or survive are important (McKay 2014). Table 8.7.1 provides a list of the currently known physico-chemical limits of life. This shows that Martian microbes could have survived for a period of time in an environment that was drying out, where the activity of water was gradually becoming restrictive, and probably where saline conditions were increasing, together with exposure to harmful UV radiation. The ways in which microorganisms cope with extreme environments are both energy- and nutrient-intensive. For example, *Deinococcus radiodurans*, an organism able to

TABLE 8.7.1
The Limits of Life

Parameter	Limit	Note
Lowest temperature	-18°C	Limited by liquid water associated with thin films along ice crystal boundaries or saline solutions
Highest temperature	122°C	Limited by protein stability
Maximum pressure	1100 atm	
pH	0–12.5	
Salinity	Saturated NaCl	Depends on the salt and the temperature

survive high doses of radiation and concomitant desiccation, has rapid cell metabolism, multiple DNA-repair mechanisms, and a turnover rate of one cell division every 30 minutes.

The habitable environment of early Mars was much more variable than that of the early Earth and included desertification and adaptation to more saline environments, as well as to the presence of chlorides. Today, Mars is considered to be a desert, but the study of life in modern extreme environments on Earth allows us to consider the possibility that viable cells on Mars could survive and maybe still flourish in the subsurface (Boston et al. 1992) and for short periods of time throughout the history of Mars in isolated, ephemeral habitable niches at the surface (Rettberg et al. 2016). If life did not emerge independently on Mars, it is still possible that extremophile terrestrial organisms could briefly colonize ephemeral habitats or the subsurface, hence the concern with planetary protection (Rettberg et al. 2016).

Dormant or slow-growing cells occupy only the amount of space required by the cell or colony; however, it is not known how long dormant or slow-growing cells can remain viable. Cells have been reportedly resuscitated from 250 My salt deposits (Vreeland et al. 2000), although this observation has been considered to be due to contamination (Graur and Pupko 2001). Studies of 600-Ka-old permafrost showed that the DNA in the cells contained therein could still be replicated, but this was not achieved in older permafrost (Johnson et al. 2007). These studies suggest that low-level gene repair in a very slowly metabolizing viable cell is better for cell viability than dormancy. The genomes of spores, for example, degrade with time because of spontaneous chemical reactions, such as hydrolysis and oxidation, that finally become fatal, preventing the cell from germinating (Johnson et al. 2007). Another example of slow-growing cells of relevance to planetary habitability are those living in the Earth's crust or deep in sediments. Deep-sea sediments host viable cells down to depths of nearly 2 km; in this oligotrophic environment, apart from a low-nutrient source, another major problem is water availability, and cells have a metabolic turnover of about one cell division every 1000 years (Ciobanu et al. 2014)! The fractured crust is a slightly different environment, in which water infiltrating deep fractures has entrained microbes over long periods of time to depths of between 3 km and 4 km (Onstott 2016). A fracture system, sometimes as small as 1 cm, is an oasis, and, although relatively nutrient-rich, the microbial biomass in the subsurface is lower than that at the surface. Autotrophy and methane cycling are the main means of support of these deep subsurface microorganisms. Cell turnover times range from one to hundreds of years.

8.7.4.2 ASTROBIOLOGY ON MARS

In terms of missions and observations, the earlier discussion of variable, punctuated habitability and its consequences on the development of life makes it clear that a potentially habitable body does not necessarily need to be globally habitable, and much of the potential active biomass may be either hidden from view, for example, in the subsurface, or not sufficiently “evolved” to produce the manifest biosignatures of phototrophic organisms, for instance, biolaminations, microbially induced sedimentary structures, and stromatolites, that are potentially easier to identify than subtle chemotrophic expressions. Indeed, if life is extinct at the surface of a planet, as is probably the case for Mars, the search for its remains will be akin to looking for a needle in a haystack, as a result of punctuated habitability. One pivotally important point to keep in mind, known to scientists but perhaps more difficult for the general public and decision-makers, is that *not* finding traces of life is not a showstopper. Finding traces of past life on Mars will require almost serendipitous landing in the right location, and there are limitations to the high-resolution coverage that can be achieved from orbit. Finding traces of extant life on the planet will require either deep drilling or some other serendipitous event that brings viable cells from the subsurface to the surface—and, at present, planetary protection regulations preclude missions to these ephemeral environments (e.g., recurrent slope lineae) (Rettberg et al. 2016). Lack of observation of the atmospheric indicators of life on a planet or exoplanet may mean only that, if inhabited, the life forms had not developed oxygenic photosynthesis or an equivalent metabolism.

The Viking mission: The first astrobiology mission to Mars, landing in 1976, comprised two landers, Viking 1 in Chryse Planitia and Viking 2 in Utopia Planitia (<https://mars.nasa.gov/programmissions/missions/past/viking/>). These two landers (Figure 8.7.9) carried a series of experiments to search for extant life on Mars. The gas chromatograph-mass spectrometer (GC-MS) determined the chemical components that evolved during the heating of untreated Martian regolith. The number of organic molecules found was insignificant (Biemann et al. 1977; Biemann 2007), a result that had profound significance for the interpretation of other experiments, such as the labeled release experiment, in which Martian regolith doped with ¹⁴C-labeled water was analyzed for potential CO₂ production related to microbial metabolic activity (Levin and Straat 1976). Although an initial gas release was observed, it was not reproduced. From this observation, together with the indication of no organics in the regolith, given by the GC-MS result, the results appeared to be inconclusive (Levin and Straat 1976). The intervening years have, however, seen an increase in controversy over the labeled release experiments, with their proponents suggesting that the experiments did, indeed, find traces of extant Martian organisms (Bianciardi et al. 2012);

FIGURE 8.7.9 Carl Sagan with a model of a Viking lander. Carl Sagan was a strong supporter of the search for life on Mars. (Courtesy of http://solarsystem.nasa.gov/multimedia/display.cfm?IM_ID=244.)

however, this view is not common consensus. The gas exchange experiment used a GC to test for consumption or release of gases by microbial metabolism from doped Martian regolith. Although CO₂ was evolved, its release is believed to have been due to oxidation of organics present in the nutrient used to dope the regolith by oxidized minerals in the samples, such as Fe₂O₃; thus, this experiment also produced negative results (Oyama and Berdahl 1977). The pyrolytic release experiment was designed to test for evidence of phototrophy, that is, microbial metabolism fueled by sunlight (Horowitz et al. 1976). Subsequent studies have shown that there are oxidizing components in the Martian regolith that could have interacted with the ingredients used during the Viking experiments and during the heating of the regolith. These include *in situ* detection of perchlorates in the Phoenix mission (Hecht et al. 2009), as well as experimental studies that showed that the radiolysis of perchlorates in the Martian regolith could also reproduce many of the Viking results (Quinn et al. 2013). The problem of perchlorates has been well-illustrated by the on-going Mars Science Laboratory mission and the analysis of organics in Gale Crater by the Sample Analysis at Mars (SAM) instrument (e.g., Freissinet et al. 2015).

The Mars Exploration Rover mission: Two rovers landed on Mars in 2003 to search for signs of water: Opportunity in Meridiani Planum and Spirit

in Gusev Crater. A spectral signature suggesting the presence of hematite was the stimulus for the Meridiani Planum location; however, in fact, Opportunity with an instrumental payload, including a camera and thermal emission, Mössbauer, and alpha particle X-ray spectrometers (together with other instruments) found nodules of hematite in layered rocks, suggestive of the presence of water (Squyres et al. 2006). Spirit landed in what was believed to have been a water-filled crater. Although Spirit stopped working a number of years ago (at the time of writing, Opportunity is still going strong), it provided evidence for limited aqueous alteration (thin films of water) of a basically basaltic lithology in the plains area (Arvidson et al. 2004; McSween et al. 2004); however, its investigation of the rocks in the Columbia Hills area showed increased evidence of water alteration and the formation of clay minerals, as well as sulfates and jarosite (Ming et al. 2006). The conclusion of the Spirit rover operation is thus that Gusev Crater may have once been filled by a lake, but as conditions became drier, more evaporitic lithologies became dominant.

One curious discovery of the Spirit rover concerned high silica deposits at Home Plate, widely accepted to be hydrothermal in origin (Ruff and Farmer 2016). These authors hypothesize that these deposits could represent traces of past Martian life, based on comparison with terrestrial hot spring analogues.

The Phoenix mission: The Phoenix mission comprised a lander that landed close to the northern polar ice cap of Mars. Its objectives were to study the history of water in the polar region and to search for evidence of a habitable zone and assess the biological potential of the ice-soil boundary. Water ice and water vapor were detected, as were calcium carbonate, aqueous minerals, and salts, all of which were likely deposited in the presence of water (Smith et al. 2010). Apart from this first direct detection of water (ice) on Mars, the most significant observation from Phoenix was the surprising significant presence of perchlorate in the soil (Hecht et al. 2009). This fundamental discovery has influenced the interpretation of previous and subsequent search for organic molecules on Mars.

Mars Science Laboratory (MSL) and the Curiosity rover: This mission has provided abundant evidence for the presence of habitable conditions in Gale Crater (Grotzinger et al. 2014) in the form of sediments deposited in fluvio-lacustrine conditions and detailed evidence of aqueous alteration of volcanic detrital deposits. The goals of this mission are to determine the role of water, to study Martian climate through changes in the deposits infilling Gale Crater, and to better understand the geology of Mars. Additional observations and measurements (e.g., environmental) will help to plan for a future manned mission to Mars.

Gale Crater was chosen because of the diversity of environments and sediments infilling the crater and also because of its potential habitability (Golombek et al. 2012). Well-preserved sedimentary structures, together with what we know of its mineralogy, are allowing the most detailed analysis of habitability and environmental changes in any one location on Mars, thanks to the well-equipped instrumental payload, which is capable of making analyses of the elemental, mineralogical, and organic compositions of sediments drilled from a depth of about 10 cm into the rock (Grotzinger et al. 2014).

The mission also has three specific goals of relevance to astrobiology involving (i) study of the nature and inventory of organic carbon compounds; (ii) investigation of the chemical building blocks of life (carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur); and (iii) identification of potential biosignatures (Summons et al. 2011). Since the Viking mission, MSL is the first to actively search for the potential for life and signs of life. With respect to organic molecules, as noted earlier, the presence of perchlorates in the Martian surface has hindered the analysis of organics but the SAM team, with their GC-MS instrument, have valiantly revealed that Martian organics in the form of chlorinated compounds, for example, chlorobenzene and dichloroalkanes, occur in the Sheepbed Member of Yellowknife Bay (Freissinet et al. 2015), while Eigenbrod et al. (2018) report a range of aromatic and aliphatic molecules, including the S-containing

molecule thiophene in the Mojave and Confidence Hills samples. Evidence for the elemental building blocks of life has also been given (Grotzinger et al. 2014). Importantly, the observations of the Curiosity rover have underlined the influence of groundwater alteration and the precipitation of impure sulfate- and silica-rich deposits as veins or horizons, followed by further alteration of the primary alteration products to produce pure sulfate veins (Schwenzer et al. 2016).

Future astrobiology missions to Mars: There are two upcoming missions whose primary goal is to find traces of life on Mars. The European-Russian ExoMars 2020 mission aims at finding traces of primarily past life (without excluding the possibility of extant life) within its geological context (Vago et al. 2017), an exploratory strategy well-demonstrated by the Curiosity rover. Following the reasoning outlined earlier regarding the punctuated habitability of Mars and the likelihood that Martian life is chemotrophic rather than phototrophic (*cf.* Westall et al. 2015a) and concerned by the modeled destruction of especially labile organics by radiation in the surface of Mars (Kminek and Bada 2006), the ExoMars rover is equipped with a 2-meter drill in order to obtain sediments and organics from the subsurface, that is, those that have been protected from surface radiation (Figure 8.7.10). While there is always the possibility of detecting morphological evidence of microbial life (for instance, clotted-textured, chemotrophic biofilms in the vicinity of hydrothermal effluent), it is more likely that chemical biosignatures could be detected by a cousin of the SAM instrument, Mars Organic Molecule Analyser (MOMA), which incorporates laser desorption with mass spectroscopy, as well as GC-MS. As with SAM, the chemical signatures sought include isomeric selectivity (enantiomeric excess and diastereoisomeric and structural isomer preference), molecular weight characteristics (uneven distribution patterns of C number, concentration and $\delta^{13}\text{C}$ of structurally related compounds, repeated constitutional subunits, and systematic isotopic ordering at molecular and group level), and isotopic fractionations of carbon (Vago et al. 2017). Despite the enhanced potential for the preservation of organic molecules deeper in the subsurface, MOMA will still be confronted with the problem of perchlorates and their effects on GC-MS analysis of organic matter, as with the SAM instrument on Curiosity. The detailed detective work undertaken by the SAM team will feed into analysis by MOMA. In addition, laser-desorption-mass spectrometry (LD-MS) will aim to obviate this problem, since the laser will release entrapped molecules, especially more refractory ones, without heating samples in the way that those analyzed by the GC-MS instrument are.

ExoMars 2020 will land in one of two broadly similar locations on the edge of Chryse Planitia: Mawrth

FIGURE 8.7.10 Artist's impression of the ExoMars 2020 rover, with its landing platform in the background. Note the drill (horizontal black cylinder) on the front of the rover. The drill will be able to take a sample from a depth of 2 meters. (Courtesy of ESA, Paris, France.)

Valley or Oxia Planum. Both have been characterized, by orbital mapping, to have diverse clay mineralogy at the surface, the supposed evidence of changing environmental conditions at the end of the Noachian (Bishop et al. 2018). Clay mineralogy is of interest for what it tells us about past habitability, as well as for the potential of clays to trap organic molecules. If these locations were habitable and inhabited, the organic remains of past Martian life could be entrapped within the clayey lithologies (Vago et al. 2017).

The NASA Mars 2020 mission will be the first step in returning samples from Mars for study in terrestrial laboratories. It has sophisticated instrumentation for mapping the elemental and mineralogical compositions of cleaned rock surfaces with the instruments Planetary Instrument for X-ray Lithochemistry (PIXL) and Scanning Habitable Environments with Raman and Luminescence for Organics and Chemicals (SHERLOC). Therein, the combination of macro- and micro-scale mineralogical and elemental contexts, with determination of the presence of organics, will aid in the choice of samples for collection (at 5 cm) and storage. The return mission is planned with collection at a later date by a fetch rover and eventual return to Earth.

8.7.5 CONCLUSION

Investigations of traces of life on early Earth and on Mars have many points in common. On a microbial scale, the habitable environments were similar, although they became

increasingly desert-like and uninhabitable on the post-Noachian Mars. In both cases, the life forms were (or are expected to be) prokaryotes: on Earth, both chemotrophs and phototrophs, whereas on Mars, likely only chemotrophs owing of the lack of long-term, clement habitable environments. Understanding the preservation of signatures of life through experimentation and observation of microbial fossils throughout the terrestrial geological record shows that microbes could be preserved on Mars in a multitude of fashions but that the probability of finding chemotrophic biosignatures would be higher in the vicinity of Si-rich hydrothermal activity than in distal oligotrophic environments. Past missions to Mars have underlined its habitability in terms of the past presence of water, nutrients, life essential elements, and energy sources. They have also highlighted the difficulty in analyzing organic molecules in Martian materials because of the oxidizing conditions at the surface of the planet and the presence of perchlorates in the Martian regolith. Nevertheless, the ongoing MSL mission and the upcoming ExoMars 2020 and Mars 2020 missions will build on the information available to date. ExoMars 2020—with its 2-meter drill—may be able to detect and analyze organics protected from the harsh surface conditions. Its results could feed into the Mars 2020 mission, providing added information to aid sampling for future collection and return to Earth.

We live in exciting times for astrobiology on Mars, and the prospect of sample return missions heralds the advent of increased technological advances, with the eventual goal of studying precious material brought back from the Red Planet.

9.1.1 INTRODUCTION

There is hardly any place on our planet, however extreme, that is not inhabited by at least some types of living organisms adapted to the environment. Thus, the physico-chemical boundaries for life on Earth are very broad. One can almost state that any place where a minimal amount of liquid water is available can support life (Mazur 1980; Madigan 2000; Xu and Glansdorff 2007; Stan-Lotter 2012). We find microbial life in very cold and very hot environments, even at temperatures exceeding 100°C in undersea springs, where the boiling point of water is elevated because of the hydrostatic pressure. We know microorganisms adapted to life in concentrated acids and in highly alkaline lakes. Life is possible in salt-saturated brines, under high levels of ionizing radiation and under pressure in the deepest parts of the ocean. Microorganisms even live in deserts, hot as well as cold, thriving on very small amounts of water that become available occasionally. The lowest water activity that still allows active growth of microorganisms appears to be around 0.63–0.64 (Stevenson et al. 2015), but many types can survive prolonged periods of desiccation until conditions again become suitable for growth.

There are also many types of microorganisms that we can call “polyextremophiles”: organisms adapted to more than one environmental extreme. Thus, we know haloalkaliphiles that grow only at salt concentrations approaching saturation and at pH >8.5–9; there are thermoacidophiles that thrive only in hot acid solutions, thermophiles that prefer the hydrostatic pressure of the deep sea, and even haloalkaliphilic thermophilic anaerobes that inhabit the sediments of some shallow soda lakes in tropical area (Capece et al. 2013; Seckbach et al. 2013).

Extremophiles are found in all three domains of life: Archaea, Bacteria, and Eukarya. The archaeal domain is particularly rich in organisms adapted to life at the extremes: high salt, high temperature, hot and acidic, hypersaline and alkaline, and more. The special structure of the archaeal lipid membrane, with ether bonds linking the glycerol moieties with the hydrophobic carbon chains, and even the possibility realized in some Archaea of a monolayer membrane, in which the glycerol moieties at both sides of the membrane are bridged by covalent bonds only, make the Archaea especially suitable for life in the hottest environments. But also among the Bacteria and the eukaryotic microorganisms, we find halophiles, thermophiles, acidophiles, alkaliphiles, and other extremophilic types.

This chapter provides an overview of the kind of extremophilic microorganisms found on our planet and of the environments they inhabit. Further information can be found in many monographs and review articles (e.g., Kushner 1978; Da Costa et al. 1989; Horikoshi and Grant 1991, 1998; Kristjansson and Hreggvidsson 1995; Madigan 2000; Wharton 2002; Rainey and Oren 2006a, 2006b; Pikuta et al. 2007; Horikoshi 2010). Further literature on specific types of extremophiles is referred to in the subsequent sections.

9.1.2 HIGH-TEMPERATURE ENVIRONMENTS AND THERMOPHILIC MICROORGANISMS

There is no lack of hot environments on planet Earth. The best studied ones are associated with volcanic activity: hot springs are abundant, for example, in the western USA (e.g., in Yellowstone National Park), New Zealand, Iceland, Japan, and Italy. Many hot springs are also highly acidic due to the oxidation of reduced sulfur compounds. Even higher

temperatures prevail in the deep-sea hydrothermal vents, where the in situ temperature often exceeds 100°C and the ambient pressure prevents the water from boiling (Stetter 1996). The anoxic, sulfide-, and mineral-loaded waters emitted by the so-called “black smoker” chimneys in marine hydrothermal vents can reach temperatures of ~350°C. Surface soils in hot deserts may heat up to temperatures as high as 70°C during daytime. Similar temperatures were also measured in compost piles and silage, heated as a result of the microbial activity of fermentative bacteria. Microbial life at high temperature may also abound deep within the crust of the Earth (Gold 1992).

All these environments have become rich sources of isolates of thermophilic (generally defined as organisms with an optimum growth temperature >45°C) and hyperthermophilic microorganisms (with optimum growth temperatures >80°C) of many kinds. Some of these have found interesting biotechnological applications (Burgess et al. 2007).

Since the pioneering studies by Tom Brock of the hot springs of Yellowstone National Park (Brock 1978), our knowledge of the diversity of life at high temperatures has greatly increased (Baross and Deming 1995). No eukaryote appears to be able to complete its life cycle above 60°C (Clarke 2014). No protists are known that live above 56°C, and the upper temperature limit for the growth of algae and fungi is about 60°C and 62°C, respectively. Photosynthesis by prokaryotes, oxygenic (by cyanobacteria) as well as anoxygenic, can proceed up to 70°C–73°C. Some chemoorganotrophic and chemolithotrophic Bacteria can grow at temperatures up to 95°C–100°C. At the highest temperatures enabling life (the highest value recorded today being 122°C), only members of the domain Archaea survive.

A detailed discussion of the mechanisms enabling thermophiles and hyperthermophiles, not only to survive at the temperature extremes but also to actively grow, in many cases even with very short doubling times, is beyond the scope of this chapter. The mechanisms by which proteins and various biological cofactors and organic intermediates are stabilized at extreme temperatures are only now becoming clear (Adams 1993; Wiegel and Adams 1998; Madigan and Oren 1999). The differences in amino acid composition of thermophilic and non-thermophilic proteins are often slight: subtle changes in the amino acid sequence of a protein can have dramatic effects on its thermotolerance. But there is a general trend that thermophilic enzymes have increased ionic bonding between basic and acidic amino acids and also have a highly hydrophobic interior that prevents unfolding. In addition, solutes such as di-inositol phosphate, diglycerol phosphate, and mannosylglycerate may help to stabilize proteins against denaturation. Some aerobic and anaerobic extreme thermophiles can grow within a span of more than 40°C. Such organisms may have two sets of key enzymes, whose synthesis is regulated by temperature, enabling them to grow in both the mesophilic and thermophilic ranges (Wiegel 1990). Archaeal lipids, with ether bonds connecting the glycerol moiety, are far more stable than the bacterial and eukaryotic lipids with ester bonds that are easily hydrolyzed at high temperatures. And the possibility

of rigid monolayer membranes spanning the entire width of the cell membrane with covalent bond adds even more stability at temperatures at which conventional membranes cannot function (van de Vossenberg et al. 1998; Daniel and Cowan 2000). At high temperatures, the stability of the DNA double helix is increased by elevated salt concentrations, polyamines, cationic proteins, and supercoiling, rather than by manipulation of C-G ratios. RNA stability is achieved both by formation of secondary structure and by covalent modifications (Daniel and Cowan 2000). In vivo, the half-lives of both RNA and DNA of thermophilic organisms are usually longer than the values estimated in vitro. Different mechanisms may be involved in the stabilization of RNAs and DNAs, both based on the intrinsic chemical structures of the nucleic acids, on their interactions with other biomolecules, and on enzymes for detecting and repairing the DNA damage or for renewing damaged RNA molecules (Grosjean and Oshima 2007).

Table 9.1.1 lists representative examples of thermophilic and hyperthermophilic microorganisms and their properties. Thermophiles can be found in different phylogenetic lineages and physiological groups. In addition to the cultivated minority, there is a large uncultivated majority yet to be characterized. This became clear already since the first pioneering 16S rRNA-based studies in hot springs: for example, a study of archaeal 16S rRNA gene sequences retrieved from the Obsidian Pool hot spring in Yellowstone National Park environment yielded many lineages for which we do not have cultivated representatives even today. These include the proposed Korarchaeota phylum (Barns et al. 1994; Hugenholtz et al. 1998). In their natural habitats, hyperthermophiles form complex food webs, and their metabolic potential includes various types of aerobic and anaerobic respiration, chemoaautotrophy, and different modes of fermentation (Huber et al. 2000a; Reysenbach et al. 2001). Even a symbiotic or parasitic lifestyle is possible at extremely high temperatures, as displayed by *Nanoarchaeum equitans*, a very small (about 0.4-μm diameter) organism that represents a separate lineage within the Archaea and lives at 90°C on another extreme thermophile, *Ignicoccus* (Crenarchaeota) (Huber et al. 2002). This non-exhaustive overview of the known types of thermophiles and hyperthermophiles does not include organisms inhabiting hot and acidic environments, hot and alkaline environments, and hot environment under high hydrostatic pressure. Such microorganisms are discussed in later sections in this chapter.

As stated earlier, the upper temperature limit of bacterial thermophiles is much below that of the most thermophilic Archaea. Examples of thermophilic Bacteria are members of the *Aquificales* and the *Thermotogales*, as well as the genus *Thermus*. Isolates of *Thermus aquaticus* growing at 70°C–75°C were retrieved from thermal springs in Yellowstone National Park and in California. *Thermus* was also found in man-made thermal habitats such as domestic water-heating systems. Members of the genus tolerate temperatures up to 79°C (Brock and Freeze 1969). Also, other phyla of Bacteria contain thermophiles. An example is *Thermaerobacter marianensis*

TABLE 9.1.1

Representative Examples of Thermophilic Microorganisms, Their Taxonomic Affiliation, Habitat, and Properties. The Table Includes Thermoacidophiles, Thermophilic Piezophiles, Halothermoalkaliphilic Species, and Radiation-Resistant Thermophiles Listed Also in Other Tables in This Chapter

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Archaea</i>						
<i>Pyrodictium abyssi</i>	<i>Crenarchaeota</i>	Sea bottom near Mexico, Iceland	Shallow hydrothermal vents	80°C–110°C (opt. 97°C)	Ferments carbohydrates and proteins; hydrogen stimulates growth; reduces elemental sulfur	Pley et al. (1991)
<i>Pyrodictium brockii</i> , <i>Pyrodictium occultum</i>	<i>Crenarchaeota</i>	Vulcano, Italy	Submarine sulfataric field	Up to 110°C (opt. 105°C)	Autotrophic on hydrogen and elemental sulfur	Stetter et al. (1983, 1986)
<i>Pyrolobus fumarii</i>	<i>Crenarchaeota</i>	Hydrothermal vent, Mid-Atlantic Ridge, 3,650 m depth	Hydrothermally heated black smoker wall	90°C–113°C (opt. 106°C), pH 4.0–6.5 (opt. 5.5), 1%–4% salt. Survives 1-hour autoclaving at 121°C. Grows at 25 MPa	Facultative aerobic chemolithoautotroph oxidizing hydrogen with nitrate, thiosulfate, or low concentrations of oxygen as electron acceptors	Blöchl et al. (1997)
<i>Staphylothermus marinus</i>	<i>Crenarchaeota</i>	Vulcano, Italy	Geothermally heated marine sediment	Opt. 95°C–92°C, max. 98°C	Anaerobic heterotrophic, fermentative	Fiala et al. (1986)
<i>Sulfolobus acidocaldarius</i>	<i>Crenarchaeota</i>	Yellowstone National Park, USA and acidic hot springs elsewhere	Acidic hot springs	55°C–85°C (opt. 70°C–75°C), pH 0.9–5.8 (opt. 2–3)	Aerobic, heterotrophic on simple organic compounds; facultative autotroph on elemental sulfur	Doemel and Brock (1970); Brock et al. (1972)
<i>Archaeoglobus profundus</i>	<i>Euryarchaeota</i>	Hydrothermal system, Guaymas Basin, Mexico	Black smoker hydrothermal vent and surrounding sediments	Up to 90°C	Anaerobic, oxidizing hydrogen with sulfate or thiosulfate as electron acceptors; mixotrophic, also requiring organic carbon	Burggraf et al. (1990)
<i>Ferroplasma acidiphilum</i>	<i>Euryarchaeota</i>	Bioleaching pilot plant, Russia	Leaching plant for gold-containing arsenopyrite/pyrite ore	pH 1.3–2.2 (opt. 1.7); 15°C–45°C	Aerobic, obligately autotrophic	Golyshina et al. (2000); Golyshina and Timmis (2005)
<i>Methanocaldococcus infernus</i>	<i>Euryarchaeota</i>	Mid-Atlantic Ridge, 3,000 m depth	Hydrothermal vent	55°C–91°C (opt. 85°C)	Methanogenic on hydrogen/carbon dioxide; reduces elemental sulfur	Jeanthon et al. (1998)
<i>Methanocaldococcus jannaschii</i>	<i>Euryarchaeota</i>	East Pacific Rise, 2,600 m depth	Hydrothermal vent—white smoker chimney	Opt. 85°C	Chemolithoautotroph methanogenic on hydrogen/carbon dioxide	Jones et al. (1983)
<i>Methanopyrus kandleri</i>	<i>Euryarchaeota</i>	Guaymas Basin, Gulf of California; Kolbeinsey Ridge, Iceland	Hydrothermal vents	84°C–110°C (opt. 98°C)	Chemolithoautotroph methanogenic on hydrogen/carbon dioxide	Kurr et al. (1991)

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Methanopyrus kandleri</i> strain 116	<i>Euryarchaeota</i>	Central Indian Ridge	Black smoker fluid, hydrothermal field	Max. 116°C at 0.4 MPa; 122°C at 20 MPa	Chemolithoautotroph methanogenic on hydrogen/carbon dioxide	Takai et al. (2008)
<i>Methanotorris formiciculus</i>	<i>Euryarchaeota</i>	Central Indian Ridge	Black smoker hydrothermal chimney	55°C–83°C (opt. 75°C)	Methanogenic on hydrogen/carbon dioxide or formate	Takai et al. (2004a)
<i>Palaeococcus ferrophilus</i>	<i>Euryarchaeota</i>	Deep Sea, Japan	Hydrothermal vent	60°C–88°C (opt. 83°C); 0.1–60 MPa (opt. 30 MPa)	Anaerobic chemoorganotroph oxidizing proteinaceous compounds with elemental sulfur or ferrous iron as electron acceptor	Takai et al. (2000)
<i>Picrophilus oshimae</i>	<i>Euryarchaeota</i>	Northern Japan	Acidic soil (pH <0.5) heated to 55°C by solfataric gases	pH opt. 0.7, growth also at pH 0; 45°C–65°C (opt. 60°C)	Heterotrophic, aerobic	Schleper et al. (1995a, 1996); Futterer et al. (2004)
<i>Picrophilus torridus</i>	<i>Euryarchaeota</i>	Northern Japan	Acidic soil (pH <0.5) heated to 55°C by solfataric gases	pH opt. 0.7, growth also at pH 0; 45°C–65°C (opt. 60°C)	Heterotrophic, aerobic	Schleper et al. (1995a, 1996); Futterer et al. (2004)
<i>Pyrococcus abyssi</i>	<i>Euryarchaeota</i>	Hydrothermal vent, SW Pacific, depth 2,000 m	Hydrothermal vent fluid	67°C–102°C, opt. 96°C at 0.1 MPa. Upper temperature 105°C at 20 MPa	Anaerobic heterotrophic, fermentative	Erauso et al. (1993)
<i>Pyrococcus furiosus</i>	<i>Euryarchaeota</i>	Vulcano, Italy	Geothermally heated marine sediment	70°C–103°C (opt. 100°C)	Anaerobic heterotrophic, fermentative	Fiala and Stetter (1986)
<i>Pyrococcus horikoshii</i>	<i>Euryarchaeota</i>	Okinawa Trough, NE Pacific Ocean, 1,395 m depth	Hydrothermal vent	Opt. 98°C (max. 102°C). Prolonged survival at 105°C	Grows on proteins and amino acids; growth is stimulated by elemental sulfur	González et al. (1998)
<i>Thermococcus barophilus</i>	<i>Euryarchaeota</i>	Mid-Atlantic Ridge, 3,550 m depth	Hydrothermal vent	75°C–100°C; opt. 85°C. Obligate barophilic at >95°C	Anaerobic, grows on complex organic compounds; elemental sulfur enhances growth	Marteinsson et al. (1999)
<i>Thermococcus gammatolerans</i>	<i>Euryarchaeota</i>	Guaymas Basin, Mid-Atlantic Ridge	Hydrothermal chimneys	55°C–95°C (opt. 88°C), survive 20–30 kGy of radiation	Anaerobic, oxidizes proteinaceous compounds with elemental sulfur as electron acceptor	Jolivet et al. (2003a, 2004)
<i>Thermococcus marinus</i>						
<i>Thermococcus radiotolerans</i>						
<i>Thermococcus fumicolans</i>	<i>Euryarchaeota</i>	North Fiji Basin	Deep-sea hydrothermal vent	Opt. 85°C, pH 8.5, 2%–4% salt.	Anaerobic, respiring proteins with elemental sulfur as electron acceptor	Godfroy et al. (1996)

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Thermococcus hydrothermalis</i>	<i>Euryarchaeota</i>	East Pacific Rise	Deep-sea hydrothermal vent	Opt. 85°C, pH 6, 2%–4% salt.	Anaerobic, respiring amino acids with elemental sulfur as electron acceptor	Godfroy et al. (1996)
<i>Thermococcus peptonophilus</i>	<i>Euryarchaeota</i>	Western Pacific Ocean	Deep-sea hydrothermal vent	60°C–100°C (opt. 85°C–90°C). Opt. 30–45 MPa. Opt. temp. shifts from 85°C at 30 MPa to 90°C–95°C at 45 MPa	Proteins, amino acids; elemental sulfur stimulates	González et al. (1995); Canganella et al. (1997)
<i>Thermococcus profundus</i>	<i>Euryarchaeota</i>	Okinawa Trough, NE Pacific Ocean, 1,395 m depth	Hydrothermal vent	50°C–90°C (opt. 80°C)	Grows on proteins and amino acids; elemental sulfur is used as the electron acceptor	Kobayashi et al. (1994)
Bacteria						
<i>Thermus aquaticus</i>	<i>Deinococcus-Thermus</i>	Yellowstone National Park, USA	Freshwater hot spring	Up to 79°C (opt. 70°C, min. 40°C); opt. pH 7.5–7.8	Heterotrophic, aerobic	Brock and Freeze (1969)
<i>Truepera radiovictrix</i>	<i>Deinococcus-Thermus</i>	Azores Islands	Hot-spring runoff	Opt. 50°C, pH 7.5–9.5. survives 5.0 kGy	Aerobic, heterotrophic	Albuquerque et al. (2005)
<i>Anaerobranca horikoshii</i>	<i>Firmicutes</i>	Yellowstone National Park, USA	Soil from geothermal pools	pH 6.9–10.3 (opt. 8.5); 34°C–66°C (opt. 57°C)	Anaerobic proteolytic, fermentative	Engle et al. (1995)
<i>Natranaerobius thermophilus</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	35°C–65°C (opt. 53°C), pH 8.3–10.6 (opt. 9.5), 3.1–4.9 M Na ⁺ (opt. 3.3 M)	Anaerobic, fermentative	Mesbah et al. (2007b); Mesbah and Wiegel (2011)
<i>Natranaerobius trueperi</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	26°C–55°C (opt. 52°C), pH 7.8–11.0 (opt. 9.9); 4.1–5.4 M Na ⁺ (opt. 3.9 M)	Anaerobic, fermentative	Mesbah and Wiegel (2009)
<i>Natronovirga wadinatrunkensis</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	26°C–56°C (opt. 51°C), pH 8.5–11.1 (opt. 9.9); 3.1–5.3 M Na ⁺	Anaerobic, fermentative	Mesbah and Wiegel (2009)
<i>Thermaerobacter marianensis</i>	<i>Firmicutes</i>	Mariana Trench	Depth of 10,897 m	50°C–80°C, opt. 75°C–76°C	Aerobic, heterotrophic	Takai et al. (1999)
<i>Thermobrachium celere</i>	<i>Firmicutes</i>	New Zealand, Italy, USA, Argentina, Germany	Geothermally and anthropogenically heated environments	pH 5.4–9.5 (opt. 8.2); 43°C–75°C (opt. 66°C)	Anaerobic proteolytic, fermentative	Engle et al. (1996)
<i>Marinitoga piezophila</i>	<i>Thermotogae</i>	East Pacific Rise	Hydrothermal chimney	Opt. 40 MPa, 45°C–70°C (opt. 26 MPa) 65°C	Anaerobic, chemoorganotrophic, uses carbohydrates and proteins, with elemental sulfur as electron acceptor	Alain et al. (2002)

(*Firmicutes*), which grows optimally at 74°C–76°C and up to 80°C as a strict aerobe that grows on yeast extract, peptone, cellulose, starch, chitin, or casein (Takai et al. 1999).

Hyperthermophiles are found in both the Crenarchaeota and the Euryarchaeota phyla. Some hyperthermophilic Archaea obtain their energy by fermentation of organic compounds. Examples are the marine isolates *Pyrococcus furiosus*, which grows on starch, maltose, peptone, and complex organic substrates (Fiala and Stetter 1986); *Pyrococcus abyssi*, fermenting peptides or mixtures of amino (Erauso et al. 1993); and *Pyrodictium abyssi*, a species of disk-shaped cells that appear entrapped within a mycelium-like network of fibers, grows at 110°C, and ferments carbohydrate and proteins (Pley et al. 1991). *Pyrodictium* species can also grow chemoautotrophically on hydrogen as energy source, with elemental sulfur as the electron acceptor (Stetter et al. 1983).

Many more anaerobic hyperthermophilic Archaea depend on elemental sulfur or are stimulated by it (Stetter et al. 1986; Kletzin et al. 2004). Examples are *Thermococcus* spp., which grow optimally at 80°C–85°C on substrates such as tryptone, peptone, and amino acid mixtures and either require elemental sulfur (*T. profundus*) (Kobayashi et al. 1994) or are greatly stimulated by it (*T. fumicolans*, *T. hydrothermalis*, and *T. peptonophilus*) (González et al. 1995; Godfroy et al. 1996, 1997). *Staphylothermus marinus* is another elemental sulfur-dependent archaeon that ferments yeast extract in the presence of sulfur to acetate, isovalerate, CO₂, and H₂S (Fiala et al. 1986). Sulfur also enhances growth of *Pyrococcus horikoshii* (González et al. 1998). Some aerobic thermophilic Archaea, such as *Acidianus* and *Sulfolobus*, depend on elemental sulfur as the electron donor for energy generation.

There are also thermophilic Archaea that use sulfate as the electron acceptor for anaerobic respiration. Species of the genus *Archaeoglobus* have been isolated from the walls of smokers' chimneys and from sediments or marine hydrothermal systems. They can grow heterotrophically on a range of organic electron donors, while reducing sulfate or thiosulfate chemolithoautotrophically on hydrogen, carbon dioxide, and thiosulfate, or as mixotrophs that require molecular hydrogen in addition to an organic carbon source such as acetate (Stetter 1988; Burggraf et al. 1990). Measurements of dissimilatory sulfate reduction above 100°C in the hot deep-sea sediments near the hydrothermal vents of the Guaymas Basin in the Gulf of California showed the process to occur at temperatures up to 110°C, with an optimum rate at 103°C–106°C (Jørgensen et al. 1992). Even arsenate and selenate can serve as the electron acceptors for certain hyperthermophilic Archaea. An isolate affiliated with the *Thermoproteales* was isolated from a hot spring near Naples, Italy, that grew chemolithoautotrophically, with carbon dioxide as carbon source; hydrogen as the electron donor; and arsenate, selenate, thiosulfate, or elemental sulfur as the electron acceptor. Arsenate was reduced to arsenite; during growth on selenate, elemental selenium was formed. Anaerobic chemoorganotrophic growth was also possible with hydrogen as the energy source (Huber et al. 2000b).

Some of the most thermophilic Archaea are methanogens. A hyperthermophilic subsurface lithoautotrophic

microbial ecosystem dominated by methanogens was found beneath a deep-sea hydrothermal field in the Central Indian Ridge. Both cultivation and cultivation-independent analyses suggested that members of the *Methanococcales* dominate the methanogenic community (Takai et al. 2004b). All the isolated hyperthermophilic methanogens grow on hydrogen and carbon dioxide for methane generation, and some have very short generation times. These include *Methanotorris formicicetus*, isolated from a black smoker hydrothermal vent and able to use formate as an alternative energy source (Takai et al. 2004a); *Methanococcus infernus*, isolated from a deep-sea hydrothermal vent in the Mid-Atlantic Ridge (optimum growth at 85°C) (Jeanthon et al. 1998); *Methanocaldococcus jannaschii*, isolated from a “white smoker” chimney on the East Pacific Rise (doubling time 26 min at 85°C) (Jones et al. 1983); and *Methanopyrus kandleri*, which grows up to 110°C, with an optimum at 98°C (Kurr et al. 1991).

Over the years, the upper temperature known to support life has increased from the boiling point of water to the current value of 122°C. For some years, *Pyrolobus fumarii* was considered the most thermotolerant organism. This crenarchaeote, isolated from the wall of a deep-sea black smoker, does not grow below 90°C, grows up to 113°C (optimum 106°C), and survives autoclaving at 121°C (Blöchl et al. 1997; Stetter 1999). An unnamed and still incompletely characterized formate-oxidizing and iron-reducing archaeon closely related to *Pyrodictium* and *Pyrobaculum*, and known as “Strain 121,” reportedly grows even at 121°C (Kashefi and Lovley 2003; Cowan 2004). Today, the record for growth at high temperatures is held by the chemolithotrophic methanogen *Methanopyrus kandleri* strain 116, isolated from a deep-sea hydrothermal vent. When incubated at high pressure (20 MPa), it grows up to 122°C (Takai et al. 2008).

A short time after the discovery of the deep-sea hot vents and the life associated with them, a report was published, claiming that “black smoker” bacteria may be capable of chemolithotrophic growth under in situ vent pressure of ~27 MPa at temperatures of at least 250°C (Baross and Deming 1983). This observation is today considered an artifact. Based on the limited thermal stability of metabolites in aqueous solution, the theoretical maximum temperature for life was recently estimated at 150°C–180°C (Bains et al. 2015).

9.1.3 COLD ENVIRONMENTS AND PSYCHROPHILIC MICROORGANISMS

Permanently cold environments are abundant on planet Earth. Most of the deep waters of the oceans have a constant temperature of 1°C–3°C. The Arctic and the Antarctic are permanently cold, and parts of northern countries such as Siberia-Russia and Canada are permanently frozen (“permafrost”). All these environments support life of cold-adapted, psychrophilic, and psychrotolerant microorganisms (Deming 2002, 2007; Miller and Whyte 2011; Goordial et al. 2013). Cryoenvironments also include glaciers, ice caps, sea ice, and cold lakes and ponds. The search for life elsewhere in the

universe and the environmental changes on Earth as a result of global warming have greatly stimulated research on the microbiology of cold ecosystems (Deming 2002).

At low temperatures, metabolism is slow. But the primary constraint to life at low temperatures is the availability of liquid water. When the cytoplasm becomes frozen, the cell may remain viable, but metabolic activity is no longer possible. The freezing point of the intracellular water thus determines the lowest temperature for growth. Accumulation of organic and inorganic solutes that act as “antifreeze” agents (antifreeze proteins and certain sugars) can, to some extent, lower the freezing temperature of the intracellular water. Because the presence of liquid water in cryoenvironments is often due to the freezing-point depression properties of solutes, many cold-adapted microorganisms also tolerate osmotic stress caused by high salinity (Cowan et al. 2007).

Table 9.1.2 summarizes the properties of a few well-characterized psychrophilic bacteria. True psychrophiles are generally defined as such organisms that grow optimally below 15°C and that still can grow below 0°C. Organisms that show growth below 0°C but have their optimum above 15°C–20°C are called psychrotolerant or psychrotrophs (Cowan et al. 2007). The ability of psychrophiles and psychrotrophs to grow at low temperatures depends on adaptive changes in their cellular proteins and lipids (Russell 1990; D’Amico et al. 2006). Psychrophilic enzymes often have a high content of α -helix and little β -sheet secondary structure, enabling a higher flexibility at low temperatures. Cold-active enzymes also tend to have a high polar and a low hydrophobic amino acid content and lower numbers of weak hydrogen and ionic bonds. Unsaturated fatty acids may abound in the cell membrane. Thus, *Polaromonas vacuolata* may contain up to 74%–79% of 16:1 ω 7c, the highest level of this fatty acid reported in any species. In addition it contains 75–95 of 18:1 (Irgens et al.

1996). A high content of polyunsaturated fatty acid is often found in psychrophiles, including members of the Bacteria domain, where occurrence of polyunsaturated fatty acids is very uncommon. Thus, *Psychroflexus torquis* (*Bacteroidetes*) isolated from Antarctic sea ice possesses the unusual ability to synthesize the polyunsaturated fatty acids eicosapentaenoic acid (20:5 ω -3) and arachidonic acid (20:4 ω -6) (Bowman et al. 1998).

The lowest growth temperature recorded for the heterotrophic gas vacuolate *Psychromonas ingrahamii* (*Gammaproteobacteria*), isolated from sea ice of Alaska, is -12°C , with a generation time of 240 h (Breezee et al. 2004). Another organism adapted to low temperatures is *Polaromonas vacuolata* isolated from Antarctic marine waters: it grows optimally at 4°C , with a minimum at 0°C and a maximum at 12°C (Irgens et al. 1996). Other species able to grow at low temperatures are *Psychrobacter cryohalensis* and *Psychrobacter arcticus* isolated from Siberian permafrost: they grow at temperatures from -10°C to $+3^{\circ}\text{C}$ and salinities up to 1.7 M (Bakermans et al. 2006). *Planococcus halocryophilus*, isolated from permafrost, even grows slowly at -15°C , the lowest growth temperature documented for any bacterium (Mykytczuk et al. 2013).

Microbial activity may be possible at even lower temperatures. During respiration measurements in cultures of the Antarctic glacial isolates *Sporosarcina* sp. B5 and *Chryseobacterium* sp. V3519-10 within ice at temperatures from -4°C to -33°C , initial high metabolic rates were followed by lower rates, when the cells entered a non-reproductive dormant metabolic state, but metabolism was sustained by viable cells, as quantified via culturability, reduction of 5-cyano-2,3-ditoyl tetrazolium chloride (CTC), and LIVE/DEAD staining. ^{14}C -labeled acetate was actively respired by these organisms in polycrystalline ice at -5° in the presence

TABLE 9.1.2

Representative Examples of Psychrophilic Microorganisms, Their Taxonomic Affiliation, Habitat, and Properties. The Table Includes a Piezophilic Psychrophilic Species Listed Also in [Table 9.1.6](#)

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Bacteria</i>						
<i>Psychroflexus torquis</i>	<i>Bacteroidetes</i>	Antarctica	Sea ice	0°C to $<20^{\circ}\text{C}$ (opt. 10°C – 15°C)	Aerobic, heterotrophic	Bowman et al. (1998)
<i>Colwellia psycherythraea</i>	<i>Proteobacteria</i>	Atlantic Ocean, Puerto Rico Trench	Seawater depth of 7,410 m	At 2°C growth at 37–103 MPa (opt. 75 MPa); best growth at 10°C and 94 MPa	Aerobic, heterotrophic	Deming et al. (1988)
<i>Psychrobacter arcticus</i> , <i>Psychrobacter cryohalensis</i>	<i>Proteobacteria</i>	Siberia	Permafrost	-10°C to $+30^{\circ}\text{C}$, 0–1.7 M NaCl	Aerobic, heterotrophic	Bakermans et al. (2006)
<i>Psychromonas ingrahamii</i>	<i>Proteobacteria</i>	Alaska	Sea ice	-12°C to $+10^{\circ}\text{C}$; 0.2–2.1 M NaCl needed; weak growth up to 3.4 M NaCl	Aerobic, heterotrophic	Breezee et al. (2004)

of abundant nutrients, in spite of the low temperatures and the physical ice matrix. *Sporosarcina* even increased in cell numbers and biomass under these conditions (Bakermans and Skidmore 2011a, 2011b). Measurements of [³H]-leucine incorporation into macromolecules by the marine psychrophilic bacterium *Colwellia psychrerythraea* showed incorporation into protein down to -20°C. Presence of exopolysaccharides enhanced the rates (Junge et al. 2006).

Cultivation-independent characterization of the microbial communities within permanently cold marine sediments by means of 16S rRNA gene clone libraries showed a predominance of sequences (43.4%); this can be attributed to sulfate reducers (*Desulfotalea* and others). Additional groups frequently encountered were *Desulfuromonas palmitatis* and groups affiliated with the myxobacteria and with *Bdellovibrio*. Many *Gammaproteobacteria* clones retrieved were related to symbiotic or free-living sulfur oxidizers (Ravenschlag et al. 1999).

Much research on microbial communities at low temperatures was performed in Antarctica (Vincent 1988). Based on ATP measurements, between 3×10^6 and 2×10^9 live bacterial cells per gram soil were calculated to be present in Antarctic soils at temperatures between -0.5°C and +3.8°C (Cowan et al. 2002). Bacterial populations of 200–5,000 cells mL⁻¹ were present in melting Antarctic snow sampled in January 1999 and 2000. 16S rRNA genes affiliated with *Deinococcus* were recovered from this environment. Low but significant rates of bacterial DNA and protein syntheses were measured in the snow at temperatures of -12°C to -17°C (Carpenter et al. 2000). Liquid pockets of concentrated brine within Antarctic sea ice may support active microbial communities, but also the ice itself harbors a diverse community (Thomas and Dieckmann 2002). A cultivation-independent, 16S rRNA gene-based survey of the communities present in Antarctic sea ice showed dominance of *Alphaproteobacteria*, *Gammaproteobacteria*, and *Bacteroidetes*, with other groups also present, showing that the ice contains niches conducive to the proliferation of a diverse array of psychrophilic bacterial species (Bowman et al. 1997).

The perennial ice that covers the Antarctic lakes in the McMurdo Dry Valleys is an interesting habitat for microbial communities that develop within liquid water inclusions in response to solar heating of internal aeolian-derived sediments. Within these complex microbial consortia embedded in the lake ice cover, photosynthesis, nitrogen fixation, and decomposition of organic matter occur (Priscu et al. 1998).

Small communities of prokaryotes were found even within ice at a depth of 3,590 m below the Vostok research station in Antarctica. Between 2.8×10^3 cells and 3.6×10^4 cells per milliliter were detected, mainly affiliated with the *Proteobacteria* and the *Actinobacteria*, but no activity could be detected based on incorporation of organic substrates or bicarbonate (Priscu et al. 1999). Ice below ~3,500 m consists of refrozen water from Lake Vostok, accreted to the bottom of the glacial ice. In the accretion ice, the carbon and energy sources in the veins within the ice can maintain significant numbers of actively metabolizing cells (Price 2000).

Attempts to assess microbial activities by using CTC as a probe for O₂-based respiration were also made in Arctic wintertime sea-ice cores (temperature gradient -2°C to -20°C and salinity of the brine inclusions 38–209 ppt). The CTC-active bacteria (0.5%–4% of the total) and cells detectable by rRNA probes (18%–86% of the total count) were found in all samples, including the coldest ones (-20°C). The percentage of active bacteria (probably affiliated with the *Bacteroidetes*) associated with particles increased with decreasing temperature (Junge et al. 2004).

A highly intriguing Antarctic ecosystem is Blood Falls, McMurdo Dry Valleys, a subglacial outflow from the Taylor Glacier. The falls have a high content of iron and sulfate, likely due to interactions of the subglacial brine with the iron-rich bedrock. The bacterial 16S rRNA gene clone library was dominated by a phylotype affiliated with *Thiomicrospira arctica*, a psychrophilic marine autotrophic sulfur oxidizer. Different representatives of the *Betaproteobacteria*, *Deltaproteobacteria*, and *Gammaproteobacteria* and the *Bacteroidetes* were also found. The brine below the Taylor Glacier hosts an anoxic microbial ecosystem with a limited supply of organic carbon, and based on an active sulfur cycle, with Fe(III) serving as the terminal electron acceptor (Mikucki and Priscu 2007; Mikucki et al. 2009).

The terrestrial permafrost environment and its microorganisms can be considered as a model for conditions for life on other cold planets. The deep cold biosphere is the most stable environment for microorganisms, and possible fluctuations should be explained by geological events only. Cold-adapted microorganisms may survive within permafrost at subzero temperatures over geological time and resume their activities upon thawing. Studies of microbial communities in permafrost sediments of different lithology and age suggest that the temperature and the length of exposure define the ratio between cells that can rapidly resume activity and deep-resting “viable but non-culturable” cells (Vorobtova et al. 1997). Microorganisms may survive within a film of unfrozen water enveloping soil particles that protects them from freezing (Gilichinsky 1997, 2002). Brine lenses called cryopegs are found in Siberian permafrost, and these were formed and isolated from ancient marine sediment layers of the Arctic Ocean ~100,000–120,000 years ago. Owing to its high salinity (170–300 g/L), the water remains liquid at the in situ temperature of -10°C, but even at -15°C, uptake of [¹⁴C]-glucose could be measured. Different types of psychrophilic prokaryotes, including aerobes, fermentative anaerobes, sulfate reducers, acetogens, and methanogens, could be retrieved from these cryopegs (Gilichinsky et al. 2003).

Metabolic activity within Siberian permafrost samples during incubation at different temperatures between +5°C and -20°C was measured by incorporation of ¹⁴C-labeled acetate into lipids. Minimum estimated doubling times ranged from 1 day (at 5°C) to 20 days (at -10°C) to ca. 160 days (at -20°C) (Rivkina et al. 2000). Metabolic activity and growth were tested in a number of bacterial isolates from Siberian permafrost as a function of temperature. Endospore-forming Gram-positive isolates proved unable to grow or metabolize below 0°C. Other Gram-positive isolates showed metabolic activity at lower temperatures but did not show any

growth at -10°C . However, one Gram-negative isolate grew at -10°C , with a doubling time of 39 days. When the temperature decreased below 4°C , more energy was generally used for cell maintenance than for growth (Bakermans et al. 2003).

9.1.4 MICROORGANISMS IN EXTREMELY ACIDIC ENVIRONMENTS

Environments with pH values below 2–3 are not very abundant on our planet (Schleper et al. 1995b). Many of these are associated with volcanic activity: hot sulfur springs, mud pots, etc. found in Italy; Iceland; New Zealand; Yellowstone National Park, USA; and a few other sites. The low pH of such solfataras is often due, at least in part, to thermophilic chemoautotrophic microorganisms that oxidize elemental sulfur and other reduced sulfur compounds to sulfuric acid. At moderate temperatures, microbial activity is generally responsible for the formation of low-pH environments. Bacterial fermentations such as the lactic acid fermentation can locally lower the pH to very acidic values, but most often, the low pH is generated by microbial oxidation of reduced sulfur compounds such as sulfide, elemental sulfur, and pyrite by chemoautotrophic microorganisms that produce sulfuric acid. Many of these organisms are highly acid-tolerant or even obligately acidophilic. Formation of “acid mine drainage” in mining areas where sulfur-containing ores are brought to the surface. Here, microbially mediated oxidation of pyrite often results in the formation of highly acidic wastewaters with a high content of iron and other metal ions (Johnson and Hallberg 2003). The very low pH (~2) and the high concentrations of heavy metals in the waters of the 100-km-long Tinto River (Huelva, southwestern Spain) are not directly associated with recent mining activity, but they originate in the same way as modern acid mine drainage: by the activity of chemolithotrophs obtaining their energy from complex sulfides present in the Iberian Pyrite Belt (González-Toril et al. 2003). Such activity of sulfur-oxidizing autotrophic prokaryotes is not always disadvantageous: acidification resulting from the activity of chemoautotrophic sulfur-oxidizing bacteria is exploited for the commercial recovery of copper and other metals from sulfur-containing ores.

Acidophilic microorganisms are very diverse, physiologically as well as phylogenetically; they occur in all three domains of life (Johnson 1998, 2007; Hallberg and Johnson 2001; Johnson and Aguilera 2016) (Table 9.1.3). The unicellular green alga *Dunaliella acidophila*, isolated from highly acidic waters and soils, is one of the most acidophilic organisms known, as it grows between pH 0 and 3, with an optimum at pH 1 (Pick 1999). The intriguing thermophilic acidophilic alga *Cyanidium* and related organisms found in acidic hot springs are discussed later in this section. There are extremely acidophilic representatives both in the *Euryarchaeota* branch and in the *Crenarchaeota* branch of the Archaea, and extreme acidophiles are also found in different bacterial phyla (*Firmicutes*, *Actinobacteria*, *Proteobacteria*, *Nitrospirae*, and *Aquificae*).

Many extreme acidophiles are unable to grow or even survive at neutral pH. *Acidithiobacillus thiooxidans* (*Proteobacteria*),

which can grow down to pH 0.5, does not grow above pH 4–6 (Temple and Colmer 1951; Kelly and Wood 2000). The most extreme case is the thermophilic (optimum temperature $\sim 60^{\circ}\text{C}$) genus *Picrophilus* (*Euryarchaeota*), with a growth optimum at pH 0.5. Its members can even grow at pH -0.06 , but the cells lyse above pH 4 (Schleper et al. 1995a).

All known acidophilic microorganisms maintain their intracellular pH value close to neutral, and their intracellular enzymatic machinery is not adapted to low pH. The cells must therefore maintain a proton concentration gradient of four or even five orders of magnitude, using powerful proton pumps in the cytoplasmic membrane (Schleper et al. 1995b).

The microbial diversity in acid mine drainage and other low-pH environments was explored using both cultivation-dependent and cultivation-independent methods. A search for eukaryotic microorganisms, fungi as well as protists, in warm (30°C – 50°C) and extremely acidic (pH 0.8–1.38) and metal-rich (Fe, Zn, As, Cu) mine drainage from the Richmond Mine (Iron Mountain, California), based on 18S rRNA gene sequences, showed the presence of a lineage of Rhodophyta (red algae) and amoeboid organisms (Vahlkampfiidae and Heterolobosea), as well as fungal groups associated with the Dothideomycetes and the Eurotiomycetes (Baker et al. 2004). The prokaryotic communities within slime biofilms that had developed on exposed pyrite ore within the same mine were dominated by *Leptospirillum* spp. (*L. ferriphilum* and smaller numbers of *L. ferrodiazotrophum*) and *Ferroplasma acidarmanus*, *Sulfobacillus*, and *Acidimicrobium*-/*Ferrimicrobium*-related species (Johnson 2007). This abandoned mine has become a model system to test metagenomics techniques in a relatively simple, low-diversity ecosystem, enabling reconstruction of near-complete genomes of a *Leptospirillum* sp. and a *Ferroplasma* sp. (Tyson et al. 2004). *Ferroplasma acidarmanus*, a relative of *Ferroplasma acidiphilum*, is an archaeal iron-oxidizing extreme acidophile capable of growth at pH 0, found in slime streamers, and attached to pyrite surfaces in this mine (Edwards et al. 2000). *Ferroplasma* spp. are facultative anaerobes, growing optimally at pH 1.0–1.7 and coupling chemoorganotrophic growth on organic substrates to the reduction of ferric iron (Dopson et al. 2004; Golyshina and Timmis 2005). Cultivation-independent studies in the Tinto River in Spain yielded 16S rRNA sequences very similar to those in acid mine drainage and in abandoned mine sites elsewhere in the world: *Leptospirillum* spp., *Acidithiobacillus ferrooxidans*, *Acidiphilium* spp., *Ferrimicrobium acidiphilum*, *Ferroplasma acidiphilum*, and *Thermoplasma acidophilum*. Archaea made up only a minor fraction of the community (González-Toril et al. 2003; Johnson 2012).

Macroscopically visible growth as streamers in acidic, metal-rich waters in an abandoned copper mine and in a chalybeate spa in North Wales was found to consist of 80%–90% of *Betaproteobacteria*, as based on fluorescence in situ hybridization studies. A single species dominated in the copper mine streamers; in the spa water, this organism was accompanied by a novel acidophilic autotrophic iron oxidizer, closely related to the neutrophilic *Gallionella ferruginea* (Hallberg et al. 2006).

TABLE 9.1.3

Representative Examples of Acidophilic Microorganisms, Their Taxonomic Affiliation, Habitat, and Properties. The Table Includes Thermoacidophilic and Haloacidophilic Species Listed Also in Other Tables in This Chapter

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Archaea</i>						
<i>Sulfolobus acidocaldarius</i>	<i>Crenarchaeota</i>	Yellowstone National Park, USA and acidic hot springs elsewhere	Acidic hot springs	55°C–85°C (opt. 70°C–75°C); pH 0.9–5.8 (opt. 2–3)	Aerobic, heterotrophic on simple organic compounds; facultative autotroph on elemental sulfur	Doemel and Brock (1970); Brock et al. (1972)
<i>Sulfurisphaera ohwakuensis</i>	<i>Crenarchaeota</i>	Japan	Acidic hot spring	pH 1.0–5.0 (opt. 2.0); 63°C–92°C (opt. 84°C)	Facultatively anaerobic, heterotrophic	Kurosawa et al. (1998)
“ <i>Ferroplasma acidarmanus</i> ”	<i>Euryarchaeota</i>	Iron mountain, California	Water from a pyrite mine	pH opt. 1.0–1.7, growth down to pH 0; opt. 35°C–42°C	Chemoheterotroph or chemomixotroph, facultative anaerobic, reducing ferric ions	Edwards et al. (2000); Dopson et al. (2004)
<i>Ferroplasma acidiphilum</i>	<i>Euryarchaeota</i>	Bioleaching pilot plant, Russia	Leaching plant for gold-containing arsenopyrite/pyrite ore	pH 1.3–2.2 (opt. 1.7); 15°C–45°C	Aerobic, obligately autotrophic	Golyshina et al. (2000)
<i>Halarchaeum acidiphilum</i>	<i>Euryarchaeota</i>	Japan	Commercial solar salt	pH 4.0–4.6 (opt. 4.4–4.5); 18–30 NaCl (opt. 21%–24%)	Aerobic, heterotrophic	Minegishi et al. (2008, 2010)
<i>Picrophilus oshimae</i>	<i>Euryarchaeota</i>	Northern Japan	Acidic soil (pH <0.5) heated to 55°C by solfataric gases	pH opt. 0.7, growth also at pH 0; 45°C–65°C (opt. 60°C)	Heterotrophic, aerobic	Schleper et al. (1995a, 1996); Futterer et al. (2004)
<i>Picrophilus torridus</i>	<i>Euryarchaeota</i>	Northern Japan	Acidic soil (pH <0.5) heated to 55°C by solfataric gases	pH opt. 0.7, growth also at pH 0; 45°C–65°C (opt. 60°C)	Heterotrophic, aerobic	Schleper et al. (1995a, 1996); Futterer et al. (2004)
<i>Bacteria</i>						
<i>Leptospirillum ferrooxidans</i>	<i>Nitrospirae</i>	Armenia	Copper mine	pH 1.5–4.0 (opt. 2.5–3.0)	Aerobic; ferrous ions as electron donor for chemolithoautotrophic growth	Hippe (2000)
<i>Acidithiobacillus ferrooxidans</i>	<i>Proteobacteria</i>	West Virginia and Pennsylvania	Coal mine drainage	pH 1.4–6.0 (opt. 2.5–5.8)	Aerobic; ferrous ions or reduced sulfur compounds as electron donor for chemolithoautotrophic growth	Temple and Colmer (1951)
<i>Eukarya</i>						
<i>Dunaliella acidophila</i>	<i>Chlorophyceae</i>	Czech Republic	Acidic water near a sulfur spring	pH 0.3–3.0; NaCl up to 0.5 M	Photoautotrophic	Pick (1999)
<i>Cyanidium caldarium</i>	<i>Rhodophyta</i>	Yellowstone National Park, USA; Japan, New Zealand	Acidic hot springs in volcanic areas	pH 0.2–4.0; 40°C–56°C	Photoautotrophic	Doemel and Brock (1970); Seckbach (1994)

Life at low pH and high temperature is also diverse (Hedlund et al. 2016). Volcanic activity results in the formation of hot springs, and these are often acidic, especially when reduced-sulfur compounds are present. Hot springs can be inhabited by algae of the species *Cyanidium caldarium* and related organisms of the genera *Galdieria* and *Cyanidioschyzon* (Rhodophyta), growing optimally at pH 2–3 and tolerating values as low as pH 0.2 (Seckbach 1994, 1999; Toplin et al. 2008). Field studies in the algae's natural habitats, $^{14}\text{CO}_2$ incorporation measurements of natural populations, and cultivation experiments have shown an upper temperature limit of 55°C–60°C for *C. caldarium* (Doemel and Brock 1970).

Early studies of the acidic hot springs of Yellowstone National Park, USA, led to the discovery of the first thermoacidophilic archaeon, *Sulfolobus acidocaldarius* (*Crenarchaeota*) (Brock et al. 1972). This facultative autotroph can obtain energy from the oxidation of sulfur or from a variety of simple organic compounds. It grows between pH 0.9 and 5.8, with an optimum at pH 2–3 and a temperature optimum of 70°C–75°C. *Sulfolobus* and related organisms have been isolated from many natural acidic thermal habitats worldwide, terrestrial as well as aquatic (e.g., Brierley and Brierley 1973). A relative of *Sulfolobus* that tolerates even higher temperatures is *Sulfurisphaera ohwakuensis*, isolated in Japan; it grows up to 92°C, with a minimum pH of 1 (Kurosawa et al. 1998).

Thermoacidophiles with an even lower pH optimum and minimum are found in the genus *Picrophilus* (*Euryarchaeota*). *Picrophilus torridus* and *P. oshimae*, isolated from solfataric locations in Japan, are heterotrophs that grow even below pH 0 at up to 65°C (Schleper et al. 1995a, 1996; Futterer et al. 2004).

A culture-independent study of rocks in a Yellowstone National Park hot spring demonstrated the presence of endolithic microorganisms in rock pore water at pH 1.0. These included organisms phylogenetically affiliated with the genus *Mycobacterium* (Actinobacteria) (Walker et al. 2005).

Deep-sea hydrothermal vents that emit hot water of low pH (<4.5) are inhabited by Archaea of the Deep-sea Hydrothermal Vent Euryarchaeota 2 (DHVE2) group, obligate thermoacidophilic sulfur- or iron-reducing heterotrophs capable of growing from pH 3.3 to 5.8 at 55°C–75°C (Reysenbach et al. 2006).

9.1.5 ALKALINE ENVIRONMENTS AND ALKALIPHILIC MICROORGANISMS

Permanently alkaline lakes (“soda lakes”), whose high pH is caused by geological-geochemical processes, are found on all continents. Some of the best investigated ones are Mono Lake (California), Lake Magadi (Kenya) and other East African soda lakes, the Wadi Natrun lakes in Egypt, and a number of soda lakes in China and Tibet. Many of these alkaline lakes also contain high salt concentrations. Thus, the organisms inhabiting them must be adapted both to high pH and to high salinity (Grant and Tindall 1986; Grant and Jones 2000; Jones and Grant 2000). The Wadi Natrun lakes have become an excellent model for the study of the ecology, physiology, and taxonomy of aerobic and anaerobic haloalkaliphilic microorganisms (Oren 2013). Many soils are alkaline, and many

isolates of alkaliphilic bacteria (here defined as organisms that grow optimally above pH 8 and usually between pH 9 and 10) have been isolated from soils, where transient alkaline conditions may be generated as a result of biological activity (Grant et al. 1990). Alkaline conditions are also commonly encountered in the surface layers of lakes and ponds, where, during daytime, CO₂ becomes depleted as a result of photosynthesis by planktonic algae and cyanobacteria.

A great diversity of alkaliphilic microorganisms is known, both phylogenetically and physiologically. The biogeochemical cycles of carbon, nitrogen, sulfur, and other elements can function at high pH, under both aerobic and anaerobic conditions (Horikoshi 1999; Banciu and Sorokin 2013). Thus, a diverse anaerobic community in the sediments of Lake Magadi (Kenya) and other soda lakes with pH ~10 was found to perform all functions known for neutral-pH environments (Zhilina and Zavarzin 1994; Zavarzin and Zhilina 2000). The eutrophic alkaline desert lakes of Wadi Natrun in Egypt (pH ~11, >300 g/L salt) are inhabited by cyanobacteria, anoxygenic phototrophs, haloalkaliphilic Archaea, sulfate reducers, and many other types of microorganisms (Imhoff et al. 1979; Mesbah et al. 2007a; Oren 2013), including an interesting group of anaerobic fermentative organisms, that, in addition to being adapted to life at high pH and high salinity, have markedly thermophilic properties (Mesbah and Wiegel 2008). The properties of these organisms are further discussed in the last paragraph of this section. Searles Lake (California), a salt-saturated lake at pH 9.8, even supports a full biogeochemical cycle of arsenic, including chemoautotrophic oxidation of As(III) to As(V) in the oxic layer and As(V) respiration in the anaerobic layers (Oremland et al. 2005). Haloalkaliphilic bacteria performing such transformation have been isolated: *Alkalilimnicola ehrlichii* (*Gamma proteobacteria*) from Mono Lake oxidizes arsenite, with nitrate or oxygen as the electron acceptor. It can also use hydrogen, sulfide, or thiosulfate as an electron donor (Hoeft et al. 2007). *Desulfohalophilus alkaliarsenatis* (*Delta proteobacteria*) from Searles Lake can respire both sulfate and arsenate (Switzer Blum et al. 2012).

Alkaliphilic microorganisms maintain their intracellular pH close to neutrality. As energy transformation is commonly based on the outward pumping of protons, the alkaliphiles must thus maintain an inverted pH gradient. Membrane-linked bioenergetic processes are then based on an exceptionally large membrane potential. Still, protons are used as the coupling ions between the respiratory chain and ATP synthase in haloalkaliphilic Archaea (Falb et al. 2005) and in most alkaliphilic Bacteria. But many cases have been reported, especially in haloalkaliphilic anaerobes, where energy transformation processes are linked with the transmembrane transport of sodium ions rather than protons. Thus, Na⁺-dependent ATPases, Na⁺-driven flagellar movement, and Na⁺-driven solute transport systems have been documented. Accordingly, many alkaliphiles are strictly dependent on sodium ions for growth (Banciu and Sorokin 2013).

Table 9.1.4 shows the properties of representative alkaliphilic Archaea and Bacteria available in culture. Hypersaline alkaline lakes such as Lake Magadi and the Wadi Natrun lakes are colored pink-red by dense communities of haloalkaliphilic

TABLE 9.1.4

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Archaea</i>						
<i>Halorubrum vacuolatum</i>	<i>Euryarchaeota</i>	Lake Magadi, Kenya	Hypersaline alkaline lake	pH 8.5–10.5 (opt. 9.5); NaCl needed 2.5–5.2 M (opt. 3.5 M)	Aerobic, heterotrophic	Mwatha and Grant (1993)
<i>Methanosalsum zhilinae</i>	<i>Euryarchaeota</i>	Wadi Natrun, Egypt	Hypersaline alkaline lake sediment	pH 8–10 (opt. 8.7–9.5); NaCl needed 0.2–2.1 M (opt. 0.4–0.7 M)	Anaerobic, methanogenic on methanol or methylated amines	Mathrani et al. (1988)
<i>Natronococcus occultus</i>	<i>Euryarchaeota</i>	Lake Magadi, Kenya	Hypersaline alkaline lake	Opt. pH 9.5–10.0; NaCl needed 1.4–5.2 M (opt. 3.5–3.6 M)	Aerobic, heterotrophic	Tindall et al. (1984)
<i>Natronomonas pharaonis</i>	<i>Euryarchaeota</i>	Wadi Natrun, Egypt	Hypersaline alkaline lake	pH 7–10 (opt. pH 8.5–9.5); 2–5.2 M NaCl (opt. 3.5 M)	Aerobic, heterotrophic	Soliman and Trüper (1982); Falb et al. (2005)
<i>Bacteria</i>						
<i>Anaerobranca horikoshii</i>	<i>Firmicutes</i>	Yellowstone National Park, USA	Soil from geothermal pools	pH 6.9–10.3 (opt. 8.5); 34°C–66°C (opt. 57°C)	Anaerobic proteolytic, fermentative	Engle et al. (1995)
<i>Natranaerobius thermophilus</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	35°C–65°C (opt. 53°C), pH 8.3–10.6 (opt. 9.5); 3.1–4.9 M Na ⁺ (opt. 3.3 M)	Anaerobic, fermentative	Mesbah et al. (2007); Mesbah and Wiegel (2011)
<i>Natranaerobius trueperi</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	26°C–55°C (opt. 52°C); pH 7.8–11.0 (opt. 9.9); 4.1–5.4 M Na ⁺ (opt. 3.9 M)	Anaerobic, fermentative	Mesbah and Wiegel (2009)
<i>Natronovirga wadinatrunensis</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	26°C–56°C (opt. 51°C); pH 8.5–11.1 (opt. 9.9); 3.1–5.3 M Na ⁺	Anaerobic, fermentative	Mesbah and Wiegel (2009)
<i>Thermobrachium celere</i>	<i>Firmicutes</i>	New Zealand, Italy, USA, Argentina, Germany	Geothermally and anthropogenically heated environments	pH 5.4–9.5 (opt. 8.2); 43°C–75°C (opt. 66°C)	Anaerobic proteolytic, fermentative	Engle et al. (1996)
<i>Tindallia magadii</i>	<i>Firmicutes</i>	Lake Magadi, Kenya	Hypersaline soda lake	pH 7.5–10.5 (opt. 8.5)	Anaerobic, fermentative	Kevbrin et al. (1998)
<i>Alkalilimnicola ehrlichii</i>	<i>Proteobacteria</i>	Mono Lake, California	Hypersaline soda lake	pH 7.3–10.0 (opt. 9.3); salinity 15–190 g/L (opt. 30 g/L)	Facultatively aerobic (oxygen or nitrate as electron acceptor), chemoautotrophic (arsenite, hydrogen, sulfide, or thiosulfate as electron donor), or heterotrophic	Hoeft et al. (2007)
“ <i>Desulfohalophilus alkaliarsenatis</i> ”	<i>Proteobacteria</i>	Searles Lake, California, USA	Hypersaline alkaline lake sediment	55–330 g/L (opt. 200 g/L); pH 7.8–9.7 (opt. 9.3)	Anaerobic, respiring sulfate or arsenate	Switzer Blum et al. (2012)

Archaea of the class *Halobacteria* (Oren 2002a). Examples are *Natronomonas pharaonis* isolated from the Wadi Natrun lakes (Soliman and Trüper 1982) and the genera *Natronobacterium* and *Natronococcus* from the East African soda lakes (Tindall et al. 1984; Mwatha and Grant 1993). Alkaliphilic halophilic methanogenic Archaea have also been isolated: *Methanosalsum zhilinae* from the Wadi Natrun lakes produces methane from methanol, methylated amines, and dimethylsulfide (Mathrani et al. 1988).

In the domain Bacteria, we also find alkalithermophiles and even haloalkalithermophiles. The group of anaerobic fermentative thermophilic (optimum 57°C–66°C) alkaliphiles (optimum pH 8.2–8.5 and growing up to pH 9.5–10.3) of *Thermobrachium* and *Anaerobranca* is especially interesting (Wiegel 1998; Kevbrin et al. 2004; Wiegel and Kevbrin 2004). *Thermobrachium celere* (*Firmicutes*) is a proteolytic, obligately anaerobic, moderately alkaliphilic (optimum pH 8.2, growing up to pH 9.5) fermentative bacterium that under optimal conditions has a doubling time of only 10 minutes. It was isolated from geothermally and anthropogenically heated environments (Engle et al. 1996). *Anaerobranca horikoshii* from Yellowstone National Park has similar properties (Engle et al. 1995).

It may be argued that the anaerobic fermentative halothermoalkaliphiles live at the physicochemical boundary for life (Mesbah and Wiegel 2008, 2012; Bowers et al. 2009). The sediments of the Wadi Natrun lakes have yielded isolates such as *Natronovirga wadinatruncensis*, *Natranaerobius thermophilus*, and *Natranaerobius trueperi* (*Firmicutes*; pH optima 9.5–9.9; temperature optima 51°C–53°C; and Na⁺ requirement and tolerance 3.1–5.3 M) (Mesbah et al. 2007b; Mesbah and Wiegel 2009). Analysis of the genome of *N. thermophilus* revealed that the organism may combine two mechanisms for adaptation to high salinity: accumulation of potassium ions together with accumulation of organic osmotic solutes (Mesbah and Wiegel 2011). Cultivation-independent characterization of the microbial community in the water and sediments of the Wadi Natrun lakes shows that they harbor a unique and novel prokaryotic diversity, different from that described from other alkaline, athalassohaline lakes (Mesbah et al. 2007a).

9.1.6 HYPERSALINE ENVIRONMENTS AND HALOPHILIC MICROORGANISMS

Hypersaline environments include salt lakes such as Great Salt Lake (Utah, USA), the Dead Sea on the border between Israel and Jordan, and many other natural hypersaline lakes worldwide. There are also man-made hypersaline lakes: salt-crystallizer ponds for the production of solar salt from seawater by evaporation. In addition, there are saline and hypersaline soils. In many of these environments, the ionic composition reflects that of seawater from which the brines were derived (“thalassohaline environments”), while in other cases (“athalassohaline brines”), the chemical composition of the salts is greatly different from that of seawater. Examples are the Dead Sea, dominated by divalent cations (Mg and Ca) rather than by monovalent cations (Na and K),

with very low sulfate concentrations and a relatively low pH (~6), and soda lakes such as Mono Lake (California, USA) and the East African lakes such as Lake Magadi in Kenya, with high pH (9–10), high carbonate/bicarbonate concentrations, and very low concentrations of divalent cation concentrations. All these environments are inhabited by diverse communities of high-salt-adapted microorganisms. Even rock salt deposited many millions of years ago may be inhabited by microorganisms; some of them may even have survived from the time the salt was formed by evaporation of seawater (Oren 2002a, 2016).

Microorganisms living at high salt concentrations need to maintain their cytoplasm at least osmotically equivalent to their surroundings, in order not to lose water. Maintenance of a turgor pressure even requires a higher osmotic pressure within the cells. Different halophiles have developed two fundamentally different strategies to allow life at the extremely high osmotic pressures exerted by salt-saturated brines. One is based on the accumulation of salts inside the cells at concentrations no less than those in the outside medium. The second strategy involves exclusion of salts from the cytoplasm to a large extent and synthesis or accumulation of simple organic solutes (“osmotic solutes” or “compatible solutes”) to balance the osmotic pressure of the medium. Thus, the highly halotolerant unicellular green alga *Dunaliella* produces glycerol for osmotic stabilization. Many halophilic and halotolerant representatives of the Bacteria and some halophilic Archaea (e.g., the halophilic methanogens) produce solutes such as ectoine, glycine betaine, simple sugars, certain amino acids, and amino acid derivatives. Use of the “low-salt, high-organic-solutes-in” strategy does not require a far-going adaptation of the intracellular osmotic machinery to the presence of high salt concentrations (Galinski 1995; Ventosa et al. 1998; Oren 2000). A different option, realized by the aerobic halophilic Archaea of the class *Halobacteria* and by a limited number of members of the Bacteria such as *Salinibacter* (*Bacteroidetes*) (Antón et al. 2002; Oren et al. 2002) and the obligatory anaerobic *Halanaerobiales* (*Firmicutes*) (Oren et al. 1997), is to accumulate molar concentrations of KCl for osmotic balance. This “salt-in” strategy of osmotic adaptation is possible only when the intracellular enzymatic machinery is fully adapted to function in the presence of high salt concentrations. Thus, many proteins of extreme halophiles such as *Halobacterium* and *Salinibacter* even require molar concentrations of salt for activity and stability. They generally show a very high excess of acidic amino acids (glutamate and aspartate) over basic amino acids (lysine and arginine) and show additional molecular adaptations to stabilize the structure of their enzymes and other proteins and to optimize their activity at high salt concentrations. At low salt concentrations, such enzymes denature and lose their activity (Lanyi 1974; Madigan and Oren 1999; Mevarech et al. 2000; Oren 2000, 2002a, 2002b).

The functional diversity of halophilic/halotolerant organisms that grow at salt concentrations >100 g/L is great: they include oxygenic and anoxygenic phototrophs, aerobic heterotrophs, fermenters, denitrifiers, sulfate reducers, chemoautotrophic sulfur

oxidizers, and methanogens. But not all types of metabolism known from low-salt environments are encountered at salt concentrations approaching NaCl saturation (~300 g/L). Examples of metabolic types missing at the highest salinities are methanogens that produce methane from acetate or from hydrogen/carbon dioxide, dissimilatory sulfate reduction with oxidation of acetate, and autotrophic nitrification. This is probably due to the high energy cost of the adaptation to life at high salt: the upper salinity limit at which each dissimilatory process takes place is correlated with the amount of energy generated and the energetic cost of osmotic adaptation (Oren 1999, 2002b, 2011).

Phylogenetically, we find halophilic and highly halotolerant microorganisms in all three domains of life. Highly halotolerant unicellular green algae of the genus *Dunaliella* are the main or sole primary producers in salt lakes in which the total salt concentration exceeds 250–300 g/L. We also know halophilic fungi (e.g., *Hortaea werneckii* and *Wallemia ichthyophaga*) and halophilic protozoa of different types. Representative types of halophilic prokaryotes are listed in Table 9.1.5.

Representatives of the archaeal class *Halobacteria* (Euryarchaeota) are the extreme halophiles par excellence: red-pink pigmented organisms that characteristically color the brines

TABLE 9.1.5

<i>Archaea</i>						
<i>Halarchaeum acidiphilum</i>	<i>Euryarchaeota</i>	Commercial solar salt	Marine salt production facilities	pH 4.0–4.6 (opt. 4.4–4.5); 3.1–5.1 M NaCl (opt. 3.6–4.1 M)	Aerobic, heterotrophic	Minegishi et al. (2008, 2010)
<i>Halobacterium salinarum</i>	<i>Euryarchaeota</i>	Different locations worldwide	Salt lakes, salterns, salted proteinaceous products	3–5.2 M NaCl (opt. 3.5–4.5 M)	Aerobic heterotrophic; potential for fermentative growth and photoheterotrophy	Oren (2002a); Gruber et al. (2004)
<i>Haloquadratum walsbyi</i>	<i>Euryarchaeota</i>	Spain, Australia	Solar salterns	2.4–6.2 M NaCl (opt. >3.1 M)	Aerobic heterotrophic, possibly also photoheterotrophic	Burns et al. (2007)
<i>Halorubrum lacusprofundi</i>	<i>Euryarchaeota</i>	Deep Lake, Antarctica	Cold hypersaline lake	1.5–5.1 M NaCl (opt. 2.6–3.4 M). Opt. growth at 31°C–37°C, slow growth at 4°C	Aerobic, heterotrophic	Franzmann et al. (1988)
<i>Halorubrum vacuolatum</i>	<i>Euryarchaeota</i>	Lake Magadi, Kenya	Hypersaline alkaline lake	pH 8.5–10.5 (opt. 9.5); 2.5–5.2 M NaCl needed (opt. 3.5 M)	Aerobic, heterotrophic	Mwatha and Grant (1993)
<i>Methanosalsum zhilinae</i>	<i>Euryarchaeota</i>	Wadi Natrun, Egypt	Hypersaline alkaline lake sediment	pH 8–10 (opt. 8.7–9.5); 0.2–2.1 M NaCl needed (opt. 0.4–0.7 M)	Anaerobic, methanogenic on methanol or methylated amines	Mathrani et al. (1988)
<i>Natronococcus occultus</i>	<i>Euryarchaeota</i>	Lake Magadi, Kenya	Hypersaline alkaline lake	Opt. pH 9.5–10.0; 1.4–5.2 M NaCl needed (opt. 3.5–3.6 M)	Aerobic, heterotrophic	Tindall et al. (1984)
<i>Natronomonas pharaonis</i>	<i>Euryarchaeota</i>	Wadi Natrun, Egypt	Hypersaline alkaline lake	pH 7–10 (opt. pH 8.5–9.5); 2–5.2 M NaCl needed (opt. 3.5 M)	Aerobic, heterotrophic	Soliman and Trüper (1982); Falb et al. (2005)
<i>Bacteria</i>						
<i>Salinibacter ruber</i>	<i>Bacteroidetes</i>	Mallorca, Spain	Solar salterns	2.6–5.1 M NaCl (opt. 4.3–5.1 M)	Aerobic heterotrophic; potential for photoheterotropy	Antón et al. (2002)
<i>Natrananaerobius thermophilus</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	35°C–65°C (opt. 53°C); pH 8.3–10.6 (opt. 9.5); 3.1–4.9 M Na ⁺ (opt. 3.3 M)	Anaerobic, fermentative	Mesbah et al. (2007); Mesbah and Wiegel (2011)

TABLE 9.1.5 (Continued)

Representative Examples of Halophilic Microorganisms, Their Taxonomic Affiliation, Habitat, and Properties. The Table Includes Haloalkaliphiles, Halothermoalkaliphilic Species, and a Haloacidophile Listed Also in Other Tables in This Chapter

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Natranaerobius trueperi</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	26°C–55°C (opt. 52°C); pH 7.8–11.0 (opt. 9.9); 4.1–5.4 M Na ⁺ (opt. 3.9 M Na ⁺)	Anaerobic, fermentative	Mesbah and Wiegel (2009)
<i>Natronovirga wadinatruncensis</i>	<i>Firmicutes</i>	Wadi Natrun, Egypt	Hypersaline soda lake	26°C–56°C (opt. 51°C); pH 8.5–11.1 (opt. 9.9); 3.1–5.3 M Na ⁺	Anaerobic, fermentative	Mesbah and Wiegel (2009)
“ <i>Desulfohalophilus alkaliarsenatis</i> ”	<i>Proteobacteria</i>	Searles Lake, California, USA	Hypersaline alkaline lake sediment	55–330 g/L total salts (opt. 200 g/L); pH 7.8–9.7 (opt. 9.3)	Anaerobic, respiring sulfate or arsenate	Switzer Blum et al. (2012)
<i>Alkalilimnicola ehrlichii</i>	<i>Proteobacteria</i>	Mono Lake, California	Hypersaline soda lake	pH 7.3–10.0 (opt. 9.3); salinity 15–190 g/L; total salts (opt. 30 g/L)	Facultatively aerobic (oxygen or nitrate as electron acceptors), chemoautotrophic (arsenite, hydrogen, sulfide, or thiosulfate as electron donors), or heterotrophic	Hoeft et al. (2007)

of saltern crystallizer ponds, the north arm of Great Salt Lake, and other hypersaline lakes red due to their presence in large numbers. Among the neutrophilic members of the group, the best known ones include *Halobacterium salinarum* (Gruber et al. 2004) and the unusual flat, square-shaped *Haloquadratum walsbyi*, first isolated only in 2004 but now known as one of the dominant components of many hypersaline brines (Bolhuis et al. 2006; Burns et al. 2007). These organisms typically require at least 200–250 g/L salt for growth, and they even grow at salt saturation. The interesting *Salinibacter ruber* (*Bacteroidetes*) shares many properties with the *Halobacteria* group, including its “high-salt-in” mode of osmotic adaptation, in spite of its disparate phylogenetic position (Antón et al. 2002). Table 9.1.5 also lists several alkaliphilic members of the *Halobacteria* (*Natronomonas pharaonis*, *Natronococcus occultus*, and *Halorubrum vacuolatum*) isolated from the alkaline hypersaline lakes of the Wadi Natrun in Egypt and Lake Magadi in Kenya. These were discussed further in the previous section on alkaliphilic microorganisms. Growth of such extreme halophiles at low pH is rarely observed. A rare exception is *Halarchaeum acidiphilum*, a non-pigmented member of the *Halobacteria*, isolated from a sample of commercial solar salt that did not have any acidic properties. It grows at pH 4.0–6.0 (optimum at pH 4.4–4.5) and 15°C–45°C (Minegishi et al. 2008, 2010). Alkaliphilic halophiles are also found among the Bacteria. An example is *Alkalilimnicola ehrlichii* from Mono Lake (Hoeft et al. 2007).

As shallow hypersaline basins in tropical areas can reach quite high temperatures during daytime, there is also a niche for thermophilic halophiles. Some aerobic halophilic Archaea

(*Haloarcula quadrata*, *Haloferax elongans*, *Haloferax mediterranei*, and *Natronolimnibius aegyptiacus*) have temperature optima between 51°C and 55°C (Bowers and Wiegel 2011). *Halothermothrix orenii*, a halophilic, thermophilic (optimum 60°C), fermentative, strictly anaerobic bacterium, was isolated from the sediment of a Tunisian salt lake (Cayol et al. 1994). The interesting haloanaerobic alkalithermophiles discovered in the sediments of the Wadi Natrun (Egypt) soda lakes (*Natronovirga* and *Natranaerobius* species) were discussed in the previous section on life at high pH.

On the Antarctic continent, there are a number of unfrozen hypersaline lakes that harbor interesting communities of cold-adapted halophiles. Deep Lake, Antarctica, was the source of isolation of *Halorubrum lacusprofundi* (Franzmann et al. 1988). Metagenomic studies showed that *Hrr. lacusprofundi* shares its ecosystem with three additional types of halophilic Archaea of different genera. These organisms have extensively exchanged genes and have even shared long contiguous pieces of DNA (DeMaere et al. 2013; Williams et al. 2014).

Different types of athalassohaline brine are also inhabited by diverse communities of microorganisms (Oren 2013). While Na and K ions stabilize proteins, Ca and Mg ions at high concentrations disrupt biological structures, based on the “Hofmeister series” of stabilizing (“kosmotropic ions”) and destabilizing (“chaotropic”) ions (Hofmeister 1888). The waters of the Dead Sea, with >2 M Mg, >0.5 M Ca, and <1.5 M Na, have now become too toxic to support extensive life. In 2007, small but diverse communities of *Halobacteria* could still be detected using a cultivation-independent approach

(Bodaker et al. 2010). Since then, the continuing drying out of the lake led to a further increase in the concentrations of Mg and Ca and a further decrease in the ratio of kosmotropic vs. chaotropic cations. It is well possible that the brines of the lake have, by now, become devoid of life. However, no recent studies have been devoted to the exploration of the current status of the lake's biota. Some fungi, including *Hortaea werneckii*, *Eurotium amstelodami*, *Eurotium chevalieri*, and *Wallemia ichthyophaga*, are extremely tolerant to high concentrations of MgCl₂ (up to 2.1 M) or CaCl₂ (up to 2.0 M), without compensating kosmotropic salts, but no obligate "chaophilic" fungi have yet been discovered (Zajc et al. 2014).

The brines of Discovery Basin, a deep anoxic basin on the bottom of the Mediterranean Sea (depth ~3,585 m) are almost saturated with MgCl₂, present at a concentration of ~5 M. Examination of the occurrence of active microbial life along the gradient from normal seawater to the MgCl₂ brines on the bottom of the basin suggested that, in the absence of kosmotropic solutes, the upper MgCl₂ concentration for life is about 2.3 M (van der Wielen et al. 2005; Hallsworth et al. 2007).

9.1.7 HOT AND COLD DESERTS AND THEIR MICROBIAL COMMUNITIES

Life depends on water. Therefore, areas with low water availability are harsh habitats for life. This is true for hot deserts as well as for very cold desert environments such as the Dry Valleys in Antarctica. Because of the relevance of such environments as model systems to evaluate the possibilities for life in space, relatively much research has been devoted to the presence and activities of microorganisms in the driest deserts on Earth.

Mars-like soils in the most arid region of the Atacama Desert in Chile contain very little organic material, and in most samples, the numbers of colony-forming heterotrophic bacteria were below the detection limits of dilution plating. Decomposition of organic material in these soils is probably due mainly to non-biological processes (Navarro-González et al. 2003). Solar ultraviolet-B (UVB) radiation kills even the most resistant microorganisms within a few hours of exposure to the conditions of the Atacama. However, endospores of *Bacillus subtilis* (*Firmicutes*) and conidia of *Aspergillus niger* (*Ascomycota*) incubated in the dark in the Atacama Desert for up to 15 months survived to a significant extent (Dose et al. 2001).

Microorganisms can survive in deserts, hot as well as cold ones, as endolithic communities below the surface of sandstone and other porous rocks. There, they are relatively protected from extreme desiccation and from excess light. The organisms rapidly switch their metabolic activities on and off in response to environmental changes. In hot desert rocks, the endolithic community consists entirely of cyanobacteria (mainly *Chroococcidiopsis*) and other prokaryotes. Growth is slow, but the communities can survive for very long times. Production of pigments,

exopolysaccharides, and osmoprotectants may also reduce the level of stress (Friedmann 1980; Omelon 2016). Characterization of hypolithic communities of *Chroococcidiopsis* and associated heterotrophs colonizing translucent stones in Atacama revealed that each stone supported a number of unique 16S rRNA gene-defined genotypes. In the most arid zone of the Atacama Desert, such hypolithic cyanobacteria are rarely found (Warren-Rhodes et al. 2006).

The Dry Valleys of Eastern Antarctica are the coldest and driest deserts on Earth (Cowan et al. 2007). Yet, a narrow subsurface zone of certain rock types is colonized by microorganisms (Friedmann 1980; Cowan et al. 2010). Lichens, growing between the crystals of porous rocks, are the dominant compound of this community (Friedmann 1982); the endolithic communities of the cold deserts of Antarctica thus differ from those of the hot deserts by dominance of eukaryotes rather than prokaryotes (Friedmann 1980). A large number of black, mostly meristematic fungi were isolated from these lichen-dominated communities. Most isolates were affiliated with the Dothideomycetidae, genera *Friedmanniomycetes* and *Cryomyces*. All had thick melanized cell walls and could produce exopolysaccharides (Selbmann et al. 2005). A small-subunit rRNA gene clone library prepared from a cryptoendolithic community from the McMurdo Dry Valleys yielded 51 phylotypes: 46 bacterial and 5 of eukaryotes; no Archaea were detected. In the lichen-dominated community, three rRNA sequences of types known to be associated with lichens, attributed to a fungus, a green alga, and a chloroplast, accounted for over 70% of the clones. Other sequences belonged to a member of the *Alphaproteobacteria* that may be capable of aerobic anoxygenic photosynthesis and to a distant relative of *Deinococcus* (de la Torre et al. 2003). Using GeoChip-based functional gene arrays, autotrophic, heterotrophic, and diazotrophic life strategies were identified in the microbial communities. The rocky substrates supported greater functional diversity in stress-response pathways than in the surrounding soils (Chan et al. 2013). But also, the soils contain unexpectedly high levels of microbial biomass, as estimated by using bioluminescent ATP assays. Estimates were as high as 3×10^6 – 4×10^8 cells per gram of surface soil in Antarctic desert sites (Cowan et al. 2002). This community is phylogenetically diverse (Cary et al. 2010).

9.1.8 MICROBIAL LIFE AT HIGH HYDROSTATIC PRESSURE

The mean depth of the oceans is about 4 km, equivalent to a pressure of 400 atmospheres or 40 MPa, and the deepest parts of the oceans are more than 10-km deep. Microorganisms living in such environments must withstand pressures of >100 MPa. The deep sea is inhabited not only by microorganisms: a variety of marine animals is adapted to life at high pressures. As most of the deep sea is also cold (typically 1°C–3°C), microorganisms living there must possess both psychrophilic

and piezophilic/barophilic) or piezotolerant/barotolerant properties (Yayanos 1995, 2000; Horikoshi 1998). Deep-sea bacteria adapted to life at high pressure and low temperature generally grow slowly, so that the overall microbial activity in the deep-sea environment is low (Jannasch and Taylor 1984; Jannasch and Wirsen 1984).

Because of the complex technical demands of performing experiments at hundreds of atmospheres of pressure, without decompression that kills obligately piezophilic microorganisms, our understanding of the special adaptations of such organisms is limited (Kato et al. 2004).

Microorganisms isolated from low-pressure environments generally do not grow well when exposed to high hydrostatic pressure. In *Escherichia coli*, DNA-binding proteins often display pressure-sensitive binding properties. Translation, involving nucleic acid-protein interactions, is another pressure-sensitive process (Bartlett et al. 2007). Bacteria from the ocean generally grow fastest at pressures close to those present at the depth from which they were isolated (Yayanos et al. 1982), showing a high degree of adaptation to the environment. Thus, a spirillum isolated from a depth of 5,700 m grew optimally, with generation times of 4–13 h, at about 50 MPa and 2°C–4°C. When grown at the same temperatures and at atmospheric pressure, the generation time was 3–4 days (Yayanos et al. 1979). A bacterium isolated from an amphipod retrieved (with decompression) from a depth of 10,476 m in the Mariana Trench did not grow at 38 MPa and showed optimal growth at 69 MPa (generation time 25 h at 2°C). At 103.5 MPa, close to the in situ pressure, the generation time at 2°C was ~33 h (Yayanos et al. 1981). Obligate piezophiles unable to grow at atmospheric pressure also exist: isolates related to *Shewanella* and *Moritella* (*Gammaproteobacteria*), retrieved from the Mariana Trench, the Japan Trench, and the Philippine Trench, require 70–80 MPa pressure for optimal growth and do not grow below 50 MPa (Kato and Bartlett 1997; Kato et al. 1998). Isolate MT41 from the Mariana Trench does not grow below 50 MPa, has its optimum at 70 MPa, and tolerates at least 100 MPa (Yayanos et al. 1981; Yayanos 2000). Different isolates of barophilic and barotolerant bacteria were also obtained from deep-sea sediment samples (Kato et al. 1995).

Molecular studies of barophilic members of the genus *Shewanella* enabled the identification of several genes whose expression is pressure-regulated (Kato and Bartlett 1997). Further molecular genetic studies using *Photobacterium profundum* led to the identification of genes important for pressure sensing or pressure adaptation, including genes required for fatty acid unsaturation, the membrane protein genes *toxR* and *rseC*, and the DNA recombination gene *recD*. Genes for the production of omega-3 polyunsaturated fatty acids are frequently found in deep-sea bacteria (Bartlett 1999).

The deep-sea hot vents are hotspots of life on the sea bottom. As discussed in Section 9.1.2, such hot vents have been a treasure trove for the discovery of interesting thermophilic

Archaea and Bacteria. As such hot vents are typically found at depths of several kilometers below the sea surface, the organisms inhabiting them must also be barophilic or at least barotolerant. The properties of some of these pressure-tolerant thermophiles are listed in Table 9.1.6. Temperature tolerance and pressure requirement are often interrelated: the higher the pressure, the higher the temperature minimum and maximum for growth (Pledger et al. 1994). A well-known case is *Methanopyrus kandleri* strain 116, a methanogenic archaeon isolated from a hydrothermal vent at the Central Indian Ridge (depth 2.5 km), reported to grow at 122°C, the highest growth temperature reported thus far, but only when incubated at high pressure (20 MPa). At 0.4 MPa, no growth was obtained above 116°C (Takai et al. 2008).

Other examples of such barotolerant thermophiles are as follows:

- *Pyrolobus fumarii*, isolated a depth of 3,650 m from a hydrothermally heated black smoker wall at the Mid-Atlantic Ridge. It can grow up to 113°C and up to at least 25 MPa pressure (Blöchl et al. 1997).
- *Pyrococcus abyssi*, isolated from 2-km-deep hydrothermal vents in the North Fiji basin. The upper growth temperature (~102°C) is extended by at least 3°C when cells are cultivated under the in situ hydrostatic pressures of 20 MPa (Erauso et al. 1993).
- *Marinitoga piezophila*, isolated from a 2,630-m deep hydrothermal chimney sample collected from the East-Pacific Rise. Its growth is enhanced by hydrostatic pressure; the optimal pressure for growth is 40 MPa, that is, higher than the 26 MPa pressure at the sampling site (Alain et al. 2002).
- *Thermococcus peptonophilus*, isolated from a hydrothermal vent in the western Pacific Ocean at a depth of 1,380 m. Its optimal growth temperature shifted from 85°C at 30 MPa to 90°C–95°C at 45 MPa. Cell viability following starvation was enhanced at 30 and 45 MPa as compared with atmospheric pressure (Canganella et al. 1997).
- *Thermococcus barophilus*, isolated from a hydrothermal vent site on the Mid-Atlantic Ridge (3,550-m depth). It grew at 48°C–95°C under atmospheric pressure, but for growth above 95°C, a pressure of 15.0–17.5 MPa was required. The optimal temperature for growth was 85°C at both high (40 MPa) and low (0.3 MPa) pressures. At 85°C, the growth rate was twice as high at the in situ hydrostatic pressure as compared with that at low pressure (Marteinsson et al. 1999).
- *Palaeococcus ferrophilus*, isolated from a deep-sea hydrothermal vent chimney in the Ogasawara-Bonin Arc, Japan, growing optimally at 83°C and 30 MPa (Takai et al. 2000).

TABLE 9.1.6

Representative Examples of Piezophilic Microorganisms, Their Taxonomic Affiliation, Habitat, and Properties. The Table Includes Thermophilic and Psychrophilic Species Listed Also in Other Tables in This Chapter

Name	Affiliation	Isolated from	Properties of the		Other Properties	References
			Environment	Limits of Existence		
<i>Archaea</i>						
<i>Methanopyrus kandleri</i> strain 116	<i>Euryarchaeota</i>	Central Indian Ridge	Black smoker fluid, 2,450 m depth, hydrothermal field	Max. 116°C at 0.4 MPa; 122°C at 20 MPa	Chemolithoautotroph methanogenic on hydrogen/carbon dioxide	Takai et al. (2008)
<i>Palaeococcus ferrophilus</i>	<i>Euryarchaeota</i>	Deep-Sea, Japan	Hydrothermal vent, 1,338 m depth	60°C–88°C (opt. 83°C); 0.1–60 MPa (opt. 30 MPa)	Anaerobic chemoorganotroph oxidizing proteinaceous compounds with elemental sulfur or ferrous iron as electron acceptor	Takai et al. (2000)
“ <i>Pyrococcus abyssi</i> ”	<i>Euryarchaeota</i>	Hydrothermal vent, SW Pacific	Hydrothermal vent fluid, 2,000 m depth	67°C–102°C, opt. 96°C at 0.1 MPa. Upper temp. 105°C at 20 MPa	Anaerobic heterotrophic, fermentative	Erauso et al. (1993)
<i>Thermococcus peptonophilus</i>	<i>Euryarchaeota</i>	Western Pacific Ocean	Deep-sea hydrothermal vent	60°C–100°C (opt. 85°C–90°C). Opt. 30–45 MPa. Opt. temp. shifts from 85°C at 30 MPa to 90°C–95°C at 45 MPa	Grows on proteins and amino acids; growth is stimulated by elemental sulfur	González et al. (1995); Canganella et al. (1997)
<i>Bacteria</i>						
<i>Colwellia psychrerythraea</i>	<i>Proteobacteria</i>	Atlantic Ocean, Puerto Rico Trench	Seawater, 7,410 m depth	At 2°C, growth at 37–103 MPa (opt. 75 MPa); best growth at 10°C and 94 MPa	Aerobic, heterotrophic	Deming et al. (1988)
<i>Marinibacter piezophila</i>	<i>Thermotogae</i>	East Pacific Rise	Hydrothermal chimney, 2,630 m depth	Opt. 40 MPa; 45°C–70°C, opt. 65°C	Anaerobic, chemoorganotrophic, uses carbohydrates and proteins with elemental sulfur as electron acceptor	Alain et al. (2002)

9.1.9 LIFE AT HIGH LEVELS OF IONIZING RADIATION

Another extreme environmental condition to which some microorganisms show a surprisingly high level of resistance is ionizing radiation, including radioactivity. The study of the mechanisms enabling microorganisms to tolerate high radiation levels is highly relevant for astrobiology. Table 9.1.7 presents some of the best known radiation-resistant microorganisms from the bacterial and the archaeal domains.

The genus best known for its extreme radiation tolerance is *Deinococcus*, which forms a deep phylogenetic lineage with the thermophilic *Thermus* and relatives. The first member of the genus, *Deinococcus radiodurans*, is still unsurpassed with respect to its tolerance toward high radiation levels: it survives exposure to >5 kGy of gamma

radiation and to 1500 J m⁻² of UV radiation. For comparison, exposure to 5 Gy is lethal for humans. Strains of *D. radiodurans* were originally isolated from canned meat that had been irradiated (Anderson et al. 1956). But the species has also been found in radioactive waste. *Deinococcus* strains have been isolated from desert soil (Rainey et al. 2005) and from many other environments. 16S rRNA gene sequences of *Deinococcus* were also found in South Pole snow (Carpenter et al. 2000). One of the secrets of *Deinococcus* is its extraordinary ability to repair damaged DNA, not only single-strand breaks but also double-strand breaks (Battista 1997; Rothschild 1999; Cox and Battista 2005). It also has special ways to package its DNA and to protect its proteins against damage (Daly 2009).

Studies on the desiccation resistance of ionizing-radiation-resistant organisms suggest that the ability of microorganisms

TABLE 9.1.7
Representative Examples of Radiation-resistant Microorganisms, Their Taxonomic Affiliation, Habitat and Properties. The Table Includes Thermophilic Species Also Listed in Other Tables in This Chapter

Name	Affiliation	Isolated from	Properties of the Environment	Limits of Existence	Other Properties	References
<i>Archaea</i>						
<i>Thermococcus gammatolerans</i> , <i>Thermococcus marinus</i> , <i>Thermococcus radiotolerans</i>	<i>Euryarchaeota</i>	Guaymas Basin, Mid-Atlantic Ridge	Hydrothermal chimneys	55°C–95°C (opt. 88°C), survive 20–30 kGy radiation	Anaerobic, oxidizes proteinaceous compounds with elemental sulfur as electron acceptor	Jolivet et al. (2003a, 2004)
<i>Bacteria</i>						
<i>Rubrobacter radiotolerans</i>	<i>Actinobacteria</i>	Japan	Hot spring	10% survival at ~12 kGy gamma radiation	Aerobic, heterotrophic	Ferreira et al. (1999)
<i>Deinococcus radiodurans</i>	<i>Deinococcus- Thermus</i>	USA	Ground pork and beef	Tolerates >5 kGy gamma radiation	Aerobic, heterotrophic	Brooks and Murray (1981)
<i>Truepera radiovictrix</i>	<i>Deinococcus- Thermus</i>	Azores Islands	Hot spring runoff	Opt. 50°C; pH 7.5–9.5; survives 5.0 kGy	Aerobic, heterotrophic	Albuquerque et al. (2005)

to repair their DNA might be a response to DNA damage caused by prolonged desiccation rather than ionizing radiation (Mattimore and Battista 1996). This is supported by the higher proportions of ionizing-radiation-resistant bacteria found in arid soils as compared with soils from less arid regions (Rainey et al. 2005). However, cells of *D. radiodurans* incubated in the dark in the Atacama Desert for up to 15 months poorly survived, because they were inactivated at relative humidity between 40% and 80%, which typically occurs during desert nights (Dose et al. 2001).

Other radiation-resistant bacteria include *Rubrobacter* spp. (*Actinobacteria*) (Suzuki et al. 1988; Ferreira et al. 1999). The desiccation-tolerant cyanobacterium *Chroococcidiopsis*, found in cold and hot deserts, is also highly resistant to ionizing radiation and possesses efficient repair mechanisms for damaged DNA (Billi et al. 2000). Following exposure to simulated space and Martian conditions, *Chroococcidiopsis* spp. from hot deserts in Chile survived better than a strain from Antarctica (Billi et al. 2011).

The ability to tolerate high radiation levels is also found in a number of thermophilic microorganisms. One of these is *Truepera radiovictrix*, a relative of *Deinococcus*, isolated from hot spring runoff on the Azores Islands. It grows optimally at 50°C, and 60% of the cells survived 5.0 kGy of radiation (Albuquerque et al. 2005). Resistance against gamma radiation resistance was also found in a number of archaeal thermophiles, including *Pyrococcus furiosus* (DiRuggiero et al. 1997) and *Pyrococcus abyssi* (Jolivet et al. 2003b). Following a dose of 2.5 kGy, the *P. furiosus* 2-Mb chromosome was fragmented into pieces, ranging from 500 kb to shorter than 30 kb, but was fully restored upon incubation at 95°C (DiRuggiero et al. 1997). Other radiation-resistant thermophilic Archaea are *Thermococcus gammatolerans* from hydrothermal chimney samples at the Guaymas Basin (Jolivet et al. 2003a) and

T. marinus and *T. radiotolerans*, also retrieved from deep-sea hydrothermal vents (Jolivet et al. 2004).

9.1.10 FINAL COMMENTS

The microorganisms on Earth can colonize at nearly every place on the planet, thanks not only to the fact that they can utilize almost any energy source available but also to the fact that the microbial world can adapt to extremes of temperature (hot as well as cold), pH (from pH <0 to pH >10–11), salt concentration and presence of chaotropic ions, hydrostatic pressure, radiation, and often combinations of one or more of these potentially stressful environmental factors.

As shown in the tables presented in the different sections, most extremophilic microorganisms listed are Archaea (Cavicchioli 2002). Above 90°C–100°C, the only life forms known to develop are Archaea. They probably are the only ones that can maintain the selective permeability of their membranes because of the special structure of their membrane lipids. But members of the Bacteria can also grow at the highest salt concentrations; they can thrive at high and low pH and at low temperatures, and they are superior to the Archaea in their tolerance of high radiation levels. Even some simple eukaryotes (algae and fungi) can grow at extremes of salinity, drought, and pH.

Where there is liquid water on Earth, virtually no matter what the physical and chemical conditions are, there is life. There are only few exceptions. When in deep-sea hydrothermal vents, the extremely high temperature of the water is incompatible with the stability of proteins, nucleic acids, lipid membranes, and other biomolecules, or when the concentration of chaotropic ions in the absence of stabilizing kosmotropic ions is too high for stability of biological structures, life cannot be sustained, in spite of the presence of water in the liquid state.

Our understanding of the possibilities and limitations of life “as we know it” on Earth and of the properties of extremophilic microorganisms of all kinds must be the basis for any search for similar life elsewhere in space (Nealson 1997; Rothschild and Mancinelli 2001).

ACKNOWLEDGMENTS

The author’s current studies of life at high salt concentrations are supported by grants no. 343/13 and 2221/15 from the Israel Science Foundation.

9.2.1 INTRODUCTION

The National Research Council (NRC) Committee’s Decadal Survey on Biological and Physical Sciences in Space reported that “microbial species that are uncommon, or that have significantly increased or decreased in number, can be studied in a ‘microbial observatory (MO)’ on the International Space Station (ISS)” (NRC 2011), and numerous NASA-sponsored studies were performed in response to the NRC recommendations. Furthermore, the NRC’s decadal survey committee recommended that, for MO studies, NASA should: “(a) Capitalize on the technological maturity, low cost, and speed of genomic analyses and the rapid generation time of microbes to monitor the evolution of microbial genomic changes in response to the selective pressures present in the spaceflight environment; (b) Study changes in microbial populations from the skin and feces of the astronauts, plant and plant growth

media, and environmental samples taken from surfaces and the atmosphere of the ISS; and (c) Establish an experimental program targeted at understanding the influence of the spaceflight environment on defined microbial populations.” There is a significant knowledge gap in understanding how the spaceflight environment affects microbial population dynamics; however, this also represents an opportunity to study how microbial populations evolve and how these populations affect crew health, as well as the associated engineering risks of closed environments for long-term space habitation.

To reduce this knowledge gap, this study has sampled several defined ISS environmental surfaces for three consecutive flights, collected air samples, and characterized microbiome by utilizing traditional cultivation procedures as well as state-of-the-art molecular technologies such as amplicon-based targeted sequencing for microbiome and shotgun metagenome

sequencing. In addition, “omics” of several microbial species (bacteria and fungi) that could be cultured were characterized for their novelty, antimicrobial resistance (AMR), and virulence profiles. Furthermore, select microbial species were also exposed outside the space station to characterize their survival capabilities in response to outer-space radiation conditions.

The ISS is a closed system inhabited by microorganisms originating from life support systems, cargo contaminants, and humans. Microorganisms associated with the ISS are exposed to selective pressures from the extreme space environment. In this chapter, attempts were made to discuss microbial (microbiome) and functional (metagenome) diversity of various elements of ISS environments (air and surface). Microbial population estimations using culture-dependent and culture-independent analyses were documented. In addition, descriptions of novel microbial species, their antimicrobial, and virulence characteristics were reported.

9.2.2 SIGNIFICANCE OF THE STUDY

The ISS is a built environment that has been specially designed to meet its physical characteristics and habitation requirements. The microgravity, exposure to space radiation, and increased carbon dioxide concentrations are conditions that are unique to the ISS. Furthermore, a large proportion of the space within the ISS environment is occupied by astronauts. Learning the makeup of the microbial community within this closed system will improve safety and maintenance procedures. The approach seeks to characterize the viable microbiome of the built environment of the ISS when molecular techniques are used and then determine if the built environments of cleanrooms on Earth designed for space exploration are a suitable simulation of the ISS environment.

The microbiome of environmental surfaces on the ISS was characterized so that its relationship to crew and hardware maintenance can be analyzed. The results of these studies will help future habitation scientists ascertain the habitability of the ISS environment over time. In addition, the results validate the usefulness of measuring viable cell diversity and population size at a variety of sites in order to identify the sites that would require more rigorous cleaning regimen. Finally, the results can be used as a basis for comparisons with future human habitation sites and to facilitate the development of enhancements to the ISS that would minimize negative effects on the health of its inhabitants.

The ISS Microbial Observatory (ISS-MO) experimental flight projects used both advanced molecular microbial community analyses and traditional culture-based methods to generate a microbial census of the ISS environment. Substantial insights into how spaceflight changes the population of both beneficial and potentially harmful microbes were documented from the extensive microbial census generated by the omics methodologies. The omics of the spaceflight samples were placed in the NASA GeneLab system, a one-stop data repository, which will enable future space biologists to determine and design suitable spaceflight experiments.

9.2.3 OVERVIEW OF THE “MICROBES IN SPACE”

In the past decade, NASA invested resources to develop capabilities in measuring microbial survival and proliferation in space, as well as in estimating the composition of microorganisms in closed system such as the ISS. In order to comprehensively understand the microbiome of the ISS environmental surfaces, microbial tracking studies were undertaken from simulated systems on the ground and the ISS. In addition, efforts were taken to maximize the use of both the interior (cabin) and the exterior (for mounting science instruments) of the ISS platform for elucidating microbial survival under space conditions. Such microbiological characterizations were intended to explore not only problematic microorganisms but also beneficial microbes for the production of novel bioactive compounds under microgravity. In this regard, known microbial strains were safely taken to the ISS to study the effect of microgravity, and samples were brought from the ISS to characterize them. In addition, environmental samples collected were explored for the microbial diversity of the closed system by using state-of-the-art molecular techniques. Figure 9.2.1 shows some of the approaches taken by NASA and executed at Jet Propulsion Laboratory (JPL; Pasadena, CA) with reference to space microbiology investigations.

9.2.4 MICROBIOME OF SIMULATED HUMAN HABITAT SYSTEM AND CREW RESUPPLY SERVICE VEHICLE (GROUND CONTROL)

A safe, enclosed habitat is needed for potential future human missions to the Moon or Mars, as well as for continued human presence in the ISS. However, long-term confinement results in a lowered immune response, leading to a potential threat to the inhabitants of a closed system from potential microbial contamination. It is critical that the design of safer habitats for crew members is informed by the lessons gathered from characterizing analogous habitats. A key question to address is how the presence of humans affects the accumulation of microorganisms in an enclosed habitat. Isolated by high-efficiency particulate arrestance (HEPA) filtration, the inflatable lunar/Mars analog habitat (ILMAH) is a closed system that was used to simulate ISS conditions and potential human habitats on other planets, except for the exchange of air between outdoor and indoor environments. Although it was mainly commissioned to assess the physiological, psychological, and immunological effects of living in isolation, it was also available for microbiological studies.

9.2.4.1 BACTERIOME OF INFLATABLE LUNAR/MARS ANALOG HABITAT

Both molecular technologies and traditional microbiological techniques were used to catalog microbial succession within the ILMAH. Surface samples were gathered at various locations over the 30-day human occupation of the ILMAH to capture a full range of viable and potential opportunistic pathogenic bacterial population. The cultivable, viable, and metabolically active microbial populations were estimated using traditional cultivation, propidium monoazide

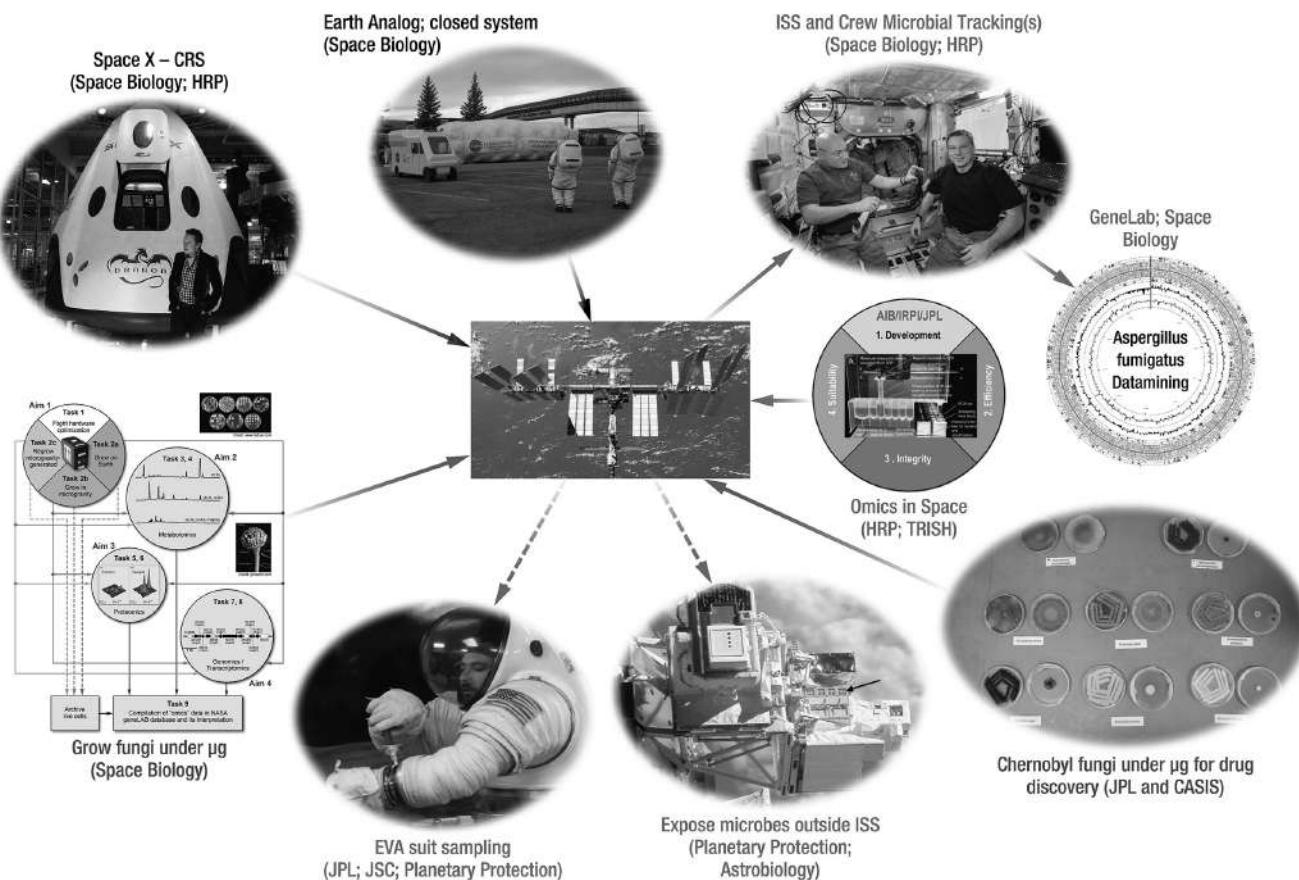

FIGURE 9.2.1 The NASA-funded projects that are interlinking International Space Station as a test bed to measure microbial community of a closed system, to utilize this unique structure to discover novel microbial byproducts, as well as to exploit the distinctive facility in characterizing microbial life in extraterrestrial conditions.

(PMA)-quantitative polymerase chain reaction (qPCR), and adenosine triphosphate (ATP) assays, respectively. Targeted amplicon sequencing was performed to reveal the microbial dynamics and community profiles of samples collected at different sites and times within the ILMAH.

Statistical analyses showed that the length of human occupation strongly affected the bacterial community profiles. The microbial diversity of the samples taken before human occupation (Day 0) was very different from those taken at three later times. Members of Proteobacteria (esp. *Oxalobacteraceae* and *Caulobacteraceae*) and Firmicutes (especially *Bacillaceae*) were most abundant before human occupation (Day 0), whereas other members of Firmicutes (*Clostridiales*) and Actinobacteria (especially *Corynebacteriaceae*) were abundant during the 30-day occupation. Samples treated with PMA (a DNA-intercalating dye for selective detection of viable microbial population) had a significantly lower microbial diversity compared with samples that were not treated with PMA.

Statistical analyses of the samples showed that the community structure changed significantly over time, particularly when comparing the bacteriomes existing before human occupation of the habitat (Day 0 sampling) with those after human occupation (Day 13, Day 20, and Day 30 samplings). Actinobacteria (mainly *Corynebacteriaceae*) and Firmicutes (mainly *Clostridiales Incertae Sedis XI* and

Staphylococcaceae) were shown to increase with the length of human occupation. These results indicate that, within a closed habitat, there is a strong link between human presence and succession of microbial diversity. Therefore, we must develop methods and countermeasure tools that can effectively maintain a safe and healthy environment within a closed habitat for future human missions to the Moon or Mars, or beyond.

9.2.4.2 MYCOBIOME OF INFLATABLE LUNAR/MARS ANALOG HABITAT

Fungi can not only be hazardous to inhabitants but also deteriorate the habitat. Consequently, it is important to characterize and understand the possible changes and succession of fungal species. The results of studying these mycobiome changes in the presence of humans will facilitate the development of countermeasures that can safeguard the health of crew members living in a closed habitat.

Both state-of-the-art molecular technologies and traditional microbiological techniques were used to characterize the succession of fungi. Surface samples were gathered at various locations over the 30-day human occupation of the ILMAH to capture both the total and viable fungal populations of common environmental and opportunistic pathogenic species. The community structure and fluctuation of the mycobiome were

measured at various times and locations within the ILMAH by using the internal transcribed spacer region-based iTag Illumina sequencing. Statistical analysis of the samples showed that the viable fungal community structure increased in diversity and decreased in fungal burden over the length of the human occupation. The fungal profiles of the samples collected at Day 20 were distinct from those of samples collected both before and after Day 20. Analysis indicates that the population of viable fungal families such as *Daudiellaceae*, *Teratosphaeriaceae*, *Pleosporales*, and *Pleosporaceae* increased over the course of the human occupation. On a genus level, *Epicoccum*, *Alternaria*, *Pleosporales*, *Daudiella*, and *Cryptococcus* showed increased abundance over the occupation time. The results of the study show that the length of human presence within the closed habitat affects the overall fungal diversity; therefore, it can be concluded that the closed habitat has to be properly maintained to ensure the health of crew members and to preserve the habitat from deterioration.

9.2.4.3 MICROBIOME OF CRS VEHICLE

Several crew resupply service (CRS) vehicles developed by commercial companies were analyzed for their microbiological characteristics. The microbial burden of the CRS vehicles' surfaces ranged from no counts to 10^4 CFU/m², with an average count being 10^3 CFU/m². The bacterial and fungal counts were similar, and only 3 out of 15 locations sampled yielded any counts. When bacterial population was detected in a given location, fungal presence was also noticed. Similarly, most of the locations were devoid of any cultivable microbial population. When amplicon-based Illumina sequencing as well as metagenome sequencing approaches were conducted, only 2 out of 15 samples yielded any results.

The cultivable microbial diversities associated with the inside surface of the CRS vehicles included *Acidovorax* sp., *Arthrobacter siccitolerans*, *Bacillus methylotrophicus*, *Brevibacterium frigoritolerans*, *Compostimonas suwonensis*, *Flavobacterium oceanosedimentum*, *Hymenobacter* sp., *Massilia* sp., *Massilia haematophila*, *Methylobacterium tardum*, *Microbacterium natoriense*, *Microbacterium paroxydans*, and *Sphingomonas asaccharolytica*. Likewise, cultivable fungal diversity of the outside surface of the CRS vehicles included *Alternaria brassicae*, *Aureobasidium pullulans*, *Cryptococcus luteolus*, *Cryptococcus rajasthanensis*, *Diozegia catarinonii*, *Laurilia taxodii*, *Pithomyces chartarum*, *Rhodotorula mucilaginosa*, and *Talaromyces variabilis*.

9.2.5 MICROBIAL CHARACTERIZATION OF ISS ATMOSPHERE OBSERVED VIA HEPA FILTER PARTICULATES

9.2.5.1 MICROBIAL POPULATIONS

Although there is an ever-growing number of ways to detect microorganisms in a given sample by using molecular techniques, a quick and robust method to assess the differential viability of the microbial cells, as a function of phylogenetic

lineage, has yet to be developed. A PMA treatment, coupled with downstream qPCR and pyrosequencing analyses, was used to capture the frequency, diversity, and distribution of viable microorganisms observed via HEPA filter particles and other debris collected from the crew quarters of the ISS. The cultured bacterial counts were found to be higher in the ISS samples than the cultured fungal counts. Rapid molecular analyses were used to provide an estimate of viable population, and the results showed a five-fold increase in bacterial (qPCR-PMA assay) burden when compared with the cultured bacterial population. Bacterial diversity varied with the methods used to identify the stains. The ribosomal nucleic acid (NA)-based technique used to identify the cultivable microbes resulted in only four to eight bacterial species in the ISS samples, but the amplicon-based sequencing used to estimate the viable bacterial diversity detected by the PMA-pyrosequencing method resulted in 12 to 23 bacterial taxa, with the majority being members of actinobacterial genera (*Propionibacterium* and *Corynebacterium*) and *Staphylococcus*. Sample fractions that were not treated with PMA (inclusive of both live and dead cells) resulted in greater diversity than samples that were treated with PMA, yielding 94 to 118 bacterial taxa and 41 fungal taxa. Although the deep sequencing capability of the molecular analysis expanded the knowledge of microbial diversity, the cultivation assay is also important because some of the spore-forming microorganisms were detected only by using the culture-based method, and some of these microorganism were novel (Venkateswaran et al. 2014).

9.2.5.2 COMPARATIVE MICROBIOME PROFILES OF ISS-HEPA AND EARTH-BASED CLEANROOM-HEPA FILTERS

Both traditional cultivation and state-of-the-art PMA-qPCR assays were used to estimate viable microbial populations with the samples collected from the HEPA filters of the ISS and two cleanrooms at the JPL. The amplicon-targeted (16S rRNA gene) Illumina sequencing provided information on microbial diversity and allowed for a comparison of ISS and Earth cleanroom microbiomes. Results of statistical analyses indicated that members of the phyla Actinobacteria, Firmicutes, and Proteobacteria were dominant in the samples examined, but their abundance varied. Actinobacteria were dominant in the ISS samples, whereas Proteobacteria were least common. However, Proteobacteria were dominant in the JPL cleanroom samples. The viable bacterial populations seen by PMA treatment were greatly decreased, but the PMA treatment did not appear to affect the viable bacterial diversity associated with each sampling site. The results of this study strongly suggest that specific microorganisms associated with human skin make a substantial contribution to the microbiome on the ISS, but it is not the case for the cleanrooms at the JPL. For example, *Corynebacterium* and *Propionibacterium* (Actinobacteria) species are dominant on the ISS in terms of viable and total bacterial community composition, but *Staphylococcus* (Firmicutes) species are not (Checinska et al. 2015).

9.2.5.3 COMPARATIVE METAGENOME PROFILES OF ISS-HEPA AND EARTH-BASED CLEANROOM-HEPA FILTERS

Previous studies have reported on the microbial composition of particulates from the ISS HEPA filters (Checinska et al. 2015), but the functional genomics have been characterized only recently (Be et al. 2017). The functional genomics are important because this approach will help to identify constituents that may potentially affect human health and operational mission success. This study analyzes the metagenome profiles at both species- and gene-level resolutions. The ISS-HEPA filter and dust samples were analyzed and compared with samples collected in an Earth-based cleanroom. In addition, dominant, virulent, and novel microorganisms were characterized using metagenome mining. The whole-genome sequences (WGS) of select cultivable strains isolated from these samples were extracted from the metagenome and compared. Results showed that *Corynebacterium ihumii* GD7 dominated the ISS samples at the species level and that ISS samples had lower overall microbial diversity than the cleanroom samples. When the study looked for microbial genes that affect human health, such as antimicrobial resistance and virulence genes, it was found that the ISS samples had a larger number of relevant gene categories when compared with the cleanroom samples. Strain-level cross-sample comparisons were made for *Corynebacterium*, *Bacillus*, and *Aspergillus* to look for possible distinctions in the dominant strain between samples. Species-level analyses of the ISS and cleanroom samples showed distinct differences, meaning that the cleanroom population is not necessarily representative of the space habitation environment found on the ISS (Be et al. 2017). The observation and study of the overall population of viable microorganisms and the functional diversity that is innate to the unique environment of an enclosed habitat are critical to the evaluation of the conditions needed to ensure the long-term health of its human occupants.

9.2.5.4 ROUND SPORE-FORMING BACTERIA ISOLATED FROM SPACECRAFT ASSEMBLY AND ISS ENVIRONMENTS

Bacterial spores are extremely recalcitrant and notoriously difficult to eradicate from contaminated surfaces. The spore's resistance derives from (1) existing in a metabolically dormant state, and (2) a series of protective structures that encase the interior-most compartment, the core, which houses the spore chromosome. The spore has a very different structure than that of a growing cell, with a number of unique features and constituents found in no other cell type (Figure 9.2.2). Organized as a series of concentric shells, starting from the outside and moving inward, spore layers include the coat, outer membrane, cortex, germ cell wall, inner membrane, and core. In some species, an additional layer, referred to as the exosporium, envelops the entire spore (Figure 9.2.2-3 and 9.2.2-4) (Driks 2002b; La Duc et al. 2004; Lai et al. 2003; Probst et al. 2009; Redmond et al. 2004; Vaishampayan et al. 2008; Venkateswaran et al. 2003; Waller et al. 2004).

The exosporium is composed largely of proteins and glycoproteins (Daubenspeck et al. 2004; Lai et al. 2003; Redmond et al. 2004; Todd et al. 2003), and while the function of these proteins and of the exosporium is unclear, preliminary studies suggest a role in protecting the spore from ultraviolet (UV) and other environmental stresses (La Duc et al. 2004; Newcombe et al. 2005; Venkateswaran et al. 2003).

In addition, several novel bacteria have been isolated from spacecraft-associated surfaces, whose spores are often observed to have what appears to be an "extraneous layer (EL; Figure 9.2.2)" (Probst et al. 2009; Venkateswaran et al. 2003). In the case of *Bacillus nealonii* and *Bacillus horneckiae*, scanning electron microscopy reveals a fibrous material that appears to connect spores together (Figure 9.2.2-5 and 9.2.2-7). However, the exact structure and molecular composition of these matrices are not known. Since the EL appears to be an abundant material that encases the spores within it, it is likely that, at a minimum, the EL also contributes to spore resistance by acting as a passive shield.

While the spore coat and exosporium/extraneous layer (E/EL) are known, or likely, to be important to spore rigidity and resistance, their specific roles are quite dissimilar. The spore coat is well studied in *Bacillus subtilis* (a species that lacks the exosporium) (Driks 1999, 2002a, 2002b; Kuwana et al. 2002; Lai et al. 2003) and has been shown to be important in resistance to chemicals and exogenous lytic enzymes that can degrade the spore cortex. *Bacillus pumilus* SAFR-032 exhibits greatly elevated resistance to UV radiation in comparison with *B. subtilis* (Driks 1999; Nicholson et al. 2000; Setlow et al. 2000), and both lack any semblance of an E/EL. This type of resistance is almost certainly not due solely to the spore core (Driks and Setlow 2000). It is highly likely that *B. pumilus* SAFR-032 encodes coat proteins that have specialized roles in resistance and are absent in *B. subtilis*. The roles of the E/EL in resistance remain unclear and are the focus of significant research. Nonetheless, as already argued, it is highly likely that these structures provide, at a minimum, passive resistance to the spore. The spore core is the analogue of the growing cell's protoplast, for it is here that most spore enzymes, ribosomes, and NAs are housed. Several features of the core protect essential molecules during spore dormancy. First, core water content is low, a major factor in resistance to wet heat (Gerhardt and Marquis 1989). Second, abundant dipicolinic acid in the core significantly enhances survival in the presence of wet heat and/or UV radiation (Slieman and Nicholson 2001). Third, small, acid-soluble proteins bind to and stabilize the spore DNA (Driks 2002a; Setlow 1992, 1995). Since the core composition of a spore does not appear to vary greatly among species, while coat and E/EL composition does (Driks 1999; Driks and Setlow 2000; Giorno et al. 2007), the most likely reason that some species (such as *B. pumilus* SAFR-032 and *Bacillus odysseyi* ATCC PTA-4993^T) survive planetary protection-relevant simulated space conditions is the protective effect of the coat, the E/EL, or both. The coat and exosporium are composed predominantly made of protein (Driks 2002a; Kornberg et al. 1968; Strange and Dark 1956; Sylvestre et al. 2002). Therefore, the E/EL team will focus its analysis on the protein components of the coat and the E/EL.

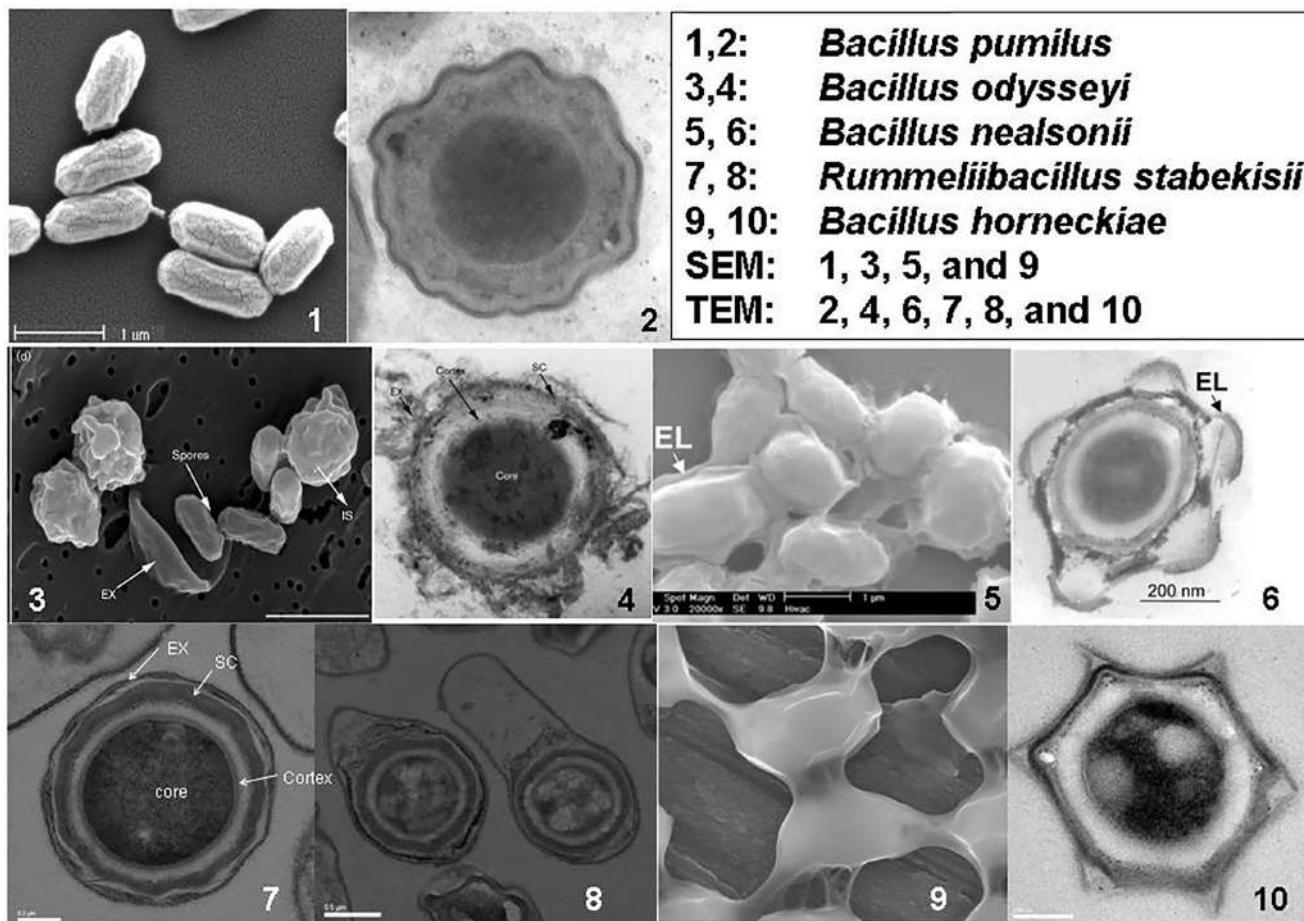

FIGURE 9.2.2 Electron micrographs of exosporium/extraneous layer (E/EL)-bearing spores. 1, 2: *Bacillus pumilus* (no-E/EL); 3: *Bacillus odysseyi* (EX+); 4: *Rummeliibacillus stabekisii* (EX+); 5, 6: *Bacillus nealsonii* (EL+); 7, 8: *Bacillus horneckiae* (EL+). IS: intact spores, SC: spore coat, EX: exosporium (3 and 4), and EL: extraneous layer (5–8).

Among the novel spore-forming bacteria associated with spacecraft assembly and ISS environmental surfaces described, the highly resistant to Mars UV conditions *B. pumilus* SAFR-032 strain was isolated from the JPL spacecraft assembly facility (Newcombe et al. 2005). Similarly, other round spore-forming bacterial species were isolated from surfaces of the Mars Odyssey Orbiter (*B. odysseyi* ATCC PTA-4993^T; Figure 9.2.2-2 and 9.2.2-3), from Phoenix spacecraft (*Rummeliibacillus stabekisii* NRRL B-51320^T [Figure 9.2.2-4] [Vaishampayan et al. 2008] and *B. horneckiae* 1P10SCT^T [Figure 9.2.2-7 and 9.2.2-8] [Probst et al. 2009]), and from the natural particulate fall-out of the JPL spacecraft assembly facility (*B. nealsonii* ATCC BAA-519^T; Figure 9.2.2-5 and 9.2.2-6) (La Duc et al. 2004; Venkateswaran et al. 2003).

Similar to spacecraft assembly facilities, ISS environmental samples also yielded novel round spore-forming bacterial species (Figure 9.2.3) described as *Solibacillus kalamii*. The 16S rRNA gene sequence analyses of this novel species showed highest similarity to several *Solibacillus* species, but DNA–DNA hybridization analysis revealed that *S. kalamii* had DNA-relatedness values in the range of 41%–47%. Based on the phylogenetic analysis, strain ISSFR-015^T

belongs to the genus *Solibacillus*. The polyphasic taxonomic data, including low DNA–DNA hybridization values, and the chemotaxonomic analysis confirmed that strain ISSFR-015^T represents a novel species, for which the name *Solibacillus kalamii* sp. nov. is given (Checinska Sielaff et al. 2017). Furthermore, the whole genomes of several of these round spore-forming bacteria were reported (Gioia et al. 2007; Seuylemezian et al. 2017, 2018).

9.2.5.5 A NOVEL CLADE OF *BACILLUS CEREUS* SENSU LATO GROUP BELONGS TO *BACILLUS ANTHRACIS* ISOLATED FROM ISS ENVIRONMENTS

The microbial characterization of the ISS samples isolated 11 *Bacillus* strains (two from the Kibo Japanese experimental module, four from the U.S. segment, and five from the Russian module), and the whole genomes of these strains were sequenced (Venkateswaran et al. 2017a). A comparative analysis of the 16S rRNA gene sequence of these strains showed the highest similarity (>99%) to the *Bacillus anthracis*–*B. cereus*–*B. thuringiensis* group. The conventional fatty acid composition, polar lipid profile, isoprenoid quinones type, and

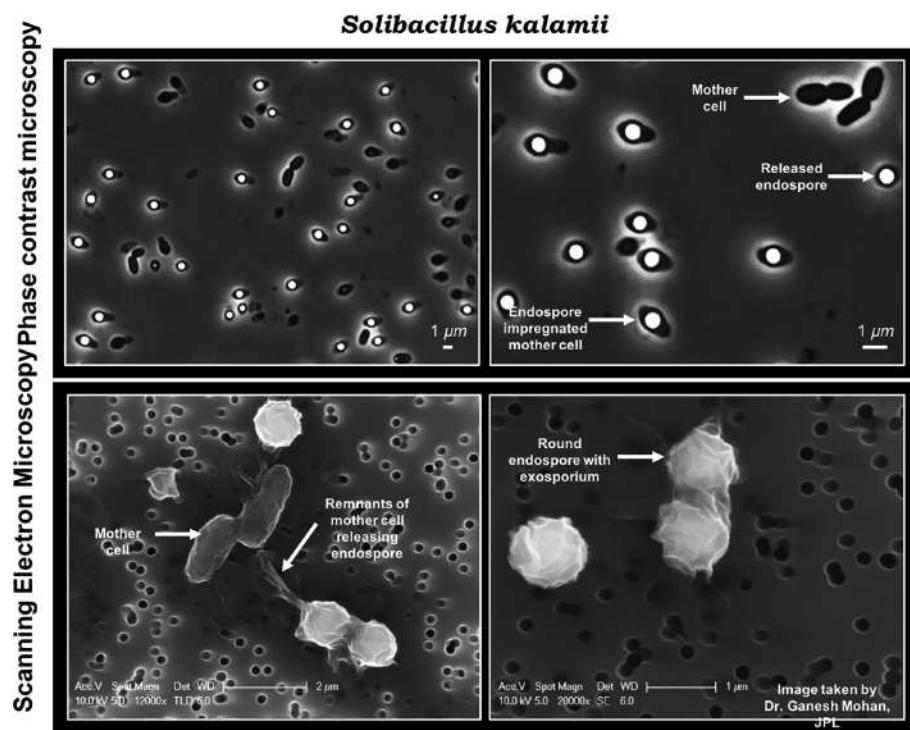

FIGURE 9.2.3 The scanning electron microscopy and phase-contrast microscopy revealed the presence of endospores, round endospores with exosporium, and mother cells of *Solibacillus kalamii*.

peptidoglycan type of the cell wall were similar to those in the *B. cereus* sensu lato group. The multi-locus sequence typing placed these strains far from any described members of the *B. cereus* sensu lato group. On the basis of lacking genes encoding protective antigen (*pag*; pXO1 marker), capsular antigen (*cap*; pXO2 marker), motile cells, and lysing sheep blood (enterotoxin), the ISS isolates were determined as not *B. anthracis*. The digital DNA–DNA hybridization analyses showed that ISS isolates are closer to *B. anthracis* (86%–88%) than to *B. cereus* (44%–47%) and *B. thuringiensis* (44%–46%). However, all isolates contained the *plcR* ancestral “C” allele and lacked significant hits to pXO1 and pXO2 plasmids and toxins specific to *B. anthracis*. Similarly, the genome analysis of these ISS isolates showed no *B. thuringiensis* biomarker, *cry* protein. The DNA G + C content of the strain ISSFR-003^T was 35.4 mol%. Based on phylogenetic analysis, these strains belong to the genus *Bacillus*. However, the collective phenotypic traits and genomic evidence were the reasons to exclude the ISS isolates from *B. anthracis*. Nevertheless, multilocus sequence typing and whole-genome SNP analyses placed these isolates in a clade that is distinct from previously described members of the *B. cereus* sensu lato group but closely related to *B. anthracis* (Venkateswaran et al. 2017b). The spore-forming *B. cereus* sensu lato group consists of pathogenic (*B. anthracis*), food poisoning (*B. cereus*), and biotechnologically useful (*B. thuringiensis*) microorganisms; their presence in a closed system such as the ISS might be a concern for the health of crew members. The pathogenicity and virulence properties of these potential pathogens should be characterized in detail in

order to develop suitable countermeasures for long-term future missions and to provide a better understanding of microorganisms associated with space missions.

9.2.5.6 OMICS CHARACTERIZATION OF VIRULENT ISS *ASPERGILLUS FUMIGATUS* STRAINS

In addition to the bacterial characterization, examining the traits and diversity of fungal isolates would increase the understanding of how fungi may adapt to microgravity environments and how this adaptation may affect their interactions with humans in a closed habitat. Two isolates, ISSFT-021 and IF1SW-F4, of *Aspergillus fumigatus* collected from the ISS were characterized, and the results were compared with the experimentally established clinical isolates Af293 and CEA10 (Knox et al. 2016). The WGS of ISSFT-021 and IF1SW-F4 showed 54,960 and 52,129 single-nucleotide polymorphisms, respectively, compared with Af293, which is consistent with observed genetic heterogeneity among sequenced *A. fumigatus* isolates from diverse clinical and environmental sources. In order to determine if the strain collected from the ISS adapted to its unique environment, the in vitro growth characteristics, secondary metabolite (SM) production, and susceptibility to chemical stresses were compared with those of the clinical strain, but the comparison did not show any exceptional differences between the ISS and clinical strains. However, a virulence assessment in a neutrophil-deficient larval zebrafish model of invasive aspergillosis revealed that both ISSFT-021 and IF1SW-F4 were significantly more lethal than Af293 and CEA10.

The proteomic profiles of the *A. fumigatus* strains were characterized to understand differentially expressed proteins that could be related to the enhanced virulence. Differentially expressed proteins in ISS-isolated strains ISSFT-021 and IF1SW-F4 and clinical isolates Af293 and CEA10 were studied once the total protein was extracted from each strain. Extracted proteins were labeled using tandem mass tag (TMT) and analyzed via LC-MS/MS, and then, a spectra analysis was performed using the Proteome Discoverer with the *A. fumigatus* Af293 database. The abundance ratios of all identified proteins were normalized to the Af293 clinical isolate, which enabled the detection of 553, 464, and 626 upregulated and 314, 289, and 317 downregulated proteins in CEA10, ISSFT-021, and IF1SW-F4 strains, respectively (Blachowicz et al. submitted). To reveal the differentially expressed proteins in space strains only, the Af293 standardized proteins of ISSFT-021 and IF1SW-F4 were further normalized to CEA10, which facilitated the detection of 60 upregulated and 32 downregulated proteins in both space strains simultaneously ($FC > |2|$). Analysis of the upregulated proteins showed that 14 proteins were associated with carbohydrate metabolic processes, eight with stress responses, five with secondary metabolism and toxins biosynthesis, and two with pathogenesis, whereas five, three, one, and zero proteins were downregulated in these categories, respectively. Only the space strains showed an increased abundance of proteins associated with cellular amino acid metabolic process [6], lipid cellular homeostasis [3], metabolic processes [2], pathogenesis [2], and translation [2]. A search of the FungiDB showed that significantly over-represented upregulated biological processes included secondary metabolic processes (40% of all upregulated proteins), carbohydrate metabolic processes (23%), and response to chemical (~15%), whereas significantly over-represented downregulated processes included carbohydrate metabolic processes (15%), response to heat (6%), and mRNA metabolic processes (6%).

The metabolomic profiles were characterized to understand the production of SMs associated with ISS-isolated *A. fumigatus* strains and were compared with clinical isolates (Knox et al. 2016). An inspection of the SM profiles of ISSFT-021, IF1SW-F4, CEA10, and Af293 showed distinctive chemical signatures for each strain under the condition tested. When SM profiles were compared with those of Af293, an increase in fumigaclavine A production was observed in IF1SW-F4 ($p = 0.0001$) but not in ISSFT-021, whereas a significant decrease in fumigaclavine C production was noticed in both strains. Fumiquinazoline production increased in ISSFT-021 but not in IF1SW-F4 compared with the two controls. Pyripyropene A production increased in both ISSFT-021 and IF1SW-F4. Observed SM yields for CEA10 were lower than that for any other strain, with a decrease in production of all but two compounds (pyripyropene A and fumagillin) observed. Nevertheless, as production of SM in media does not necessarily replicate the pattern of production of SMs during infections, the potential *in vivo* SM profiles of the ISS strains remain unclear.

9.2.6 MICROBIAL CHARACTERIZATION OF ISS ENVIRONMENTAL SURFACES (CHECINSKA ET AL. 2018 UNPUBLISHED)

9.2.6.1 MICROBIAL BURDEN ESTIMATION AND CULTIVABLE MICROBIAL DIVERSITY

Cultivable bacterial population. Both traditional culture counts and molecular methods were used to analyze bacteria and fungi samples collected from eight different locations of ISS surfaces. The first two flight sampling sessions (1 and 2) resulted in similar bacterial counts that ranged from 10^4 to 10^9 CFU/m². However, the third flight sampling session resulted in at least 2-logs greater bacterial populations. Three phyla (Actinobacteria, Firmicutes and Proteobacteria) were identified from the 134 bacterial isolates characterized for their phylogenetic affiliations. *Staphylococcus*, *Pantoea*, and *Bacillus* were the most dominant genera at the genus level (Hendrickson et al. 2017).

Cultivable fungal population. The average fungal burden was 10^6 to 10^7 CFU/m². No difference was noticed in the density of the fungal population of flight samples 1 and 3, but the density of the fungal population of flight sample 2 was at least 1 log less than samples 1 and 3. Fungal population ranged from 10^5 to 10^7 CFU/m², and no statistically significant spatial variation in their abundances was noticed. Five different genera were observed among the 64 fungal strains that were identified using molecular phylogeny targeting internal transcribed spacer (ITS) sequences. *Rhodotorula mucilaginosa* and *Penicillium chrysogenum* were dominant among the fungal species. *Rhodotorula mucilaginosa* was found in all location samples from flights 1 and 2, except for location 2 from flight 1. However, *R. mucilaginosa* and *P. chrysogenum* were not found in any samples from flight 3. Furthermore, because it has been reported to be a causative agent for human pathogenicity, it should be noted that *Cryptococcus* (yeast) was also isolated (Furman-Kuklinska et al. 2009; Rimek et al. 2004). Opportunistic human pathogen (*Aspergillus fumigatus*) and plant pathogen (*Fusarium oxysporum*) were also isolated in low numbers. *Aspergillus fumigatus* is a saprophytic, filamentous fungus that is commonly found both outdoors and indoors, and it is able to adapt to various environmental conditions and form airborne conidia that are the inoculum for a variety of diseases in immunocompromised hosts (Hendrickson et al. 2017).

Viable microbial population as measured by PMA-qPCR. The total (dead and alive) and viable bacterial and fungal gene copy numbers were measured using PMA-treated (viable) and non-PMA-treated samples. Flight 1 PMA-treated samples (viable)

compared with non-treated samples (total) resulted in an average of an approximately 50% reduction in bacterial burden, with flight 2 samples resulting in an approximately 75% reduction, but fungal numbers did not change drastically. Both PMA-untreated samples (total) and PMA-treated samples (viable) demonstrated the same trends in microbial load at the various sampling locations. The PMA-qPCR assay was used to estimate the total viable bacterial burden, but there were no statistically significant differences in microbial load from the three flight samples. Flight samples 1 and 2 resulted in similar copy numbers of bacteria and fungi, but flight 3 samples resulted in higher viable bacterial (~60%) and lower fungal (~2-logs less) abundance. It was found that approximately 46% of the viable population were cultivated, when a comparison was made between the cultivable bacterial density and the viable bacterial population detected by the PMA-qPCR (Hendrickson et al. 2017).

9.2.6.2 OPPORTUNISTIC PATHOGENS OF ISS MICROBIAL POPULATION AND THEIR ANTIBIOTIC RESISTANCE

Seven (*Staphylococcus aureus*, *S. haemolyticus*, *S. hominis*, *Acinetobacter pitti*, *Enterobacter* sp., *Klebsiella quasipneumoniae*, and *Pantoea conspicua*) of the 30 different bacterial species cultivated are classified as biosafety level 2 (BSL-2) bacteria. The cupola area samples from the ISS resulted in the isolation of multiple strains of *A. pitti*, with one strain tested using various antimicrobial agents and showing resistance to cefazolin, cefoxitin, oxacillin, penicillin, and rifampicin. The space toilet samples from the ISS resulted in several *Enterobacter* isolates, which were found to be resistant to multiple drugs. The *Enterobacter* species belongs to the coliform group of bacteria; these are reported to be pathogenic, causing opportunistic infections in immunocompromised hosts, and are commonly associated with urinary and respiratory tract infections (Mezzatesta et al. 2012). The cupola, space toilet, and exercise platform samples from the ISS resulted in *Klebsiella* isolates. *Klebsiella quasipneumoniae* is a blood-borne opportunistic pathogen (Brisse et al. 2014). When tested with various antibiotics, *K. quasipneumoniae* strain was found to be resistance to all of them, except for tobramycin. *Pantoea conspicua* was only found in one sampling location on the ISS during two different flights, but it is the second most prevalent species. When tested with various antibiotics, *P. conspicua* was found to be resistant to erythromycin, oxacillin, penicillin, and rifampin. *Pantoea conspicua* was originally isolated from human blood (Brady et al. 2010).

Staphylococcus isolates were the most prevalent cultivable bacteria found from the ISS surface samples, with *Staphylococcus aureus* being the most abundant in all ISS surface samples. Although this species is a common human commensal (Skawinska et al. 2009), it can lead to various types of minor skin infections, bacteremia, or scalded skin syndrome,

particularly for those who are immunocompromised (Archer 1998). The Vitek 2 system (BioMerieux, France) was used for additional testing of the *S. aureus* isolates, and it was found that they were not resistant to methicillin (i.e., not Methicillin-resistant *Staphylococcus aureus* [MRSA] strains). However, most of the *S. aureus* isolates were resistant to penicillin, and some of them were resistant to erythromycin, gentamycin, and tobramycin. A few isolates became resistant to rifampicin during the study. *Staphylococcus haemolyticus* and *S. hominis* belong to coagulase-negative staphylococci (Barros et al. 2012; Mendoza-Olazarán et al. 2013). One *S. hominis* strain was tested and found to be resistant to penicillin and erythromycin, but the *S. haemolyticus* strain was found not to be resistant to these antibiotics. It has been reported that all three *Staphylococcus* species become methicillin-resistant by acquiring the Staphylococcal Cassette Chromosome *mec* (SCCmec) (Katayama et al. 2000), but the methicillin-resistant phenotype was not observed in strains that were isolated from samples collected on ISS surfaces (Urbaniak et al. 2018).

The isolation of *A. fumigatus* is noteworthy among the fungi, because it can cause pathologies ranging from allergic asthma to invasive aspergillosis. Several pathogenic characteristics of the ISS isolates were compared with those of two experimentally established clinical isolates (Nierman et al. 2005; Rizzetto et al. 2013). Virulence assessment in a larval zebrafish model of invasive aspergillosis showed that both strains from the ISS were significantly more lethal than the two clinical isolates (Knox et al. 2016). The omics of strains from the ISS may be able to expose the molecular mechanisms behind the increased virulence. If it turns out that the increased virulence is a result of exposure to microgravity, then NASA should consider creating countermeasures that would protect astronaut health, because it has been reported that the immune systems of astronauts are compromised under microgravity (Crucian et al. 2014). *Cryptococcus laurentii* was previously considered to be a saprophyte and non-pathogenic to humans, but infections caused by cryptococci have been increasingly recognized. It seems to be an important pathogen in cases where immunity has been diminished (Furman-Kuklinska et al. 2009). Furthermore, a case of meningitis caused by *Cryptococcus adeliensis* has been reported in a patient who had acute myeloid leukemia and was undergoing allogeneic peripheral blood stem cell transplantation (Rimek et al. 2004).

9.2.6.3 ISS MICROBIOME PROFILES AS SEEN VIA TARGETED AMPICON SEQUENCING

Up until now, traditional culture techniques have been used for obligatory microbial monitoring and for observational studies of spacecraft and space stations. However, this study also makes use of molecular techniques to analyze microbial communities sampled from various defined ISS locations over three flight missions (Checinska et al. 2018 in submission). The amplicon sequencing was able to detect more bacterial phyla than the culture-based analyses was able to detect, but

the number of identified fungal phyla was similar, regardless of the technique used. In general, amplicon sequencing showed temporal distribution across the three flights but not spatial distribution for the bacteriome, whereas the mycobiome did not show any difference.

The dominant organisms found from the samples of the ISS environmental surfaces were those that are associated with humans, with some of them considered to be opportunistic pathogens on Earth. It is unknown if these organisms could cause disease in astronauts on the ISS, since that would depend on the health of the astronaut and how these organisms function while in the unique environment of the ISS. Nevertheless, the detection of these potential disease-causing organisms emphasizes the value of further genomic and transcriptomic studies to analyze how these ISS microbes function in the space environment and how they may affect the health of astronauts. Because no differences were detected in the composition and richness of the community between PMA-treated (intact cells) and non-PMA-treated (both dead and alive microbes) samples, it implies that the DNA analyzed from these possible opportunistic pathogens found on the ISS is intact/viable and these are not dead organisms. It should be noted that approximately 46% of intact/viable bacteria and 40% of intact/viable fungi could be cultured with the culture media used during this study. These percentages are high when compared with the only 1%–10% of intact/viable microorganisms that can be cultured using samples collected from spacecraft assembly cleanrooms on Earth (Ghosh et al. 2010). One possible reason could be that the ISS is not deprived of nutrients (unlike spacecraft assembly cleanrooms), hermetically sealed, and relatively young (~25 years) in terms of human (maximum six astronauts at a given time) and cargo transport (~4–6 times per year), which are the only methods by which these organisms are transferred.

Many of the organisms identified from the ISS samples form biofilms, such as members of the genus *Acinetobacter* (*Moraxellaceae*), *Sphingomonas*, *Bacillus* (*Bacillaceae*), *Burkholderiales*, *Corynebacterium* (*Corynebacteriaceae*), and *Klebsiella* (*Enterobacteriaceae*) (Biteen et al. 2016), as well as the fungi *Penicillium*, *Aspergillus*, *Cryptococcus*, and *Rhodotorula* (Nunes et al. 2013). These biofilms are known to promote resistance to antibiotics and therefore could be problematic for the health of astronauts if they become infected. Biofilm formation on the ISS itself could also affect the stability of the infrastructure by causing mechanical blockages, reducing heat transfer efficiency, and inducing microbial-influenced corrosion (Beale et al. 2014). Some of the microorganisms identified from the ISS samples that have been associated with microbial-induced corrosion on Earth include *Methylobacterium*, *Sphingomonas*, *Bacillus*, *Penicillium*, and *Aspergillus* (Dai et al. 2016; Pavissich et al. 2010; Rajasekar and Ting 2010; Yang et al. 1998), but what function they play in corrosion aboard the ISS has not been determined. Understanding the potential ability of these microorganisms to form biofilms and the amount of actual biofilm formation on a spacecraft during extended space missions is crucial to

ensuring the structural stability of the crew vehicle when regular indoor maintenance cannot be performed easily.

Members of the family *Staphylococcaceae* and *Enterobacteriaceae* were the most dominant organisms found on samples of the ISS surfaces from the U.S. module, which is similar to the results published for samples from the Japanese module of the ISS (Ichijo et al. 2016); these organisms were found in almost every sample, regardless of the method of detection. Both of these organisms are associated with humans, with *Staphylococcaceae* being commonly found on the skin and in the nasal passage and *Enterobacteriaceae* being commonly linked with the gastrointestinal tract. These two taxa are also commonly found in fitness centers (Mukherjee et al. 2014), office buildings (Rintala et al. 2008), and hospitals (Lax et al. 2017), implying that the microbiome of the ISS is similar to that of other built environments on Earth in that it is influenced by the presence of humans (Mayer et al. 2016). Additional studies examining how long these organisms can survive on the surfaces of the ISS and how easily they can be transferred from one person to the next in space can help to develop countermeasures to reduce the spread of infections among astronauts during simultaneous or even separate flight missions.

Methylobacteriaceae/Methylobacterium was also dominant across samples from various surfaces on the ISS and has been found in NASA spacecraft assembly cleanrooms (Moissl et al. 2007), hospital intensive care units (ICUs) (Poza et al. 2012), and the MARS500 habitat (Schwendner et al. 2017). It is a robust organism that can withstand harsh conditions, such as ionizing radiation and strong cleaning detergents. *Moraxellaceae*, another abundant organism found on samples from the ISS, is also resilient in harsh conditions, and it has been found in higher relative abundances in spacecraft assembly cleanrooms (Bashir et al. 2016), areas of the home that are exposed to many chemicals (i.e., washing machine) (Savage et al. 2016), and deep-sea sediment of inactive hydrothermal vents (Zhang et al. 2016).

9.2.6.4 ISS METAGENOME PROFILES TO ELUCIDATE FUNCTIONAL DIVERSITY

Analysis of metagenomic characteristics of ISS samples targeted both total (dead and live cells) and viable (after PMA treatment) microorganisms. The metagenomic analysis indicates that the AMR footprint mirrors a nosocomial environment. Three pathways that govern the ISS antimicrobial resistance scenario are beta-lactam resistance, cationic antimicrobial peptide (CAMP) resistance, and vancomycin resistance. The study indicates a gradual increase in the AMR profile from the first to the third flight sampling. In-depth metabolic pathway analysis was attempted to examine the parts played by the multiple genes involved in the AMR functions. The shotgun metagenome sequence analysis demonstrated that beta-lactam resistance was prevalent due to a penicillin-binding protein and beta-lactamase enzyme, whereas a two-component system, *ompR* histidine kinase, was key to CAMP resistance. Vancomycin resistance was

primarily due to the presence of alanine racemase and support by other factors. Microbial genes were annotated using a curated Kyoto Encyclopedia of Genes and Genomes (KEGG) database. Read-based analysis indicates that the phage, pro-phage, transposable element, and plasmid gradually increase from the first to the third flight sampling. The findings of the metagenomics study will help NASA understand the functional characteristics associated with the ISS environment, thereby enabling the development of suitable countermeasures to eradicate problematic microorganisms and ensure the health of the crew.

9.2.6.5 FUTURE STUDIES: IN SITU MEASUREMENT OF “OMICS IN SPACE”

The omics in space (OIS) project that is in progress will develop instrumentations for extracting NAs and sequencing methodologies for inflight detection and measurement of several biomolecules related to physiological and immunological effects related to spaceflight (e.g., aging, crew health, elevated antimicrobial resistance, and virulence).

Since Sanger’s founding discovery of dideoxynucleotide sequencing, researchers have successfully developed automated instruments to rapidly sequence the DNA of biological materials. The generation of large data sets was problematic throughout the 1990s, but next-generation sequencing (NGS) platforms emerged in 2005 to solve this issue and to lower cost barriers. The interplay and optimization of chemistry, engineering, software, and molecular biology with NGS development enabled the examination of previously unresolvable biological questions. The ability to generate genome-scale data sets, thoroughly reviewed elsewhere (Mardis 2013), is transforming the nature of biological inquiries and investigations. The NGS biomolecule sequencer (BSeq), using the MinION platform (Ashton et al. 2015; Jain et al. 2015) and PCR instruments (SmartCycler and RAZOR), was adopted by NASA last year; it has successfully sequenced libraries that had been prepared on Earth and shipped to the ISS (Castro-Wallace et al. 2016; McIntyre et al. 2016). A limitation in this study was that samples had to be prepared on Earth before sequencing could be performed on the ISS, as there are no technologies onboard the ISS to process samples, extract biomolecules, and prepare libraries.

The Translational Research Institute for Space Health (TRISH) administered by NASA selected the OIS project to address these limitations by developing an automated Sample-Processing Instrumentation (SPI) for NA extraction that is streamlined, minimizing crew time, reducing the amount of contamination between samples, and producing consistent results. Factors such as the quantity and physical characteristics of the NAs and the desired application(s) will be addressed by preparing high-quality sequencing libraries (Head et al. 2014). The OIS project will generate microbiome data (targeted for bacteria, fungi, and viruses) to address microbial composition, metagenome (crew and environments) for functional characteristics, and miRNA for immunological

function. Moreover, the OIS project will examine epigenetic data to better understand radiation-induced damage, cellular disruption, and aging of astronauts.

The mission of the TRISH is to lead a national effort to apply innovative terrestrial research to human risk-mitigation strategies for long-duration space exploration missions. The OIS project will target biomolecules that may be responsible for physiological and immunological conditions that affect humans during spaceflight missions. The OIS project is a consortium of investigators from various NASA centers, industries, and academia to solve microgravity-related sample-processing issues. This is a 4-year TRISH Core Research Project (TCore), consisting of an interdisciplinary team of omics researchers, experts in biomolecule assay development, and clinicians. Three science principal investigators (PIs) will lead the team and ensure that everyone works in a coordinated fashion.

Advances in molecular biology, including the MinION system recently demonstrated on the ISS through the BSeq project, will enable inflight detection of biomolecules of physiological and psychological stressors (Castro-Wallace et al. 2016). Molecular technologies can be used to identify candidate biomolecules and biomarkers for a variety of medical conditions and could be used to investigate/explore spaceflight-associated physiological changes or to measure the efficacy of countermeasures. The objective of the proposed OIS project is to develop omics capabilities suitable for use in the spaceflight environment. The OIS project will include ground-based state-of-the art gold standard methods and measurements of OIS to reveal changes that are relevant to the mission.

The OIS project will generate vast amount of data by utilizing molecular methods in space to provide TRISH with an opportunity to understand the omics changes under microgravity conditions and microbial communities of both the crew and the habitat. The state-of-the-art molecular methods will allow researchers to not only describe the changes in microbial communities of the ISS but also distinguish whether these biological signatures would negatively affect crew health and engineering systems. Focused and targeted molecular approaches are likely to reveal a subset of novel and medically important microbes posing particular threats to crew health. Archiving of omics data and their availability for extensive datamining may feed into functional genomics activities. It is expected that a range of metadata will allow NASA to correlate microbial community information with temporal or environmental changes.

The development of an all-encompassing, integrated OIS database will enable various phylogenetic- and pathogenetic-based strategies to screen for, and identify, specific subsets of microorganisms (e.g., dominating viral and microbial pathogens, as well as those that bear resistance traits relevant to antibiotics). This data set will (1) create a capability for NASA to compare fluctuating microbial communities to “baseline” standards; (2) enable more accurate assessments of crew health associated with mission planning; (3) allow

evidence-based development of future bio-load management policies, particularly for long-duration missions; and (4) capitalize on parallel research from non-NASA institutions efforts (Hoisington et al. 2014; Ma et al. 2014).

9.2.7 UTILIZATION OF ISS AND INFLUENCE OF MICROGRAVITY IN THE PRODUCTION OF NOVEL DRUG DISCOVERY

Fungi are a great source of natural products that are of use to humankind in the pharmaceutical industry, agriculture, and beyond. Antibiotics (penicillin and cephalosporins), immunosuppressants (cyclosporine A), statins (lovastatin), and citric acid are only a few examples of molecules used by humans. The advance in genome sequencing and its increased availability revealed that the number of known fungal SMs is significantly lower than the predicted gene clusters. These orphan clusters are either dormant under laboratory conditions or expressed at extremely low levels. Artificial induction of silent clusters, such as co-culturing with bacteria or fungi, gene deletion, and heterologous expression in different host, is a subject of study for many scientific groups around the world.

The Natural Products under Microgravity (NP μ G) project seeks to investigate whether unique conditions of the ISS, such as microgravity and enhanced radiation, would trigger changes in the molecular, biochemical, and genetic suit of selected filamentous fungi, resulting in the production of novel SM. This approach would lead to *novel drug discovery that potentially benefits astronauts' health*. In the ISS-NP μ G project, fungal strains isolated from the Chernobyl Nuclear Power Plant (ChNPP) accident were also screened for the secretion of natural products that could be beneficial for biomedical and agricultural applications. Particular radiation-tolerant microorganisms were selected, because they were known to produce valuable natural products, their genomic sequences contain SM pathways, or they display radiotropism. Seven fungi selected for the flight experiment were isolated after the explosion of Reactor 4 of the ChNPP in 1986, and one was isolated from the ISS. It has been hypothesized that growing fungi under potentially stressful microgravity conditions would induce the production of novel SMs, because orphan clusters would be activated.

Total genomic DNA was extracted from each strain by using a PowerSoil® DNA Isolation Kit (MoBio), following the manufacturer's instructions. The whole-genome sequences of these eight fungal strains were obtained by shotgun sequencing performed on an Illumina HiSeq2500 platform with a paired-end module. The draft genomes and their preliminary genomic characterizations were already published (Singh et al. 2017). The single-nucleotide polymorphism analyses and comparative genomics of the space-grown and ground-grown (control) fungal strains are in progress.

The SM analysis of the ISS and ground-grown strains was carried out immediately after sample retrieval from space. Three plugs taken in triplicate from each strain were extracted with methanol and a methanol:dichloromethane

1:1 mixture (Sanchez and Wang 2012). The extracted samples were analyzed using liquid chromatography-mass spectrometry (LC/MS) (Sanchez and Wang 2012). The resulting spectra revealed significant differences in SM production in *Cladosporium sphaerospermum* IMV 00045 (radiotrophic) and *Aureobasidium pullulans* IMV 00882 that were space-exposed as compared with the ground control. The SMs produced by each strain are being characterized by large-scale extraction, high-pressure liquid chromatography (HPLC) purification, and nuclear magnetic resonance (NMR) spectroscopy. The compound produced by *A. pullulans* IMV 00882 was identified as BK223-C, and two compounds produced by *Cladosporium cladosporioides* IMV 00236 (radiotrophic) were identified as viriditoxin and its derivative (Liu et al. 2016). These compounds may be novel, and further characterizations are in progress.

9.2.8 EXPLOITING OUTSIDE PLATFORM OF ISS IN MEASURING SURVIVAL OF MICROORGANISMS UNDER SPACE CONDITIONS

To avoid forward contamination from terrestrial microorganisms and uphold the scientific integrity of future missions to find life on other planets, it is crucial to characterize and attempt to eradicate these microorganisms from exploratory spacecraft and landing vehicles. Microorganisms that hitch-hike on a spacecraft can end up contaminating other celestial bodies, making it difficult for scientists to determine whether a life-form existed on another planet or was introduced by the arrival of explorers. Consequently, it is crucial to the success of future exploration to know what types of terrestrial microorganisms can survive on a spacecraft or landing vehicle.

Presently, spacecraft landing on planets where life might exist (e.g., Mars) must meet requirements for a maximum allowable level of microbial life, or bioburden (Benardini et al. 2014). The determination of what constitutes acceptable levels was based on studies of how various life-forms survive exposure to the unique conditions of the space environment. If it is possible to reduce the numbers to acceptable levels (a proxy for cleanliness), then the assumption is that the life-forms will not survive under harsh space conditions. However, the latest research has revealed that some microbes are tougher than expected and that others may use various protective mechanisms to survive exposure to the space environment. Three recently published peer-reviewed scientific articles used the ISS to examine the risks of interplanetary exchange of organisms and are given in the subsequent paragraphs and discussed in detail.

In the first study (Vaishampayan et al. 2012), *B. pumilus* SAFR-032 spores were flown to the ISS and exposed to a variety of space conditions via the European Technology Exposure Facility (EuTEF). After 18 months of exposure in the EXPOSE facility of the European Space Agency (ESA) on EuTEF under dark space conditions, SAFR-032 spores showed a survival

rate of 10%–40%. For comparison, when these spores were kept aboard the ISS under dark, simulated Martian atmospheric conditions, they showed a survival rate of 85%–100%. In contrast, when SAFR-032 spores were exposed to UV (>110 nm) radiation for the same length of time and under the same conditions as used on the EXPOSE facility, there was a 7-log reduction in viability. A parallel experiment was conducted on Earth with identical samples under simulated space conditions. Spores exposed to ground simulations showed less of a reduction in viability when compared with the “real space” exposed spores (~ 3-log reduction in viability for “UV-Mars,” and ~ 4-log reduction in viability for “UV-Space”). A comparative proteomics analysis indicated that a higher concentration of proteins that provide resistant traits (superoxide dismutase) was found in space-exposed spores when compared with the ground control spores. In addition, the first-generation cells and spores derived from space-exposed samples showed higher resistance to UVC when compared with the ground control spores. The data generated are important for calculating the probability and mechanisms of microbial survival in space conditions and for assessing microbial contaminants as risks for forward contamination from terrestrial microorganisms and the validity of in situ life detection.

In the second study (Horneck et al. 2012), the spores of *B. pumilus* SAFR-032 and *B. subtilis* 168, another spore-forming bacterium, were dried on pieces of spacecraft-quality aluminum and exposed to space vacuum, cosmic and extra-terrestrial solar radiations, and temperature fluctuations on EuTEF for 18 months. These spores were also simultaneously exposed to a simulated Martian atmosphere at the ISS by using EuTEF. Most of the organisms exposed to solar UV radiation in space and in the Mars spectrum were killed, but when UV rays were filtered out and samples were kept in the dark, approximately 50% or more of those spores exposed to other space- and Mars-like conditions survived. These results show that it is likely that spores could survive the spaceflight to Mars if they are shielded from solar irradiation, which may be possible in a tiny pocket of the spacecraft surface or underneath a layer of other spores.

The third experiment (Onofri et al. 2012) placed rock-colonizing cellular organisms in the EuTEF facility for 1.5 years to test a theory of how organisms might move from one planet to another, known as lithopanspermia. This theory postulates that rocks ejected from a planet by impact with another object (e.g., a meteor) can carry organisms on their surface through space and then land on another planet, thereby transferring these organisms from one planet to the next. In this experiment, researchers selected organisms that have adapted to the extreme environments of their natural habitats on Earth; they found that some are also able to survive in the even more hostile environment of outer space. The process of lithopanspermia would require thousands or even millions of years to occur, much longer than the experiment’s 18 months, but the results demonstrate the resilience of these organisms in space and suggest that rocks traveling through space could indeed carry life between planets.

Future space exploration missions can apply the results of these experiments to develop methods to reduce the risk of forward contamination, which will prevent the misidentification of a hitchhiking organism as a native of planet being explored.

9.2.9 CONCLUSION

The results of the ISS Environmental Omics project (basic science) should be leveraged to enhance the health and well-being of astronauts living in an enclosed habitat. To put it simply, the ISS Environmental Omics research seeks to translate the results of fundamental research into medical practice (pathogen detection) and meaningful health outcomes (countermeasure development). The omics data sets were placed in the NASA GeneLab bioinformatics environment, which consists of a database, computational tools, and improved methods, and are already made available to the scientific research community to encourage innovation (<https://genelab.nasa.gov/>). Appropriate countermeasures should be continuously developed to maintain the stability of the closed system and to ensure the health of the crew. NASA’s approach will assist spacefaring nations in recognizing the functionality of microbiomes associated with a close habitat, thereby facilitating the development of appropriate countermeasures. The AMR information could result in mitigation strategies to ensure the health of astronauts during long-duration space missions, when a return trip to Earth for treatment is not feasible or possible.

The results of the microbial monitoring with omics technologies give NASA the ability to precisely assess the spectrum of microorganisms associated with the closed habitat and to maintain crew health. In addition to providing overall microbial profiles, the molecular omics approach can identify the microbial taxa that pose particular threats to the health of the crew and spacecraft systems. The extensive microbial census produced by the omics methodologies allowed researchers to gain substantial insights into spaceflight-induced changes in the populations of beneficial and/or potentially harmful microbes.

FUNDING

These projects were funded by several NASA funding: 2012 Space Biology NNN12ZTT001N grant nos. 19-12829-26 and 19-12829-27 under Task Order NNN13D11IT award to KV, which also funded post-doctoral fellowship for ACS, NS, GMM, and AB; NNX15AB49G for CW and KV; NNX17AE50G for NK and KV; 80NSSC18K0113 (previously NNX15AJ29G) for CJ, KV, SM, and DJS; and NASA Space Biology program sponsored NASA Postdoctoral Program (NPP) post-doc for CU (2016 to present).

COMPETING INTERESTS

None.

ETHICS APPROVAL AND CONSENT TO PARTICIPATE

Not applicable.

DISCLAIMER

The author declares that all these materials were published elsewhere as peer-reviewed journal articles, and scientific contents are compiled as a book chapter.

9.3.1 INTRODUCTION

Adaptation to extreme environments can be a rapid process, especially after a cataclysmic event such as a volcanic eruption, a wildfire, or a severe drought due to climatic disruptions. In most cases, organisms are unable to adapt, and die. However, in many extreme environments we find organisms thriving, even organisms that don't normally live under extreme conditions. How does this adaptation occur? Rapid adaptation cannot be accommodated by the slow changes of Darwinian evolution, but microbes can provide new genetic material to facilitate rapid changes. For example, plants were able to thrive on land only through the help of fungal endophytes, and fungi are found in plants that have adapted to extreme environments such as geothermal, high salinity, and drought-ravaged soils (Rodriguez and Redman 2008). Another source of novel genetic information is viruses. Although viruses are often thought of as strictly pathogenic, there have been a number of studies in recent years that demonstrate the beneficial nature of many viruses (Roossinck 2011, 2015, Virgin 2014, Roossinck and Bazán 2017). Viruses are probably the most neglected entities in the field of astrobiology (Berliner et al. 2018).

Unlike all other extant life, viruses utilize either RNA or DNA as their basic genomic material, and their genomes can be single-stranded (ss) or double-stranded (ds). Archaea are the only organisms in which all of the known viruses have DNA genomes. Although there has been some indication of an RNA virus from a metagenomic study, it has not been verified (Deimer and Stedman 2012).

Viruses of bacteria and archaea are intimately involved in the ecology of their hosts (Gustavsen et al. 2014); however, their roles in adaptation to extreme environments are less clear. Plants use viruses to confer tolerance to heat, cold, and drought, and bacteria and archaea that thrive in extreme environments are also often infected with potentially beneficial viruses. In addition, viruses are responsible for horizontal gene transfer among many organisms across kingdoms; this has led to further rapid adaptation (see Chapter 8.3).

9.3.2 PLANT ADAPTATIONS

Vascular plants have a narrow range of temperature tolerance and generally cannot grow in soil above 45°C (Brock 1985). However, plants can be found around the geothermal areas of Yellowstone National Park at temperatures well above 50°C (Stout and Al-Niemi 2002), as well as other volcanic areas in the world. In Costa Rica, plants can be found thriving in volcanic soils at temperatures of 65°C (unpublished). These plants are colonized by endophytic fungi that are required for thermotolerance (Redman et al. 2002). However, in the plants in Yellowstone, the fungus does not act alone. It is, in turn, infected by a small RNA virus that is also required: when fungi are cured of the virus, they no longer confer thermal tolerance (Márquez et al. 2007). Closely related fungal endophytes from nearby plants growing in normal soils are not infected by the virus. In experimental studies, the fungal-virus combination could confer heat tolerance to both monocots and dicots, indicating that the players in this interaction are ancient (Márquez et al. 2007).

Plant can also adapt to other extreme environments, such as hypersaline soils, extreme cold, and extreme drought. Examples are found in all of these conditions that include fungal endophytes (Rodriguez et al. 2008), but the viral status of these fungi has not been carefully studied. However, plant viruses also can play a major role in drought tolerance. In experimental infections, several plant viruses were found to confer drought tolerance to infected plants (Xu et al. 2008). These viruses are generally pathogenic under normal conditions but convert to mutualists under drought stress (Bao and Roossinck 2013). Field studies have confirmed the potential role of viruses in drought tolerance (Davis et al. 2015). One mechanism for drought tolerance imparted by *Cucumber mosaic virus* (CMV) involves RNA silencing (Westwood et al. 2013), although other factors may also be involved; a variety of metabolites were elevated in virus-infected plants experiencing drought stress (Xu et al. 2008).

Viruses may also be involved in plant tolerance to cold. *Cucumber mosaic virus* conferred cold tolerance to red beet plants in an experiment designed to mimic freezing nighttime temperatures at the beginning or end of a normal growing season (Xu et al. 2008).

9.3.3 ANIMALS IN EXTREME ENVIRONMENTS

Very little work has been done on the potential role of viruses in the adaptation of animals in extreme environments. In general, viruses found in polar animals have been assumed to be pathogens. Recently, Smeele et al. used high-throughput sequencing to screen a variety of vertebrate life in the extreme environment of the Antarctic seas, including seals, penguins, and a few seabirds, as well as summarized what has been found to date through serology and early sequencing methods. Numerous viruses were identified, all within the families that one would expect from what is known about wildlife in tropical and temperate zones. There is no evidence either for or against a role of viruses in adaptation of macroanimal life to extreme environments (Smeele et al. 2018).

9.3.4 MICROBES IN THE EXTREME

The last decade has seen an explosion in virus discovery, largely due to advances in sequence technologies. Most of these studies have been metagenomic in nature, where an environmental sample is enriched for viruses or virus sequences and massively sequenced (see volume 239 of the journal *Virus Research*, a themed issue on deep sequencing in virology [Berkhout et al. 2017]). The early studies were done in the sea (Suttle 2005), but many studies have been conducted in extreme environments, including deep-sea vents, hypersaline regions, extreme drought conditions, and polar or arctic seas and lakes. Discovery leads to a deeper understanding of what is there, and we now know that viruses are the most diverse and widely distributed entities on earth. However, it is still challenging to link discovery to function, and in many cases, it is not clear who the viral host is. A majority of virus-related sequences are still novel, meaning they do not have any similarities to

anything known, and this complicates understanding. In this section, I review the studies of prokaryotic viruses in extreme environments and detail a few that give clues as to what the viruses might be doing in the process of adaptation.

Viruses of prokaryotes can be lytic, lysogenic, or chronic. In lytic infections, the virus replicates to high levels until the cell becomes full and bursts. In lysogenic cycles, the viral genome is integrated into the host and replicated along with the host. Lysogenic viruses often protect their host from superinfection by related viruses. A virus can convert from lysogenic to lytic due to a number of external inducers. Chronic infections have not been found in bacteria but are common archaea. The virus does not integrate into the host genome but remains in the host cell and replicates at a low level. The lytic cycle is often credited with controlling host populations, while the lysogenic cycle is often associated with immunity. The chronic cycle is not well understood, but if the virus is providing essential functions to the host, a chronic cycle would be likely to facilitate that.

The microbes in extreme environments are dominated by archaea, but there are numerous bacterial species as well. A review of archaeal viruses published in 2014 described only 117 archaeal viruses that had been characterized (Dellas et al. 2014). By now, there are more, but the number is still very limited. Viruses have only been identified in a small subset of the diversity of archaea. This most likely reflects a lack of looking rather than a lack of viruses (Snyder et al. 2015). Little is known about virus-host interactions, beyond population regulation, and not much is known about how they impact their hosts or are involved in adaptation to extreme environments (Krupovic et al. 2018).

9.3.4.1 NOVELTY OF ARCHAEOAL VIRUSES

The morphology of archaeal viruses is extremely diverse. There are archaeal viruses that are structurally related to bacterial virus, but they are genetically unrelated, and there are also many with novel morphology (Figure 9.3.1).

Those similar to bacterial viruses have similar life cycles, but the novel viruses are very different (Pietilä et al. 2014). This could be because they evolved before the division of the three domains of life and hence are fossils of the viral world (Prangishvili 2015). Even though very few viruses of archaea have been characterized, they are pushing the boundaries of our understanding of virus structures and genomes. For example, *Aeropyrum* coil-shaped virus, from the hyperthermophilic archaeon *Aeropyrum pernix*, has a completely novel structure of a hollow cylindrical coiling fiber. Moreover, it has the largest known ssDNA genome of nearly 25,000 nucleotides (Mochizuki et al. 2012). The hyperthermophilic archaeon *Halorubrum lacusprofundi* releases membrane-surrounded vesicles from the cell that contain a plasmid genome that can then infect plasmid-free cells; this makes it more similar to a virus than to a plasmid (Erdmann et al. 2017), bridging the gap between different mobile elements. Viruses and related entities in archaea have been dubbed as the mobilome (Lossouarn et al. 2015). The need for further discovery is

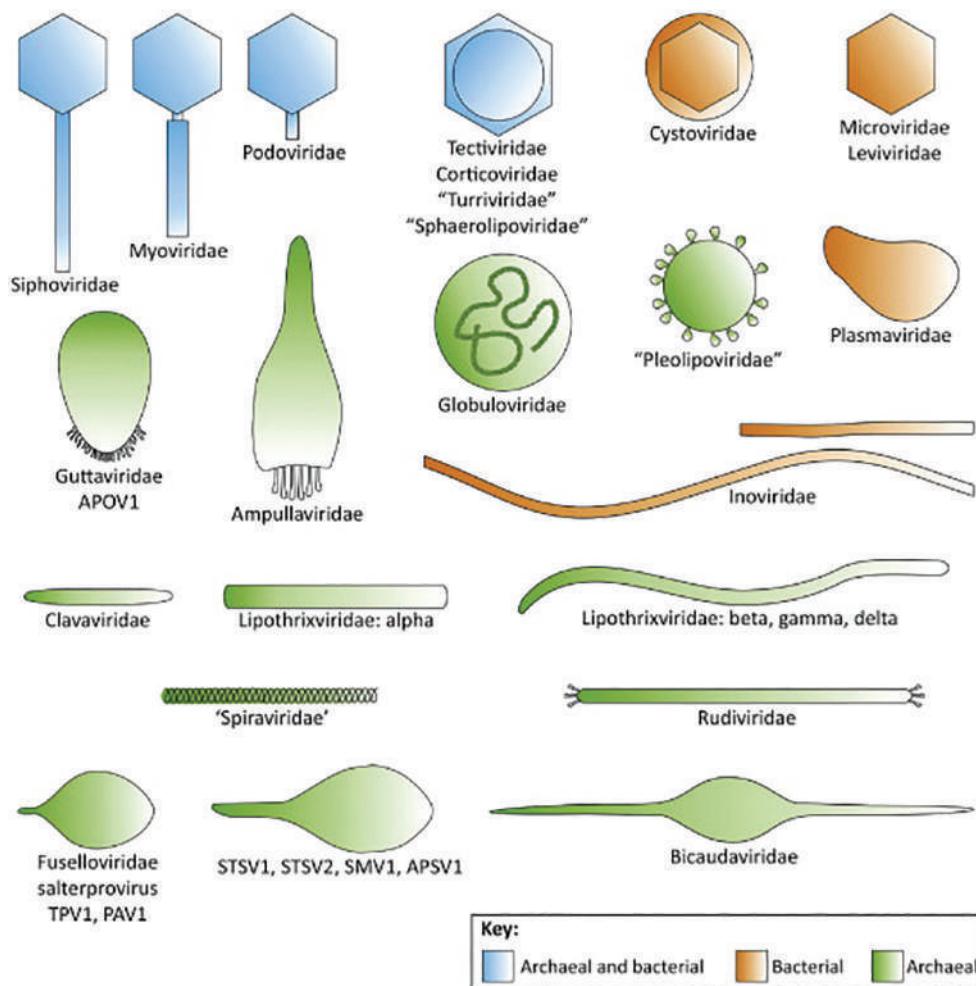

FIGURE 9.3.1 The viruses of archaea have dramatically increased our knowledge of virus structure. The shapes in blue are shared between bacteria and archaea but are genetically distinct. (From Pietilä, M.K. et al., *Trends Microbiol.*, 22, 324–344, 2014.)

exemplified by a recent analysis of the acidic hot springs of Yellowstone National Park, which found over 100 new virus groups in this single environment (Bolduc et al. 2015).

9.3.4.2 TOOLS FOR DEEPER UNDERSTANDING

Metagenomics have dramatically increased our knowledge base for viruses, but they are not without drawbacks. There are no universal genes for viruses, so all sequencing must be done with random priming that does not bias the results. This is especially important in extreme environments, where so many of the viruses have no similarity to known viruses. For example, a metagenomic analysis of microbes in a high-sulfur saline lake that could mimic conditions on Mars found many bacteria and archaea, but there was no evidence of viruses. However, it is not clear if viruses were really missing, as the lack of detection was based on looking for similarities with known viruses (Pontefract et al. 2017).

Evidence of past infections by viruses are revealed by the presence of Clustered Regularly Interspaced Short Palindromic Repeats, or CRISPRs, the adaptive immune

system in bacteria and archaea (Horvath and Barrangou 2010). When prokaryotes are infected by viruses, they generate short sequences, identical to the viral sequences, that are incorporated into CRISPR genes. Upon reinfection with the same or a related virus, CRISPRs target the foreign genomes for degradation. CRISPRs have been found in about 40% of sequenced bacterial genomes and about 90% of archaeal genomes. Metagenomic studies show a significantly higher level of CRISPRs in thermophiles (bacteria and archaea) than in their counterparts in mesophilic organisms (Cowan et al. 2015).

Researchers often use the virus:prokaryote ratio (VPR) to assess the ecology of viruses in metagenomic studies. However, these relationships vary across environments and in different studies. In extreme environments, VPRs have not been studied very much, but in saline environments, this number varies from 1 to 100, and in thermal environments, it varies from 1 to 20 (Parikka et al. 2016). This could be due to the instability of virus particles in hot environments. Most infections in thermophilic archaea are lysogenic or chronic. Haloviruses are more often lytic. The VPR may be a reflection

of these relationships but needs to be interpreted with caution, as the environment may dramatically affect virus stability too (Parikka et al. 2016).

9.3.4.3 HYPERTHERMIC AND HYPERSALINE ENVIRONMENTS

Hypersaline environments are populated with archaea, bacteria, and eukaryotic microbes. Nearly 100 viruses have been identified in the archaeal halophyte family of Halobacteriaceae, whereas only about 10 are known to infect bacterial halophytes. Unlike thermal vent viruses, the archaeal viruses in halophytes are mostly of *Caudovirales* type, that is, they have head-tail morphology. These viruses also have very broad host ranges. Eukaryotic halophytic virus in the Mimivirus group have also been identified (Atanasova et al. 2015). In a different approach, metagenomic studies of halophytes used fosmid clones of *Haloquadratum walsbyi* genomes; these studies show the viral infection history in the CRISPR genes. They then sequenced viruses from same environment that had matching sequences and recovered 42 nearly complete viral genomes, most with some similarity to *Caudovirales*. No *Fuselloviridae* were found, although these are the most common viruses of thermophilic archaea (Garcia-Heredia et al. 2011). Using a combination of viruses in the environment and their counterpart signatures in host CRISPRs clearly identifies the host-virus relationships.

Looking at a gradient of salinity from brackish to near saturation in sites in West Africa, bacterial and archaeal abundance increased with higher salt concentrations, as did the viruses, but while a majority of viruses at the brackish level were lytic, at the highest levels of salinity, most viruses were lysogenic (Bettarel et al. 2011).

9.3.4.4 POLAR ENVIRONMENTS

Polar seas and lakes have high levels of microbes and viruses. The VPR levels were measured in an Antarctic lake at different times of year, when the lake was completely frozen over or experienced surface thaws. The VPR ranged from about two to eight and was higher at 4.5-meter depths than at 1-meter depths. In addition, the ratio was highest in mid-January, when the lake had the least amount of ice (Rochera et al. 2017). RNA viruses sampled over 4 years in an Antarctic lake showed very little change in the population structure of one virus, but three other related viruses showed much greater diversity. However, when isolated from cyanobacterial mats rather than water, the diversity was very low (López-Bueno et al. 2015). Studies of polar freshwater lakes in Norway found a dominance of DNA viruses with small circular DNA genomes, not related to viruses from most other environments, but some had similarity to Antarctic viruses. In a few cases, they found the same virus (90% similarity) in Arctic and Antarctic environments (deCácer et al. 2015). This is surprising and not easily explained, but it implies that transfer has occurred fairly recently between these environments.

In a saline permafrost site in Alaska, a cryopeg from 7 meters deep was analyzed for bacteria and viruses. Compared with the surrounding ice, the bacteria counts were very high. The viruses were mostly lysogenic and had less diversity than those in the surrounding surface area. The viruses were related to marine phage, supporting a marine origin for the cryopeg (Colangelo-Lillis et al. 2016).

9.3.4.5 DESERT ENVIRONMENTS

Under an extreme drought and heat environment, several bacteriophages were identified, but most of these were lysogenic, only becoming detectable after incubation of the host bacteria and induction in the lab. This differs from a cold desert environment, where phage particles are observable in soil samples (Prestel et al. 2013), perhaps because the phage may be very labile in the heat, similar to what is seen in deep vents. Metagenomic analyses of four ponds within the Sahara Desert found that virus diversity was lowest in the site most impacted by human activity (Fancello et al. 2013). In the barren soils in the cold deserts of Antarctica that were sampled for DNA viruses, tailed phages were abundant, and diversity varied based on altitude and soil chemistry. Phycodnaviruses and mimiviruses (viruses of algae and amoeba, respectively) were also found in the sites (Adriaenssens et al. 2017). Phage populations in the dry valleys of Antarctica may be important for bacterial population regulation (Wei et al. 2015).

9.3.4.6 VIRUS ROLES IN ADAPTATION

In some extreme environments, such as deep-sea vents and soda lakes, the metabolism is dominated by sulfur oxidizers. The soda lakes of East Africa represent an extreme environment with high salinity, pH, and temperature. Soda lakes host numerous bacteria and archaeal species, including nitrifiers and sulfur oxidizers (Grant and Jones 2016). Sulfur-oxidizing bacteria are also abundant in marine hydrothermal vents and oxygen minimum zones. In a recent study of DNA viruses infecting sulfur-oxidizing bacteria, 15 out of 18 had genes involved in sulfur metabolism, indicating that they provide essential functions to their host bacteria in adapting to these extreme environments (Anantharaman et al. 2014).

The Namib Desert in southwestern Africa is home to hypoliths, microbial communities that inhabit the underside of translucent rocks. In this hyperarid environment, cyanobacteria are prevalent, and the viruses were dominated by dsDNA viruses, with a majority of these in the *Siphoviridae*, but these differ significantly from the cyanophage found in marine environments. Auxiliary metabolic genes that are thought to assist the host in metabolism in photosynthesis are common in marine cyanophage (Lindell et al. 2005, Avrani et al. 2012). In the hypolith environment, auxiliary genes for nucleotide metabolism and for an unknown function (*phoH*) were common in the viruses, indicating that they are involved in adaptation to the extreme environment. *PhoH* may be involved in phosphate uptake, but this is unproven (Adriaenssens et al. 2015).

9.3.4.7 EXPERIMENTAL STRATEGIES

Very few studies have included any experimental work to look at virus adaptation to extreme environments. However, Singhal et al. adapted RNA bacteriophage phi6 to high-temperature growth by either gradually increasing temperatures or rapidly increasing temperatures. Gradual increase was more successful. Mutants in end populations were not all thermo-adapted; however, some had simply increased their replication rates (Singhal et al. 2017).

In experimental studies with an icosahedral virus with an internal membrane, *Haloarcula californiae* icosahedral virus 1, the virus could experimentally infect its archaeal halophyte host under low-salt conditions as well as conditions mimicking the environment from where it was isolated (Demina et al. 2016).

9.3.5 CONCLUSIONS

The critical role of viruses in the evolution of life is widely accepted (see Chapter 8.3), and we might expect that evidence for this would be common in extreme environments. However, so little work has been done in this area that it is difficult to make a strong case. In plants, the most detailed studies have unequivocally demonstrated the roles of viruses in adaptation to heat, drought, and cold stress. Virtually, nothing has been done in the area of animal adaptation. In microbes, most of the work in extreme environments is in the era of discovery. Tools are being developed to try to take metagenomics to a level of ecological understanding (Simmonds et al. 2017, Dolja and Koonin 2018), but these have not been applied to any extent in extreme environments. However, the discovery itself lays an important groundwork for further understanding, and it seems almost certain that microbial viruses are also playing a fundamental role in the adaptations of their hosts.

Habitability is a commonly used word. Its usage is usually vague...

(Cockell et al. 2016)

The number one goal of NASA's astrobiology roadmap is to "understand the nature and distribution of habitable environments in the universe" (Des Marais et al. 2008, NASA 2011). The search for habitable planets simultaneously addresses two distinct questions: Which planets are habitable for extraterrestrial life of any kind? Which planets could we inhabit? These are existential questions because our survival may depend on our ability (1) to find and understand aliens (Stevenson and Large 2017) and (2) to find a second habitable Earth in order to become a multi-planet species (Musk 2017) (Figure 10.1.1).

10.1.1 EARLIER VIEWS OF HABITABLE PLANETS

Our notions of habitability can be traced back to pre-scientific analogies:

to consider the Earth the only populated world in infinite space is as absurd as to assert that in an entire field sown with millet only one grain will grow.

(Metrodorus of Chios, pupil of Democritus,
fifth century BC)

Ancient fanciful speculation (e.g., Lucian of Samosata second century AD) developed into modern speculation (e.g., Nicolas of Cusa 1440, Bruno 1584, Kepler 1634, de Fontenelle 1686, Huygens 1698, see also Duhem 1987), like Metrodorus

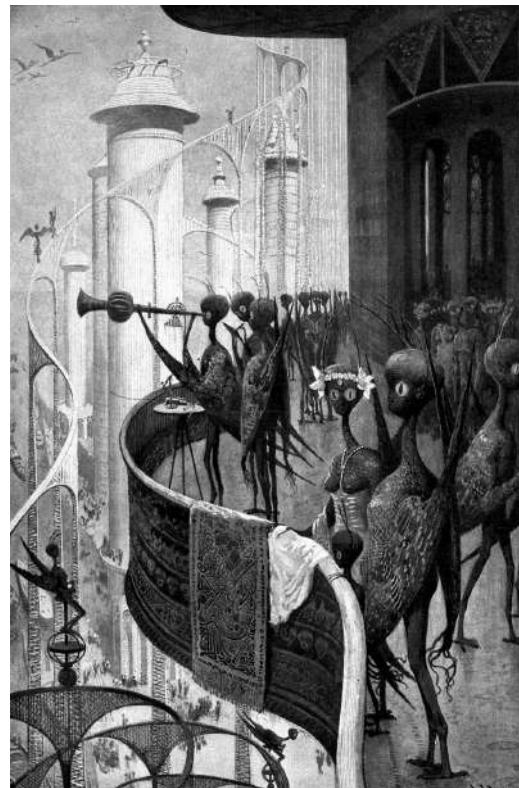

FIGURE 10.1.1 Martians circa 1908. "There are certain features in which they are likely to resemble us. And as likely as not they will be covered with feathers or fur. It is no less reasonable to suppose instead of a hand, a group of tentacles or proboscis like organs." (Drawing by William R. Leigh, "The Things That Live on Mars" by H.G. Wells, *Cosmopolitan Magazine*, March 1908.)

years earlier, William Herschel (the discoverer of Uranus) believed in an infinity of inhabited planets:

Since stars appear to be suns, and suns, according to the common opinion, are bodies that serve to enlighten, warm, and sustain a system of planets, we may have an idea of numberless globes that serve for the habitation of living creatures.

(Kawaler and Everka 1981, Herschel 1795)

According to Clerke (1893), Herschel also thought the Sun might be inhabited, since it was a “cool, dark solid globe clothed in luxuriant vegetation and richly stored with inhabitants protected by a heavy cloud-canopy from the intolerable flare of the upper luminous region.” The idea of the Sun being habitable is currently out of favor. For more on earlier ideas of habitable worlds, see Wallace (1904), Brooke (1977), Dick (1984), Crowe (1999), and Sullivan III and Carney (2007).

10.1.2 THE PHYSICS OF HABITABILITY

10.1.2.1 CIRCUMSTELLAR HABITABLE ZONES, ATMOSPHERES, AND WATER

Wet rocky Earth-like planets in the circumstellar habitable zones (CHZs) of their host stars are the focus of much current research (Kasting and Catling 2003, Gaidos et al. 2005,

Nisbet et al. 2007, Zahnle et al. 2007, Lammer et al. 2009, Kopparapu et al. 2013, Seager 2013, Cockell et al. 2016, Kaltenegger 2017). Figure 10.1.2 shows the accretion of the Earth and estimates of the CHZ. The wide orange band labeled “circumstellar habitable zone” (CHZ) has a positive slope because the luminosity of the Sun is increasing. Compared to Hart’s (1979) CHZ (blue line), the width of the CHZ has increased considerably due to estimates of the thermally stabilizing effect of the carbonate-silicate cycle (Walker et al. 1981), but also see Section 10.1.4.

Since all life on Earth needs liquid water during some part of its life cycle, and the surface of the Earth is covered with it, the presence of liquid water on a planet’s surface is taken as a necessary (but not sufficient) condition for life (Domagal-Goldman et al. 2016). Liquid water can exist only within the relatively narrow range of pressures and temperatures, indicated in Figure 10.1.3. If we are interested in water-based life on the surface of a planet, then the surface of that planet, like the surface of the Earth, must lie within the blue region.

10.1.2.2 INSOLATION, ESCAPE VELOCITY, AND ATMOSPHERES

The concept of a CHZ (e.g., Kasting et al. 1993) is primarily useful because it is based on two observables from an exoplanet detection: the distance from the host star and the luminosity of the host star. These tell us whether a planet is in,

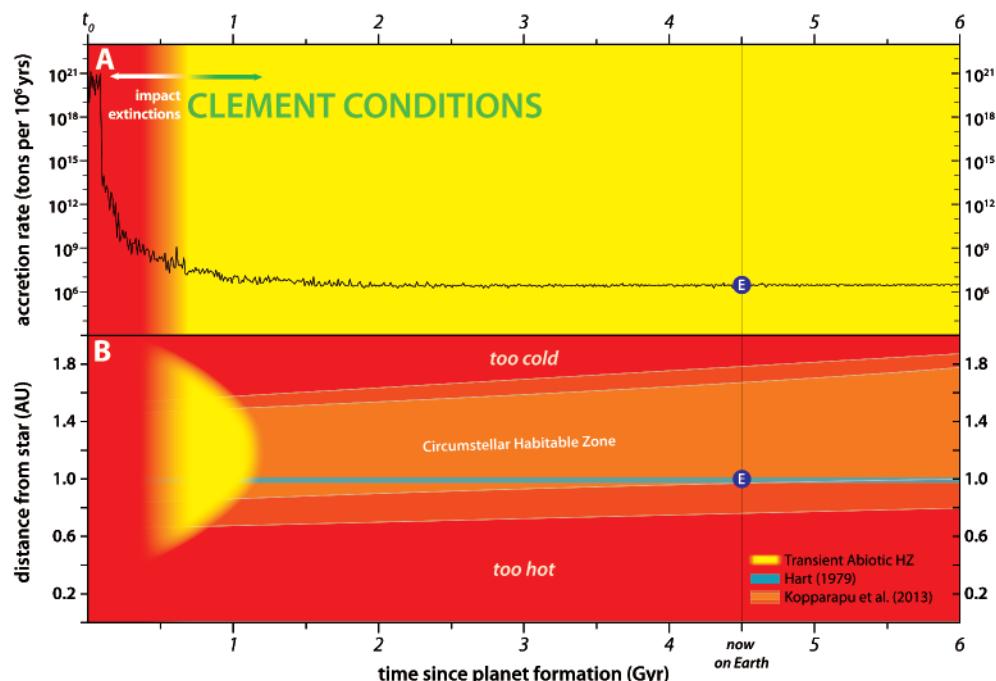

FIGURE 10.1.2 The accretion of the Earth (panel A) and circumstellar habitable zones (panel B). In A, the heavy bombardment during the first ~0.5 billion years includes the Moon-forming impact and many other impacts capable of sterilizing life (Maher and Stevenson 1988, Sleep et al. 1989, 2001, Davies and Lineweaver 2005, Cockell et al. 2012). The first few hundred million years of the formation of any rocky planet may be so impactful that the emergence of life is frustrated (hence the initial red color, which shades into the yellow clement conditions on the right side of panel A). Panel B shows several versions of circumstellar habitable zones (CHZs). The orange bands show two modern estimates of a CHZ from Kopparapu et al. (2013). These CHZs are more than 10 times wider than the narrow continuously habitable zone (thin horizontal blue band) computed by Hart (1979) before Walker et al. (1981). The Earth is plotted as a blue dot at 4.5 Gyr. (Modified from Chopra, A., and Lineweaver, C.H., *Astrobiology*, 16, 7–22, 2016.)

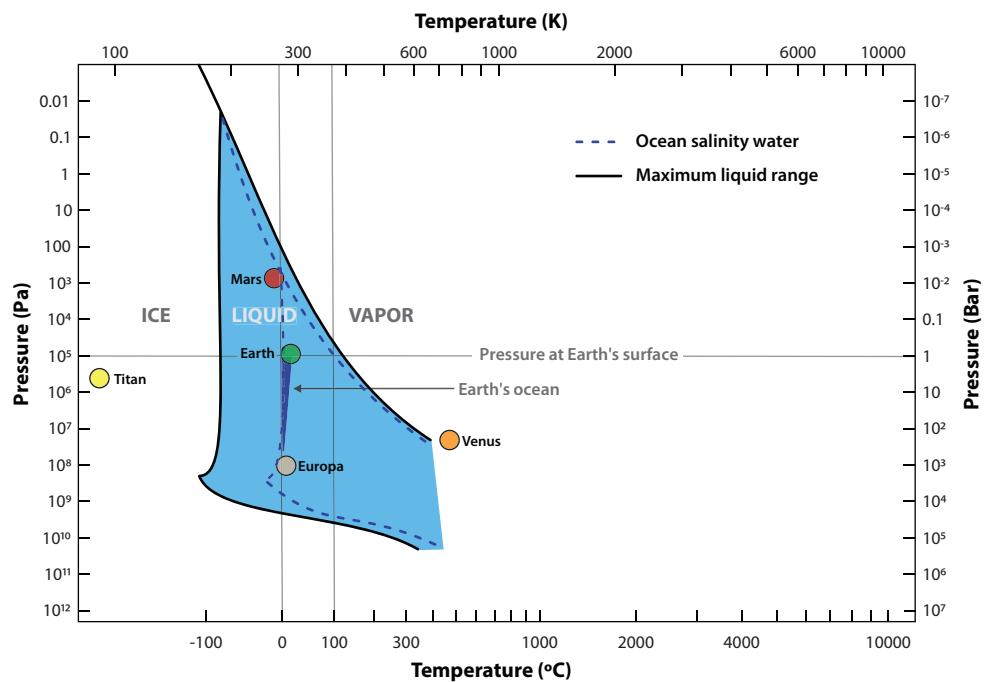

FIGURE 10.1.3 The phase diagram of H₂O. The dotted contours circumscribe ocean salinity water, while the solid contours circumscribe the maximum range of liquid water. The thin vertical sliver of dark blue represents the Earth’s oceans. The surfaces of Mars, Venus, and Titan are plotted. The surface of Mars has a pressure just below the triple point pressure of ocean salinity water but well within the maximum liquid range. The subsurface water in Europa is plotted. (Modified from Jones, E.G., and Lineweaver, C.H., *Astrobiology*, 10, 349–361, 2010.)

or close to, the CHZ. These two parameters can be usefully combined into a single parameter: insolation (the amount of light falling on a planet). Although the CHZ depends only on insolation, the presence of a liquid at the surface of a rocky body depends on that rocky body having an atmosphere with a surface pressure higher than the triple point pressure of the substance of interest.

The presence of an atmosphere and the contents of that atmosphere depend pre-dominantly on insolation and surface gravity. For example, the Moon has the same insolation as the Earth, and so, the Moon is in the CHZ, but it is not large enough to hold onto an atmosphere. The Moon, Mercury, Ganymede, Ceres, and Vesta do not appear in Figure 10.1.3, because these bodies are not massive enough to hold onto an atmosphere with a surface pressure larger than the triple point of water. The presence or absence of an atmosphere is an important pre-requisite for surface water. Since the presence of an atmosphere depends on a planet’s escape velocity, to take the next step in understanding surface water and habitability, we need to plot escape velocity versus insolation. In a groundbreaking paper, Zahnle and Casting (2017) made such a plot (Figure 10.1.4).

In the lower left of Figure 10.1.4, Sedna’s insolation is so low that its mean surface temperature is 12 K. It is thought to have a neon atmosphere. All the other gases are condensed out as ices on its surface. At their triple point pressures, neon condenses at 25 K, nitrogen at 77 K, methane at 91 K, carbon dioxide at 217 K, and water at 273 K. Thus, as we move diagonally up the brown band to higher surface gravities, higher

insolations, and, on average, higher surface temperatures, the more volatile ices begin to seasonally sublime—Pluto, Triton, and Titan have nitrogen and methane atmospheres. As we move further up diagonally, CO₂ and then H₂O also begin to contribute to atmospheric gases. Further up, liquid water becomes so abundant that we are in the realm of water worlds or ocean planets (e.g., Léger 2004). In the upper right, escape velocities are so high that hydrogen and helium atmospheres are maintained through planet formation. The initial abundance of H and He is ~100 times more abundant than any rock-forming material, so these planets will be gaseous hot Jupiters and hot Saturns rather than rocks with atmospheres—and therefore are of less interest to habitable-planet hunters.

If a body has a high eccentricity, like Sedna ($e \sim 0.8$), then its insolation is variable. This can produce a “see saw” atmosphere that freezes out around aphelion to produce an icy surface with no atmosphere. Around perihelion, the ice revaporizes and reinstates the atmosphere. Eris’s eccentricity of $e \sim 0.4$ produces a nitrogen seesaw atmosphere. Triton’s low eccentricity gives it a stable insolation and therefore a stable nitrogen atmosphere. Large bodies with high escape velocities and low insolations (lower right in Figure 10.1.4) will have atmospheres that dominate to such an extent that they don’t have an identifiable rocky surface (e.g., Jupiter, Saturn, Uranus, and Neptune).

Detection of a planet by both radial velocity and transit photometry yields an estimate of both mass and radius, from which density can be estimated. Densities reveal whether a planet is rocky (like Mercury, Venus, Earth, and Mars) or

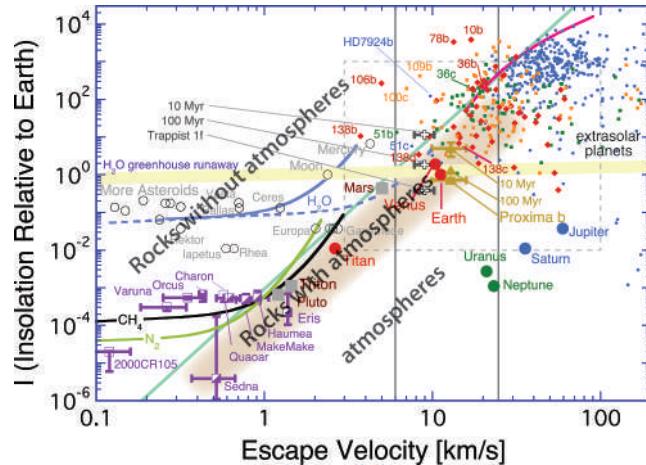

FIGURE 10.1.4 Insolation and escape velocities. The diagonal turquoise line seems to be the empirical boundary between rocks with and without atmospheres. Rocks in the upper left have no atmospheres—their escape velocities are too low and their insulations are too high to keep atmospheres. Rocks to the lower right have escape velocities high enough and insulations low enough to keep atmospheres. Rocks in the far lower right have so much atmosphere that we call them gaseous planets (i.e., Jupiter and Saturn). The brown region indicates rocky planets or moons with atmospheres. Starting from the right, the closer a rock is to the turquoise line, the more tenuous is its atmosphere. For example, Titan (red dot) has a relatively thick atmosphere, while closer to the turquoise boundary, Mars, Triton, Pluto, and Ganymede have almost negligible atmospheres. The horizontal yellow band corresponds to the insolation assumed to characterize the CHZ. Notice that the Moon is in the CHZ but is also in the “rocks without atmospheres” region. The small blue dots in the upper right are mostly gaseous hot Saturns and hot Jupiters with insulation ~ 3 orders of magnitude larger than the insulation of Saturn and Jupiter. The next figure shows a blowup of the region within the dashed rectangle. (Modified from Figure 1 of Zahnle, K.J., and Catling, D.C. *Astrophys. J.*, 843, 122, 2017.)

gaseous (like Jupiter and Saturn) or something else. Most planets with masses less than $\sim 2.5 M_{\oplus}$ or with radii less than $\sim 1.4 R_{\oplus}$ are rocky (Rogers 2015, Kaltenegger 2017, but see Fulton et al. 2017). If they are to the right of the turquoise line in Figure 10.1.4, they will have atmospheres. If they are in the CHZ insulation region (yellow), these become the most interesting potentially habitable Earth-like planets.

For larger planets, somewhere in the mass range $2.5 M_{\oplus} < M < 4 M_{\oplus}$ or in the radius range $1.4 R_{\oplus} < R < 1.6 R_{\oplus}$, surface gravity becomes large enough to hold H_2O and H_2 , producing lower densities. Thus, we do not expect planets with radii more than $\sim 2 R_{\oplus}$ to be rocky. The escape velocity v'_{esc} of a planet with a radius R' and density ρ' is:

$$v'_{esc} = v_{esc \oplus} \left(\frac{R'}{R_{\oplus}} \right) \sqrt{\left(\frac{\rho'}{\rho_{\oplus}} \right)} \quad (10.1.1)$$

Thus, for the largest rocky planets with twice the radius of the Earth and about the same density, we have:

$$v'_{esc} \approx 2 v_{esc \oplus} \approx 22 \text{ km/sec} \quad (10.1.2)$$

This value is indicated with a vertical black line in Figures 10.1.4 and 10.1.5. At the low-mass end, to be in the

yellow CHZ insulation and to be to the right of the turquoise line, a planet needs an escape velocity of half Earth’s or ~ 6 km/sec. At the same density as the Earth, this corresponds to a planet with half the Earth’s radius. This 6 km/sec escape velocity is also indicated with a vertical black line in Figures 10.1.4 and 10.1.5. The notional “habitable” green region is between these limits and centered on the CHZ insulation band. Both Mars and Venus are to the right of the turquoise boundary and have atmospheres, but their insulation is just below and just above the yellow CHZ, respectively. If Mars had been more massive, it would have had a larger escape velocity and a thicker atmosphere and would presumably have been habitable longer for water-based life at its surface. If Venus had been less massive (lower escape velocity), it would have had a thinner atmosphere that presumably would be less susceptible to a runaway greenhouse and would probably have been more habitable. These are the considerations that notionally tilt the green habitable region (for water-based life) compared with the horizontal yellow insulation levels of the CHZ. Proxima Centauri b and TRAPPIST-1f are currently within this notional habitable zone, but they may have lost all their initial water because of the long and luminous pre-main sequence evolutionary paths of their M-star hosts (Ribas et al. 2016, Barnes et al. 2018, Grimm et al. 2018).

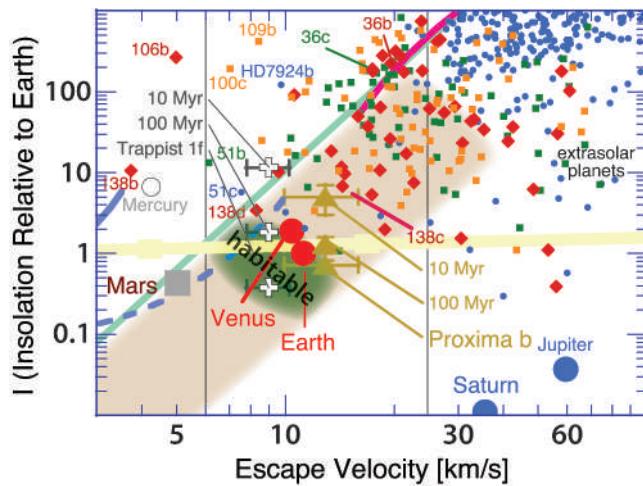

FIGURE 10.1.5 Blow up of the region around the Earth, from the previous figure. The vertical black line on the right indicates the surface gravity of a roughly Earth-composition planet with a radius approximately twice the Earth's radius. The vertical black line on the left is surface gravity of a planet just enough to hold onto an atmosphere in the CHZ. This corresponds to a rocky planet with approximately half the Earth's radius. See text below for discussion of the time dependence of the three points for Proxima Centauri b and TRAPPIST-1f. (Modified from Figure 1 of Zahnle, K.J., and Catling, D.C. *Astrophys. J.*, 843, 122, 2017.)

10.1.2.3 THE M-STAR HABITABILITY PROBLEM (EARLY DEVOLATILIZATION)

Low-mass M-stars are the most numerous stars in the universe, and therefore, they may host the largest number of habitable planets. TRAPPIST-1 and Proxima Centauri are M dwarfs with 9% and 12% of the mass of the Sun, respectively. Pre-main sequence Hayashi tracks tell us that during the first few hundred million years, the luminosity of these stars decreased by ~ 2 orders of magnitude (Ramirez and Kaltenegger 2015). Thus, when one plots the insolation as a function of time of the two planets (TRAPPIST-1f and Proxima Centauri b), which are currently in or near the CHZ of these two stars, their insolation decreases by the factors of 38 and 7, respectively (compare the three points for each planet in Figures 10.1.4 and 10.1.5). Accordingly, if a rocky planet is currently in the CHZ of an M dwarf, during the first half a billion years of its existence, it experienced an insolation (and an extreme UV flux) probably large enough to devolatilize its surface, removing most or all its water (Luger and Barnes 2015, Zahnle and Catling 2017). This effect is larger for lower-mass stars, as can be seen in Figure 10.1.5 by the larger spread in insolation between the three TRAPPIST-1f points compared with the three Proxima Centauri b points.

The CHZ insolation and atmosphere-securing escape velocities plotted in Figure 10.1.4 are important factors affecting habitability. A planet's position along the brown-shaded region of Figure 10.1.4 can help us make educated guesses

about atmospheric compositions based on the condensation temperatures of the half dozen likely candidates for atmospheric gases (Ne , N_2 , CH_4 , CO_2 , H_2O , and H_2).

The detailed volatile content of the atmosphere controls both albedo and greenhouse warming and thus strongly influences the habitability of a rocky planet (Catling and Kasting 2017). But volatile content is volatile. The strength, rapidity, and universality of abiotic positive feedbacks and the rapid evolution of the atmosphere, probably within the first billion years, as happened for Venus and Mars (Jones et al. 2011), can lead to temperatures too hot or cold for life (through runaway greenhouse or runaway glaciation) and loss of liquid water (through atmospheric escape of hydrogen), which can preclude long-term planetary habitability (Chopra and Lineweaver 2016).

The variability in the initial inventories of ices and volatiles (e.g., H_2O) of CHZ planets is probably quite large, because it is the result of a small number of impacts with the largest volatile-rich planetesimals. This variability is unobservable in exoplanets but may be large enough to strongly modify the assumed effects of a given insolation. A good example of this is the 750°C surface temperature of Venus, dominated not by its insolation or effective temperature but by its greenhouse gas composition and a runaway greenhouse effect. The detailed atmospheric compositions and greenhouse gas fractions of rocky exoplanets in the CHZ of their host stars are not observables and will remain guesswork for the next decade or so.

A variety of other astrophysical and geological factors may play important roles in modifying habitability, including volcanism (Ramirez and Kaltenegger 2017), plate tectonics (Valencia et al. 2007; Noack and Breuer 2014; Noack et al. 2014; Foley 2015), bulk chemistry (Jellinek and Jackson 2015), albedo (Joshi and Haberle 2012), magnetic fields (Christensen 2010; Stevenson 2010; Tarduno et al. 2015), eccentricity (Dressing et al. 2010; Linsenmeier et al. 2015), tidal heating (Driscoll and Barnes 2015; Barr et al. 2018), tidal locking (Yang et al. 2013; Barnes 2017), impact events (Cockell et al. 2012; Lupu et al. 2014), and stellar type (Fritz et al. 2014; Ramirez and Kaltenegger 2015).

10.1.3 USING THE EARTH AS A HABITABILITY CALIBRATOR

The radius of the Earth is about 6000 km. The thickness of the biosphere (Δx) is about 6 km (Figure 10.1.6). Thus, only a tiny fraction of the Earth is habitable:

$$\frac{\text{Thickness of biosphere } (\Delta x)}{\text{Radius of Earth } (R)} \approx \frac{6 \text{ km}}{6000 \text{ km}} \approx \frac{1}{1000} \quad (10.1.3)$$

or in terms of fractional volume:

$$\frac{\text{Volume}_{\text{biosphere}}}{\text{Volume}_{\text{Earth}}} \approx \frac{\frac{4\pi R^2 \Delta x}{3}}{\frac{4}{3}\pi R^3} \approx \frac{3\Delta x}{R} \approx \frac{3}{1000} \quad (10.1.4)$$

Thus, an overwhelming majority of the volume of the Earth is uninhabitable, and not even all the liquid water on Earth is habitable (Jones and Lineweaver 2010). Even the ~6-km-thin bioshell of the Earth is not equally habitable. The density of life (as a proxy for habitability) on the surface of the Earth, from polar caps and deserts to rain forests, varies by many orders of magnitude (Figure 10.1.7, Lineweaver and Chopra 2012a).

Earthlife (Feinberg and Shapiro 1980) is NOT everywhere. The entire volume of the Earth beneath a depth of ~5 km is a temperature desert, with temperatures above the 122°C maximum temperature of life (Takai et al. 2008). Also, the polar caps with temperatures below -20°C are cold-temperature deserts. Lack of water is the bottleneck for life in the traditional deserts such as the Atacama and Sahara. But there may also be places on Earth where a paucity of carbon or phosphorus or sulfur precludes the existence of life (Harrison et al. 2013). These chemical deserts have not been well-explored.

The Earth thus contains environments over the entire spectrum, from completely uninhabitable to very habitable (and richly inhabited). So, the Earth is both uninhabitable and habitable, depending on location. Similarly, nuances in understanding habitability can be made if we discourage the common zero-dimensional dichotomy, habitable or uninhabitable, and talk rather about the extent of habitability. Habitability is at least a one-dimensional continuous variable (Figure 10.1.8). Discussion of planets more habitable than the Earth (“super-habitability”) makes a useful contribution to this adjustment (Heller and Armstrong 2014). In this view, the CHZ has no sharp boundaries (sometimes characterized by the inappropriate precision of three significant figures). To remove the unrealistically close connection between the words “habitable zone planet” and “planet with life,” the phrase “circumstellar habitable zone” should be replaced by “circumstellar temperate zone,” as in Gillon et al. (2017).

One large clue that we do not understand about the habitability of the Earth is that the vast majority of life-forms on Earth cannot be cultivated. We do not know what are their requirements to stay alive. Apparently, isolation from other organisms and diets of agar-agar in petri dishes are not habitable environments for most organisms. It is for this reason that metagenomics (as opposed to the genomics of cultured organisms) has been able to find entirely new phyla in the tree of life (Hug et al. 2016).

Culturing problems are issues of micro-habitability. One can also discuss habitable zones at other size scales (Nisbet et al. 2007). For example, one can identify the galactic

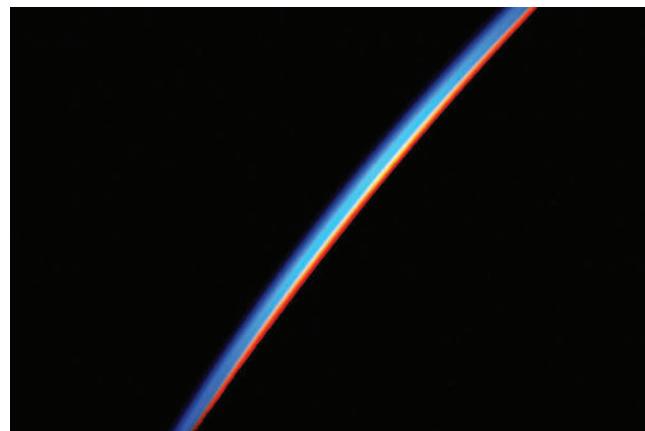

FIGURE 10.1.6 Photograph of the Earth’s atmosphere at sunrise on February 9, 2016, taken by astronaut Scott Kelly from the International Space Station.

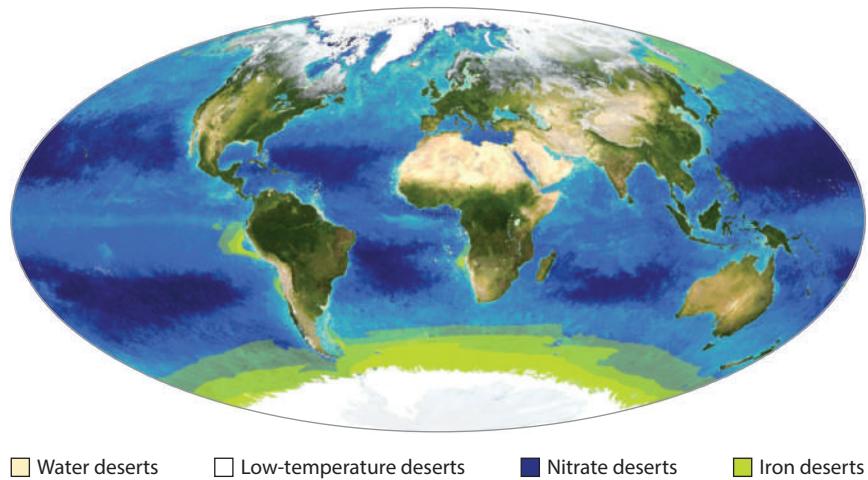

FIGURE 10.1.7 Four types of deserts where life in Earth’s bioshell is relatively rare. If we take biomass density as a proxy for the habitability of the surface of the Earth, then the habitability of the surface varies by many orders of magnitude. (From Lineweaver, C.H., and Chopra, A., *Annu. Rev. Earth Planet. Sci.*, 40, 597–623, 2012.)

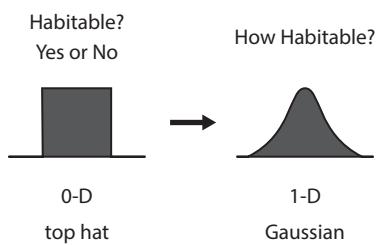

FIGURE 10.1.8 A conceptual transition is needed from a zero-dimensional model of a circumstellar habitable zone to a more nuanced Gaussian distribution, which can parametrize the extent of habitability.

habitable zone—regions of the galaxy most conducive to life (e.g., Lineweaver et al. 2004) or, more speculatively, discuss the habitable island universes in the multiverse—universes in the multiverse, that are most conducive to life (Ćirković 2012, Lineweaver 2014).

10.1.4 THE BIOLOGY OF HABITABILITY

In our discussion of CHZs, insolation, surface gravity, and atmospheres, we have only considered the physics and chemistry of habitability. However, if it is the case that only inhabited planets are habitable—if life plays a major role in modifying its environment to make it habitable—then we have so far ignored what may be the dominant parameter controlling the habitability of a planet: the life on it.

10.1.4.1 THE CASE FOR A GAIAN BOTTLENECK

The pre-requisites and ingredients for life seem to be abundantly available in the universe. However, we have yet to find any evidence for extraterrestrial life. A common explanation

for this is a low probability for the emergence of life (an emergence bottleneck), notionally due to the intricacies of the molecular recipe. An alternative Gaian bottleneck explanation argues that if life emerges on a planet, it only rarely evolves quickly enough to regulate greenhouse gases and albedo, thereby maintaining surface temperatures compatible with liquid water and habitability (Chopra and Lineweaver 2016). Such a Gaian bottleneck suggests that (1) extinction is the cosmic default for most life that has ever emerged on the surfaces of wet rocky planets in the universe and (2) rocky planets need to be inhabited to remain habitable (Figure 10.1.9).

The most important data needed to constrain, validate, or invalidate the Gaian Bottleneck model will probably come from estimates of the strength of the abiotic negative feedback of the carbonate-silicate cycle in the first billion years of Earth’s history, when the area of continental crust (and therefore the amount of sub-aerial silicate weathering) was probably negligible. If negative feedback from silicate weathering is to create a stable CHZ during the first billion years, several conditions need to be fulfilled. Sub-aerial or sub-aqueous silicate weathering needs to be strong enough, to make its negative feedback dominate the positive feedbacks from a runaway greenhouse or a runaway ice-albedo glaciation.

Biotic regulation could provide the necessary level of negative feedback (lower panel of Figure 10.1.10). However, the emergence of metabolisms and ecosystems that could regulate planetary-scale greenhouse gases or albedo may be a rare and quirky result of evolution—like vertebrate heads, mammalian hair, bird feathers, or human language. Dependence on the evolution of such quirks may present a Gaian bottleneck to the persistence of life on inherently unstable planets. In the Gaian bottleneck model, the maintenance of planetary habitability is a property more associated with a quirky and unusually rapid evolution of biological regulation of surface volatiles than with the luminosity and distance to the host star.

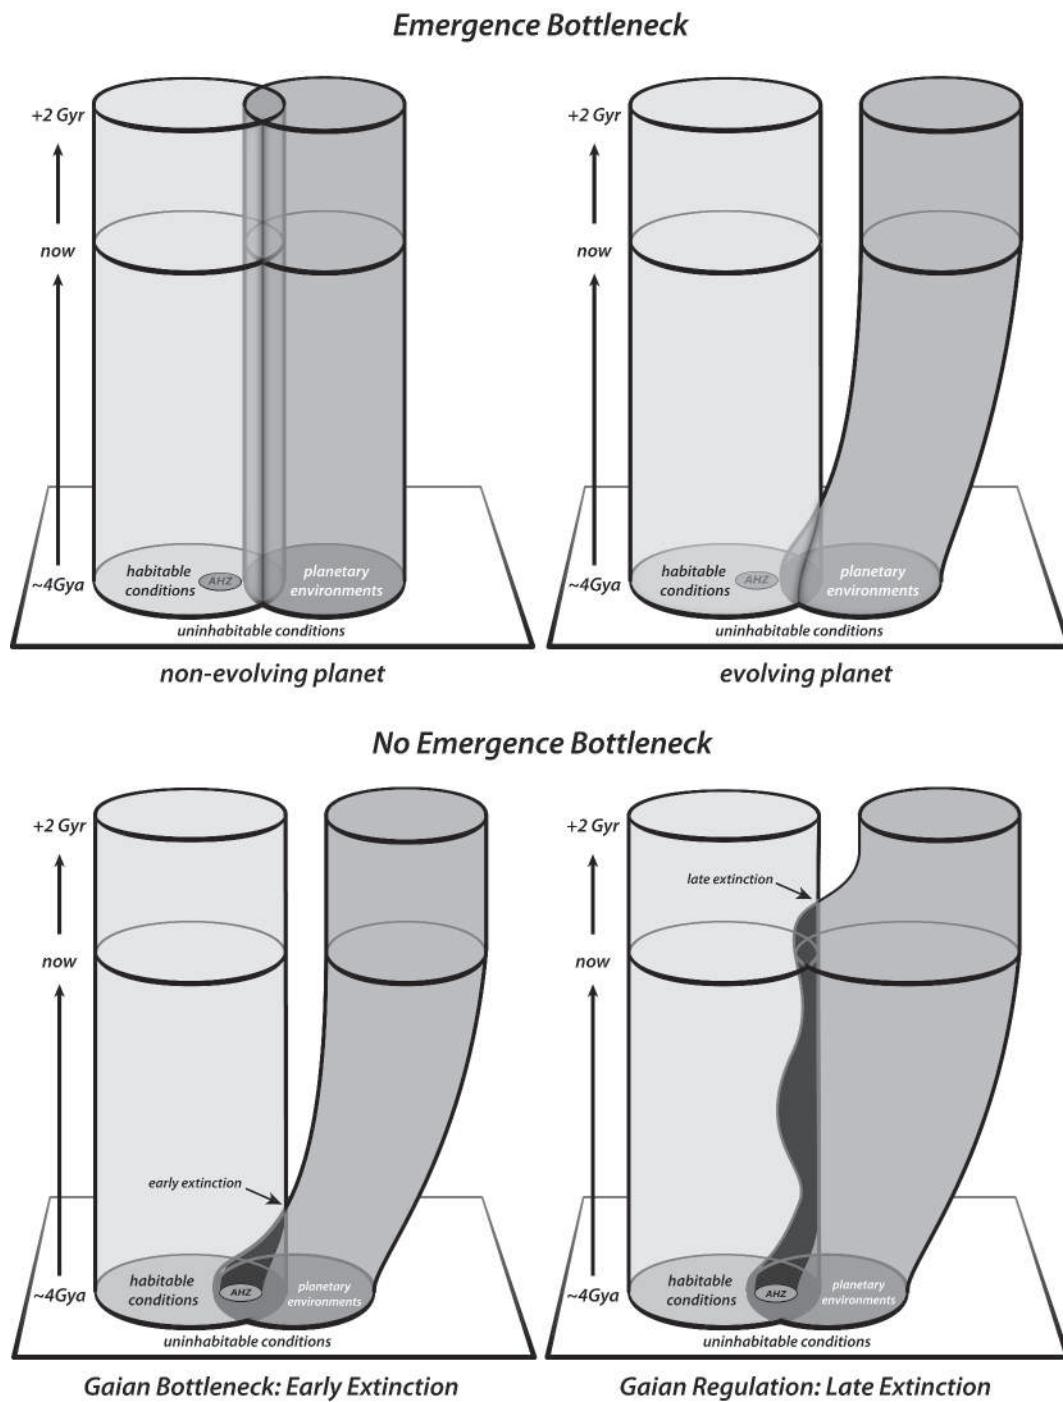

FIGURE 10.1.9 Emergence bottleneck (top panel) versus no emergence bottleneck (bottom panel). The yellow tubes represent habitable conditions that we have assumed to be unchanging through time. The orangish spot at the base of the yellow tubes, labeled “AHZ” (abiogenesis habitable zone), represents a more restrictive set of conditions necessary and sufficient for life to get started from non-life. The blue tubes represent the environments on a planet as a function of time (~4 billion years ago at the base, and ~2 billion years into the future at the top). The environments on emergence bottleneck planets (blue tubes in the top panel) do not overlap with the AHZ, so life is unable to get started. Even if such planets have habitable conditions, they are uninhabited by life that evolved in situ. No emergence bottleneck planets (bottom panel) are planets in which life can get started, since their environments initially overlap with the AHZ. The Gaian bottleneck is the idea that even if the emergence of life is a common occurrence (as in the two blue tubes on the bottom panel), the evolution of biotic regulation of greenhouse gases and/or albedo (needed to maintain habitable conditions and life) is a rare and random adaptation (blue tube on the bottom right). The most common default on wet rocky planets would be early extinction (blue tube on the bottom left). On such planets, life emerges but never acquires globally adaptive properties that permit biotic regulation of an inherently unstable surface environment. This is an extension to the planetary level of the idea that most mutations are maladaptive. (From Doolittle, W.F., *J. Theor. Biol.*, 434, 11–19, 2017.)

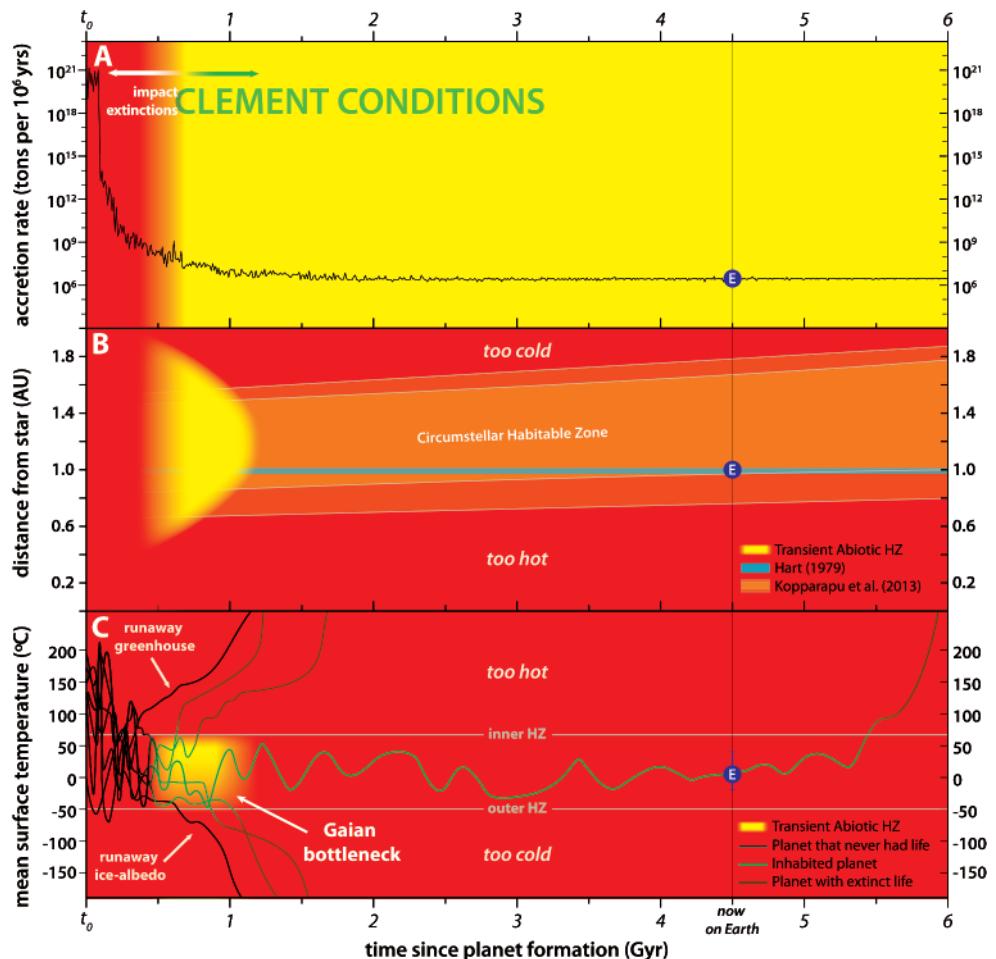

FIGURE 10.1.10 Same as Figure 10.1.2, but here, we have added the bottom panel, which shows the Gaian Bottleneck model, in which, unlike the Earth, most planets go either runaway greenhouse and get too hot or runaway ice-albedo and get too cold, to have liquid water at their surfaces. The yellow region in panel C between 0.5 Gyr and 1 Gyr is where life could have gotten started—after the early heavy bombardment but before the runaway greenhouse or runaway ice-albedo.

10.1.4.2 THE ABIOTENESIS HABITABLE ZONE: CONDITIONS REQUIRED TO START LIFE

We are unsure how life got started (Oparin 1968, Lahav 1999, Peretó 2005, Sutherland 2017), but there are several plausible non-mutually-exclusive candidates: metabolism first, also known as the garbage bag world (e.g., Dyson 1999); compartmentalization first (Deamer 1997, Segre and Lancet 2000); and information first, also known as the RNA world (Gilbert 1986, Joyce 2012).

The abiogenesis habitable zone (AHZ) could depend on impact events of a heavy bombardment, hydrothermal activities (enhanced on younger, more tectonically active planets), lightning, or large tides producing cycling between hydration and dehydration (Figure 10.1.11) (Brandes et al. 1998). To make more specific educated guesses about the requirements to get Earthlife started, we need to find out more about the metabolism and environment of the last universal common ancestor (LUCA). Possible scenarios of proto-biological molecular evolution before the LUCA have been proposed (Mann 2013).

The problem of how and where Earthlife got started can be approached through genomics (e.g., Weiss et al. 2016) or

by trying to identify promising potential AHZ environments. The two most popular scenarios for the origin of Earthlife are alkaline hydrothermal vents in the deep sea (e.g., Martin and Russell 2007, Smith and Morowitz 2016) and freshwater hydrothermal systems on land (Djokic et al. 2017, Damer et al. 2017). Hydrothermal vents (acidic or alkaline) seem to harbor a promising variety of prebiotic chemistries (Holm and Andersson 2000; Orgel 2004; Padgett 2012; Sojo et al. 2016). See also Joyce and Orgel (1993), Wächtershäuser (2000, 2008), de Duve (2000), Burmeister (2000), Cleaves (2015), and McDonald (2015). Since our ideas about the Earth's AHZ are quite speculative, our ideas about the origin of life elsewhere and a universal AHZ are even more so.

10.1.4.3 THE EVOLUTION OF HABITABILITY

Bananas can't survive in a desert. Cacti can't survive in a rain forest. In our discussion of habitability, it seems we need to specify the kind of life we are talking about. If we're curious about whether a planet is habitable or not (or how habitable it is), we need to know what life-form we are talking about. We need to ask the question: Habitable for whom?

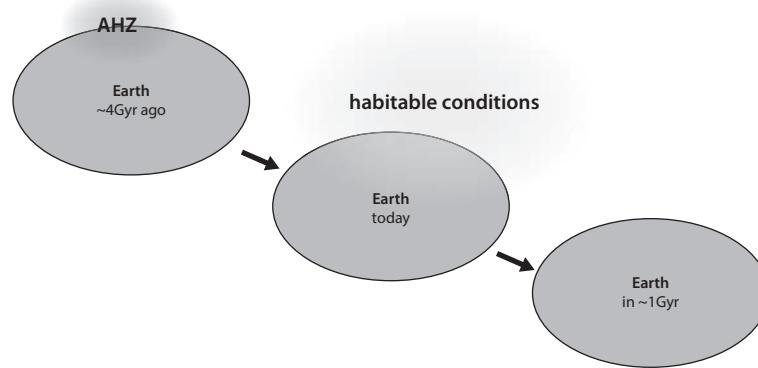

FIGURE 10.1.11 The abiogenesis habitable zone (AHZ) and habitable conditions. In Figure 10.1.9, we assumed that the AHZ was a subset of the yellow tubes representing habitable conditions. Here, we drop that assumption. The three ovals represent the evolution of the environments on Earth. Four billion years ago, there were environments on Earth in which Earthlife got started. Despite the Earth evolving away from the AHZ, habitable conditions evolved and were maintained. A billion years from now, the Earth will no longer have habitable conditions, probably because of the loss of hydrogen and therefore the loss of the ability to maintain surface water.

The concept of habitability is inextricably coupled to the concept of life (but see Cockell 2011). Cockell et al. (2016) suggested to define habitability as “the ability to support the activity of at least one known organism.” However, for microbiologists, who can culture only a tiny fraction of known bacteria, this definition is operationally difficult. The number of known organisms is growing, but our ability to culture, isolate, and characterize them is severely limited (Rinke et al. 2013). This being the case, how can we know whether a given environment is habitable, even for some of the most common organisms on Earth?

For astrobiologists, primarily interested in the habitability of wet rocky Earth-like planets, the limitations of Cockell et al.’s (2016) definition are severe. If we are interested only in the question: “Could any known organism on Earth, live on that planet?,” then we are left with the obvious problem that organisms do not live alone. Individual organisms are obligately embedded in ecological webs made of other mutually dependent life-forms. An obvious example is the dependence of aerobic organisms (e.g., us) on the availability of molecular oxygen produced by photosynthesizers.

The presence of liquid water at the surface of a planet could be an abiotic property set by temperature and pressure (as is usually assumed), or it could be a biotic feature regulated by a biosphere (Harding and Margulis 2010). The effect of physical parameters such as insolation and escape velocity can be strongly modified by biotic regulation of albedo and greenhouse gas content of the atmosphere. In other words, the existence of feedback between life and its environment—and even the distinction between life and environment—is problematic. The biotic regulation of the carbon-silicate cycle is an example (Walker et al. 1981, Schwartzman and Volk 1989). If life plays a strong role in creating a habitable planet, then it is possible that to be habitable, a planet needs to be inhabited (Kasting 2010, Goldblatt 2016, Hall 2016, however see also Cockell 2011).

If life and environment are in a tight feedback, then we should not conceive of them as being separate. We cannot compute the width of a CHZ with any useful precision without

taking biotic regulation into consideration. Circumstellar habitable zone computations seek to define the region within which a planet should be capable of harboring life...

... yet whether the planet is inhabited will determine whether the climate may be habitable at any given distance from the star. This matters because future life detection missions may use habitable zone boundaries in mission design.

(Goldblatt 2016)

It is generally agreed that the very early Earth was uninhabitable. A few hundred million years later, life got started, and since we are here today, the Earth necessarily became habitable. It is also generally agreed that in 1 or 2 billion years from now, the Earth will have lost its water and be uninhabitable again. Obviously, habitability changes and evolves under the influence of an evolving planet and the evolving life on it.

10.1.4.4 DEFINITIONS OF LIFE AND DEFINITIONS OF HABITABILITY ARE NOT HELPFUL

It seems obvious to many people that if we want to find life—if we want to develop an instrument to identify life—and if we want to find an unambiguous biosignature that can be remotely detected (Lovelock 1965, Meadows and Seager 2010, Seager et al. 2016, Krissansen-Totten et al. 2018), then we need to be as specific as possible about how life differs from non-life. This suggests that we need a definition of life.

Biology textbooks are full of definitions of life. Most definitions have been sculpted around the flora, fauna, and fungi we know on Earth. They usually mention growth, self-regulation, self-reproduction, and chemical complexity (Lineweaver and Chopra 2012b). Much thought has gone into the development of an operational definition of life suitable for application elsewhere in the universe (Sagan 1970, Joyce 1994, Chyba and McDonald 1995, Gould 1995, Nealson and Conrad 1999, Cleland and Chyba 2002, 2007, Koshland 2002, Lineweaver 2006, Benner 2010, Kolb 2010, Bains 2014). None is universally accepted (Popa 2015).

The title of an influential article by Jack Szostak (2012) is “Attempts to Define Life Do Not Help to Understand the Origin of Life,” in which he argues that if one wants to understand the origin of Earthlife, it is not useful to define it. After all, one is trying to understand what is probably a relatively complicated and drawn-out transition from non-life to what we now call life.

if the emergence of life is seen as the stepwise (but not necessarily slow) evolutionary transition between the non-living and the living, then it may be meaningless to draw a strict line between them... as argued long ago by Immanuel Kant, precise definitions may be achievable in mathematics and philosophy, but empirical concepts (as is the case for what life is) can only be made explicit through descriptions that depend on the historical context (Fry 2000).

(Tirard et al. 2010)

Like democracy and eyeballs, life itself has a history and, therefore, according to Nietzsche, cannot be defined:

Only that which has no history can be defined

(Nietzsche 1887)

An all-encompassing goal for astrobiology is to understand cosmic evolution—cosmic history—and since it is history, precise definitions are not the way to go.

This conundrum is very similar to the problem of defining *Homo sapiens*. “There never was an Australopithecus mother who gave birth to a Homo child.” (Dawkins 2017). As long as we were unaware of *Homo erectus*, Neanderthals, Denisovans, Australopithecines, and the large number of ancestors and extinct cousins that connect us to our common ancestor with chimps, we could naively congratulate ourselves for having workable definitions of *Homo sapiens* that depend for their success on our ignorance of these transitional forms. But *Homo sapiens*, like all life-forms (and, we postulate like life itself), has a history. The more we find out about the history of the evolution of life and what might be called transitional forms, the more meaningless it becomes to draw a strict line between life and non-life (Szostak 2012).

The whole system of labeling species with discontinuous names is geared to a time slice, such as the present, in which ancestors have been conveniently expunged from our awareness. If by some miracle every ancestor were preserved as a fossil, discontinuous naming would be impossible.

(Dawkins 2017)

We can apply Dawkins’ reasoning about species more generally to life:

The whole system of labeling things life or non-life is geared to a time slice, such as the present, in which transitional forms are no longer present or are ignored. If by some miracle every ancestor, and every transitional form were preserved as a fossil, discontinuous naming of some things “life” and other things “non-life” would be impossible.

These same caveats about defining life apply to attempts to define habitability. Since the concept of “habitability” depends

on the concept of “life,” it may be meaningless to draw a strict line between habitable and non-habitable. If there are no minimal properties required for a system to be considered alive, it follows that there are no minimal properties required for an environment to be considered habitable.

Habitability becomes more precise if we are talking about habitable for us. But then, it becomes less precise because we modify our environments. In a spacesuit, the surface of the Moon is habitable. Without one, it is uninhabitable. Humans are not alone in this respect. Life has a long tradition of modifying its environment, from the formation of the first lipid bilayers to termite nests and beaver dams (Odling-Smee et al. 2013). In trying to understand life and habitability, studying the important feedback between life and its environment and their coevolution will bear more fruit than insisting that what we are looking for has a precise definition (Chopra and Lineweaver 2018).

10.1.5 OUTSTANDING ISSUES

Studies of the habitability of a planet and the characteristics of habitable planets are problematic because of our ignorance about the following issues:

1. What is life? If we don’t understand what life elsewhere is, we cannot understand what habitability elsewhere is. How can we talk about habitability without having a reasonable idea of what life is?
2. What are the conditions under which life can originate? Does it make sense to talk about habitability on a planet on which life could not originate?
3. What are the conditions that maintain life? Since we have very little idea about the limits of life elsewhere, we have very little idea about what could maintain life elsewhere.
4. Negative feedbacks are necessary to prevent Earth-like planets from becoming runaway greenhouses and runaway glaciations and thus uninhabitable. Are these feedbacks abiotic, biotic, or both? Are there different negative feedbacks over the habitable lifetime of a planet?
5. It is not easy to detect something if you don’t know what you are looking for. As we learn more about exoplanet atmospheres, the ambiguity between biotic and abiotic chemical disequilibrium may not go away.

11.1.1 INTRODUCTION

It is an exhilarating thought to stand on a clear night, gazing at the countless numbers of stars above and wondering if there could be someone out there who—in that very same moment—wonders if we exist. To think about the existence of life out there—be it unicellular organisms or perhaps even strange, more complex creatures—is indeed astonishing. The possibility that these extraterrestrial beings might also think, feel, dream, intend, strive, and wonder about their own existence would be even more mind-boggling. And moreover, if we could exchange thoughts with each other about our existence and about what it means to live, feel, and think, that would be the most overwhelming experience of the human mind.

Even supposing there is nobody out there who wonders whether we exist or not, we know at least that we think that we exist. Because we think about our own existence and our own place in the universe, one could say that the universe is aware of its own existence and that the universe thinks. Through the self-conscious human being, the universe can be considered self-conscious and able to reflect upon itself. It seems that the universe is not only bio-friendly (Davies 2007) but also

cogito-friendly. The universe is not only living; it contains not just self-reproductive entities, but it also has apparently led to self-reproductive organisms that are able to reflect upon the universe they live in, upon their place in that world, and upon their own thoughts and existence.

This chapter concerns exactly this: the thinking universe or intelligence in space. It concerns the presence of intelligence and its possible origin, evolution, and distribution. We know at least that we think, but are there other creatures out there that think, and would it be possible to understand them? I raise three main questions about mind in the universe in this chapter. The first concerns *terrestrial intelligence*: What happens to the human mind when it tries to understand extraterrestrial phenomena and environments? The second concerns *extraterrestrial intelligence*: Are there intelligent living beings out there, and if so, what makes them possible? What are the necessary or sufficient conditions for intelligence to evolve? The third question concerns *terrestrial-extraterrestrial interaction*, or in other words: If there are other intelligent beings out there, could we understand them, and they understand us, and could it be possible to mutually exchange thoughts between the two of us? The following text could be seen as

an attempt not only to reach outward to the stars and to the minds that we hope to find out there, it also reaches inward into the uncharted depths of the human mind. This chapter concerns the human mind in front of the unknown as well as the evolution of an unknown potential mind in the unknown space—and finally, the mutual understanding of minds in the universe.

11.1.1.1 ASTROCOGNITION

The scientific search for life in space, called astrobiology, tries to find the answers to the questions about the origin, evolution, and distribution of life in the universe (Bertka 2009). How did intelligent life emerge, how did it evolve, and does it exist elsewhere in the universe? Astrobiology is, according to the 1996 NASA Strategic Plan's definition, “the study of the living Universe” (NASA 1998; Chyba and Hand 2005). In this chapter, I go a step further and ask not only for the conditions for life but also for the conditions for life with awareness or self-awareness, that is, *intelligent life*, about the origin, evolution, and distribution of intelligent life in the universe. This scientific endeavor could be called *astrocognition*, which is the study of the origin, evolution, and distribution of intelligent life in the universe. What necessary or sufficient conditions must be in place in order for more complex intelligence to emerge and evolve? And does it exist elsewhere in the universe?

The multidisciplinary field of astro cognition—first proposed in 2009 (Dunér 2011a)—could be generally defined as “the study of the origin, evolution and distribution of cognition in the Universe,” or simply “the study of the thinking Universe.” Astro cognition concerns the cognitive processes in space, the origin and evolution of cognitive abilities, and the distribution of cognition in extraterrestrial environments (Dunér 2011a; Osvath 2013). “Cognition” could, in this context, be understood as the ability of processing sensory inputs for action in the environment. If we are discussing the existence of extraterrestrial intelligence in space, then we should take into account the research within cognitive science and affiliated research areas, in order to find answers to these questions: What is needed for higher cognitive skills to evolve? What physical, biological, societal, cultural, and other environmental factors shape cognition? What cognitive abilities are needed for a living organism to be able to manipulate its environment or, in other words, to develop technology? Like the astrobiology field, of which it is a part, astro cognition requires a multidisciplinary approach that brings together cognitive science, philosophy of mind, animal cognition, semiotics, linguistics, anthropology, cultural studies, history of science, computer science, neuroscience, evolutionary theory, physics, astronomy, space technology, and other fields of research.

Astro cognition could give us further theoretical, scientific knowledge of how we encounter the unknown and how the human mind interacts with space and the environment around us. It could also give us a better understanding of the evolution and prerequisites needed for cognition to emerge. These achievements will be valuable, even though we might never find intelligent life in outer space. From this, we would learn

more about human cognition and how it has been developed here on Earth. The perhaps most important outcome is that possible encounters with other minds here on Earth or on extrasolar foreign planets in deep space among billions of stars and galaxies can give a more universal answer to the question: “What is thinking?”

11.1.2 TERRESTRIAL INTELLIGENCE

The human desire for exploration and human encounters with the unknown are a fundamental part of the cultural history of humankind, from the first stumbling steps on the African plains to the recent explorations of our globalized and urbanized world. From the very dawn of the hominids to the days of the modern human being, this mutable terrestrial being has expanded in ever-widening circles of spatial consciousness, in an endeavor to climb over mountains to the next valley, cross vast oceans, and fly through the air. The next small step for man, or giant leap for humankind, that of going far beyond the atmosphere and gravity of the Earth to the unknown extrasolar space, is decisive, but that too is part of the long history of humankind.

This preference for the unknown and for new things and new experiences—“neophilia”—is probably one of the explanations for human expansion and human endeavors such as art and science. This enabled us to gain more knowledge of the world around us, but it also led to severe cognitive challenges, which in its turn led to new thoughts and ways of thinking. The exploration of extraterrestrial environments and the possible contact with other forms of life and civilizations will most likely change our thinking, conceptual frameworks, and belief systems. In the following, I will discuss the first main question concerning mind in the universe: the challenges of terrestrial intelligence. What cognitive challenges are we likely going to face when we encounter the unknown (Dunér 2011a; Dunér and Sonesson 2016a)? In other words, it concerns the challenges our Earth-bound perceptual, cognitive, and psychological capacities face in a space context (Pálsson 2009).

In the course of everyday events and encounters, the human mind has been enabled, through an evolutionary process, to understand, interact, deal with, and adapt to the environment of this particular planet and to the minds of other human beings. Thus, the human brain is well adapted to the biological, ecological, and physical characteristics of our planet, as well as the cultural, social, and cognitive characteristics of the tellurian species *Homo sapiens*. But how would the human mind, which is entirely a product of a terrestrial environment, function in extraterrestrial environments and understand extraterrestrial minds?

The success of our search for intelligent life beyond our solar system will depend on, first, obviously, that there really exists intelligent life to be discovered, and second, that we have the technology to discover it. But that is not enough. The discovery depends on—and this is the most critical—the capability of the human brain and the organization and efficiency of that systematic search for knowledge that we call science, which is a product of the socio-cultural history of our species (Dunér 2016a). Our endeavor depends on human

cognition and our ability to understand and interpret what we observe in our surrounding world.

Even though intelligent life might not exist out there, it is we human beings, with our brains, bodies, and cultures, who are searching for it. The scientific endeavors of astrobiology and interstellar communication are dependent on the human mind and human culture (Dunér 2011a, 2013a; Dunér et al. 2013). Astrobiologists have brains, for sure; they are using cognitive tools that are a result of the bio-cultural coevolution of human cognitive abilities. Certain cognitive processes are at work when astrobiologists encounter unknown things, when they interpret their observational data, when they gather and classify it, and when they make conclusions. This does not go on in subjective isolation. Astrobiologists live in a culture, in a certain time in history, and in a specific research environment and collaborate with other thinking beings (Vakoch and Harrison 2011; Billings 2012; Dick 2012; Race et al. 2012; Vakoch 2013; Traphagan 2015a, 2016).

Cognitive science can give clues to how we understand and think about the universe and reveal new perspectives on human encounters with the unknown. In short, cognitive science studies how the external world as well as our inner worlds are represented and how we use cognitive tools for our thinking, such as language, image schemas, mental maps, metaphors, and categories. Cognitive science also studies how we use and interpret signs, objects, drawings, images, etc., to enhance communication. It is about perception, attention, memory, learning, consciousness, reasoning, and other abilities that we include in what is called “thinking.”

Cutting-edge thought in cognitive science portrays the mind as embodied, extended, distributed, and situated. According to the theory of the embodied mind (Varela et al. 1991; Lakoff and Johnson 1999; Krois 2007; Thompson 2007), the mind is not something independent and detached from the body. There is no “brain in a vat,” to borrow a turn of phrase from Hilary Putnam’s famous thought experiment (Putnam 1981). Instead, we think with the body. Therefore, bodies of other kinds and evolutionary backgrounds, like those that might exist on other planets in the universe, will have other minds and ways of thinking. The brain not only needs the body but also the surrounding world in order to function efficiently. The environment has an active role in driving cognitive processes. According to the extended-mind hypothesis of Andy Clark and David Chalmers (Clark and Chalmers 1998; Clark 2008), the mind leaks in various substantive ways into the environment. The boundary between self and non-self, and between self and world, is one that is never fixed but is constantly being re-negotiated. In a similar way, distributed cognition (Hutchins 1995) stresses the non-localizability of much of cognition: that we are using our environment and tools for enhancing thinking and that we place our ideas and memories in things, such as books and computers. Mind is not isolated; it is situated, in space and time, in a specific physical and social environment.

The search for extraterrestrial intelligence is not just about possible intelligent life-forms out there but also about

ourselves and our ability to perceive and interpret our surrounding world, in phenomenological terms, our lifeworld (Dunér and Sonesson 2016b). Space is “the ultimate mirror we hold up to ourselves,” as Parthemore (2013, p. 83) puts it. In confronting the depths of the cosmos, we confront the unseen depths in ourselves. In other words, astrobiology and astrocognition challenge our everyday conception of ourselves as human thinking beings in the universe. In the following, I will discuss what is “intelligence” and highlight some cognitive functions or capacities that are in work when a terrestrial mind confronts the unknown.

11.1.2.1 INTELLIGENCE

What is intelligence? When we search the skies for extraterrestrial intelligence, we should at least have some ideas of what kind of phenomena we are looking for (Chick 2014; Marino 2015b; Ruse 2015; Schneider 2015). Within the Search for Extraterrestrial Intelligence (SETI) community, this question has been rather overlooked. The Drake equation (Drake 2011; Vakoch and Dowd 2015; Dunér 2017), and much of the SETI research, has instead an operative, pragmatic understanding of “intelligence” and just looks for a civilization able to transmit electromagnetic waves. “Intelligence” is, in that sense, “the ability to transmit electromagnetic waves.” This is of course not what we mean when we recognize something as “intelligent” in ordinary life. Nor is it sufficient to help us understand the distribution of intelligence in space. In order to detect content-rich and meaningful signals from an extraterrestrial civilization, it is not sufficient to rest on the belief that the “intelligent” being is able to construct advanced devices; a creature that constructs meaningful messages should also be able and willing to communicate, that is, to share experiences through a medium.

A recent attempt to define intelligence in connection to extraterrestrial life and evolution of intelligence is more elaborated. Ted Peters defines intelligence in terms of seven traits: interiority, intentionality, communication, adaptation, problem solving, self-reflection, and judgment (Peters 2017). Even microbes exhibit the first four traits; humans, along with some other animals, exhibit all of them. Where there’s life, there’s intelligence, so to speak, according to Peters. Intelligence seems to be a matter of degree rather than of kind. However, to this list of traits, I would add a most critical one: intersubjectivity, which I will explain in more detail in the following. Intersubjectivity, the ability to understand other minds, is an important trait in order to explain intelligence and how an intelligent creature can evolve complex communication, civilization, and technology (Dunér 2014).

The definition of intelligence has commonly been connected to problem solving (Sternberg 1985, 2002). As such, intelligence is understood as the ability to solve problems, to make rational choices, to reason logically, and to handle the constraints and limitations of time, space, and materials. However, it is not sufficient to describe intelligence as a mere problem solving in order to explain the development of advanced technology. As a broader concept, cognition

includes not only the abilities that we call rational, logical, or intelligent. An important part of what it is to be intelligent is to have emotional skills, a capacity to emotionally appraise the relevant environment with attraction, disgust, etc., and to respond to socializing, bonding, coupling, etc., in a social group. By this, I mean that intelligence is an efficient strategy to cope with, not only the physical but also—which is important—the social environment.

There are two features (among many other possible ones) of an “intelligent” life-form that are particularly important. First, it can imagine things not existing, that is, things, events, etc., not present in time or space, right in front of the thinking subject. Second, an intelligent being is also able to engage in intersubjective interactions, understand other minds, and imagine and envision what they will do, what they feel, and how they reason. To be intelligent is to have intersubjective skills, to be able to understand and make inferences about other minds. If the extraterrestrial being that we encounter is lacking these two abilities, it would probably not have complex communication and advanced technology, and we would not be able to communicate with it. Without the ability of imaging non-existing things, it would not be able to construct abstract concepts, anticipate future needs, and invent new technology. Without intersubjective skills, it would not be able to collaborate for achieving shared goals.

“Intelligence” could be explained—rather than a mere problem solving—as a kind of cognitive flexibility, an ability to adjust to changes in the physical and socio-cultural environment. It is an evolved mental flexibility required to survive and reproduce within a specific environment. This includes the capability of representing activities and being able to make inner models of reality and other minds. “Extraterrestrial intelligence” is actually a rather misleading and narrow concept, referring, for the most part, to the problem solving and rational reasoning skills and not to those mental abilities, for example, intersubjectivity, that are indispensable for a life-form to have civilization, culture, and technology. Thus, instead of searching for extraterrestrial intelligence, we should search for extraterrestrial cognitive flexibility. We should search for a certain cognitive flexibility that is a result of a more or less unique adaptation to the specific habitable environment in which it has its origin.

Within in the human mind, which is a product of a bio-cultural coevolution of cognitive abilities of our terrestrial species, there are a number of cognitive tools by which we can understand and handle the world around us. Next, I will highlight three cognitive functions that are particularly striking in the human search for life in the universe, when astrobiologists try to interpret and understand encountered unknown phenomena: *perception*, how we interpret what our senses convey and how the information we get from the surrounding world is processed in our minds; *conceptualization*, how we form concepts of life, how we define and categorize things, and the relation between our concepts and our knowledge of the world; and finally, *analogy*, how we see similarities between things and, with inductive, analogical reasoning, go from what we know to what we do not know.

11.1.2.2 PERCEPTION

Where we are in time and space is essential for cognition. What the senses convey have to be interpreted through means of specific cognitive processes. The cognitive agent is never just a passive recipient of images and information from the surrounding world. Instead, the brain actively searches out patterns in what is conveyed to it through the senses and interprets them through a process that is determined by both biological and cultural factors. Striking examples of this *epistemic perception* are the maps of Venus and Mars from the seventeenth century and onward that delineated the surface of the planets (Dunér 2013c). We see what we expect to find. In 1877, at the Brera Observatory in Milan, Giovanni Schiaparelli recorded a detailed network of canals on Mars. This finding was confirmed by the American astronomer Percival Lowell, who detected hundreds of Martian canals that he interpreted as an artificial irrigation system (Lowell 1895). Quite soon, it became clear that this was a mistake. However, it was neither the telescopes nor the eyes of the observers that caused the fallacy. It was the interpretation of the sensory inputs that led them wrong. The Martian canals existed only in the mind of the observers.

In the optical observations of distant worlds, preconceived understanding often shapes the interpretation of what the observers see. Through their senses, the observers receive impressions from outer space, and they collect and collate information by using their sight. The interpretation of what is observed is based on a preconceived understanding, concepts, and prior knowledge. Observations are not separate from theory. In contrast to the tendency to place excessive trust in “objective” observations, many philosophers of science, such as N.R. Hanson, Thomas Kuhn, and Michael Polanyi, have emphasized that observations are theory-laden and that there is no sharp dichotomy between observation and theory in scientific research (Crowe 1986). We need theories to understand what we see, and our preconceptions and expectations lead us in one or another direction, sometimes the wrong course. It is not uncommon to see what we expect to find.

Perception is not a neutral, objective, and realistic recording of reality. This conceptual or epistemic perception implies an identification of what is seen and takes place by applying our concepts to visual perceptions, or in other words, concepts affect what we see, and, should we lack any concept of a specific phenomenon, then it will be difficult to distinguish it among all our impressions. The world distorts our concepts, and the concepts distort our world.

11.1.2.3 CONCEPTUALIZATION

To have concepts is to be able to categorize things, to see a thing as something different from something else, but also to see similarities between things (Lakoff 1990; Taylor 2003). All living creatures seem to categorize the environment in terms of edible versus inedible, benign versus harmful, and so forth. Categorization becomes more complex in human cognition. The human mind tends to categorize and see hierarchies and similarities between things, such as species and genera in

taxonomy (Berlin 1992; Dunér 2013b) or the classification of stars and other astronomical objects. We need categories and invent new ones in order to handle the world around us; otherwise, we would fall into a chaotic abyss of unsorted impressions.

Constructing concepts in order to be able to think and talk about the new phenomena encountered is a major task for astrobiological research. Astrobiologists use a wide range of concepts, such as biosignature, habitability, habitable zones (see, e.g., Kane and Gelino 2012), Earth analogues, exoplanets (Perryman 2012), and other concepts and terms inherited from already well-established scientific disciplines. These concepts together form that multidisciplinary field of research we call astrobiology. The most debated and discussed conceptual issue in astrobiology is the concept of life (Losch 2017). If we are searching for non-terrestrial life, we ought to know what it is we are looking for and what characteristics it might have. If life is a recipe, what are the essential ingredients and which are optional? Should these criteria pertain to metabolism, entropy, genes, reproduction, or something else? So far, the debate has intuitively employed an Aristotelian conception of definition (Aristotle, *Posterior Analytics*, 2.3.90b30–31), in which a “definition” is a limited list of characteristics that are both necessary and sufficient for something to be of the type of object it is and from which all the characteristics of the object originate. In our daily lives, however, we make relatively little use of Aristotelian-type definitions and depend much more on prototypes (Rosch 1975, 1978). Dogs, cats, and horses may seem to be more typical representatives for “life” than arsenic microbes. The debate on the definition of life could certainly benefit from the insights of contemporary philosophy and cognitive science about human categorization. The problem of defining life has to do with how the human mind categorizes things.

Science—and this is certainly true for astrobiology as well—concerns concepts. We need names and abstract concepts in order to be able to talk and reason about objects, structures, processes, etc., that we gather from our senses, through observations and experiments. When we are using these terms, they need to be reasonably well defined and some sort of consent needs to be established, so we can agree on what we talk about. We need definitions. One might think that these concepts already exist out there—the task is just to discover them. However, the input we get from the surrounding world has to be processed by our brains and depends on the cognitive abilities we possess. The scientific concepts we use are not just dependent on the particular characteristics of human cognition that is a product of a biological evolution of the human brain, it is also a product of a specific cultural evolution here on Earth and many generations of natural philosophers and scientists in the history of human, terrestrial science (Dick 1982; Crowe 1986, 2008; Dick 1996; Dunér 2012, 2016b; Dunér et al. 2012, 2013, 2016).

Future discoveries in astrobiology will most likely challenge our categorizations and definitions, that is to say, our preconception of what the world is and not is. So, we should be prepared to re-categorize and redefine our concepts. Future exobiological systematics and taxonomy will face problems

concerning categorization, identification, and description. The taxonomy of future extraterrestrial fauna and flora will be a product of the human mind. It is our human way of understanding the world, by using certain categories and concepts, that makes some problems for us, when we are dealing with phenomena, far beyond the well-known of our daily lives.

11.1.2.4 ANALOGY

Through the history of astrobiology, we find a certain common form of argumentation: the analogy, the thought moving from what we know to what we do not know (Dunér 2013c). An analogical argument could be explained as a search for similarities, that is, a way of selecting features in the source domain that are to be mapped onto the target domain and of transferring relevant properties from the source to the target. If x has the properties $P_1, P_2, P_3, P_4 \dots P_n$, and there is a y that has P_1, P_2 , and P_3 , we may conclude that it also has P_4 . If we know there is an x that has these qualities and we discover a y that also has some of these qualities, then we conclude that all y also have the quality that we are seeking, P_4 , or formulated in first-order logic: $\exists x(P_1x \wedge P_2x \wedge P_3x \wedge P_4x \dots P_nx) \wedge \exists y(P_1y \wedge P_2y \wedge P_3y) \Rightarrow \forall y(P_4y)$.

The challenge is then to select the correct and relevant salient features from an infinite number of possible ones in the source domain, which will then be transferred to and mapped onto the target domain. In the *Sidereus Nuncius* from 1610, Galileo showed, based on his telescopic observations and analogical reasoning, that the Moon had mountains and therefore had the same solid, opaque, and rugged nature as the Earth (Galilei 1610; Spranzi 2004). If the Moon and Earth are similar in many respects, why should the former lack life, if the latter has it? In some sense, astrobiology as a whole is one single, great analogy. Starting from the one particular type of life we happen to know something about, namely life on Earth, we proceed to search for life on other planets. We predominantly look for life as we know it: something needing oxygen, liquid water, being based mainly on carbon, inhabiting a planet of a certain magnitude, atmosphere, chemistry, temperature, etc.; something that revolves within the habitable zone, at a certain distance, period, eccentricity, inclination, etc., of a solar-type star (a G2 main sequence star of 4.5 Gyr of age), which in turn has to be of a certain size and temperature, and so on.

There are a number of problems with such an analogical argument: first of all, do we know all the necessary or sufficient conditions for life? Another problem is that we restrict ourselves to one particular sort of life, that is, the one we happen to know—life as we know it—and might overlook other forms of “weird life”—life as we do not know (Davies et al. 2009). The third problem lies in the unpredictability of evolution that there are some stochastic events involved in the evolutionary process. The question is: If all ingredients of life are in place, will that inevitably, by necessity lead to the emergence of life? Is life a natural manifestation of matter (cf. de Duve 1995).

Logically speaking, analogical arguments are invalid. However, in providing us with some point of departure, they

still might hold some heuristic benefits in the search for life. For example, studies of analogue sites on Earth might give us valuable knowledge that could support and guide us toward future discoveries of life in space (Martins et al. 2017). What we are actually looking for is something that reminds us of ourselves, something similar to us. Life, however, might be very different from what we imagine. The history of science is actually a history of surprises. The world we are living in turned out to be very different from what we first thought: richer, more complicated, more advanced, more peculiar, and more astonishing than what we could have dreamt of. This will also be true for astrobiology. Future discoveries in astrobiology will take us completely by surprise.

11.1.2.5 SUMMARY

From these cognitive theories concerning the human mind, we can conclude that encounters with the unknown outer space will change our spatial consciousness. Furthermore, it will change our thinking, conceptions, categories, belief systems, culture, and meanings of things. What we have come to believe so far through science and human cogitation will face anomalies. The old concepts, categories, systems, and beliefs will most likely fall short when we try to understand these new unfamiliar things. Our thinking, science, and belief systems will then have to be revised, which will lead to adjustments, adaptations, and compromises. A task for astrocognition is to search for the limits of our bio-culturally evolved, earthly brains to try to find out what we can know and what we are likely to encounter in the future. As thinking beings, we are earthbound and historically constrained. Our intellect does not transcend space. Instead, our cognition is situated in space.

One day, we might encounter another living planet. The travelogues and descriptions of these new worlds will inform us about ourselves and our place in the universe and how we interpret and understand the “reality” around us. An independent world outside us might exist, but we will never be able to reach it without filtering it through our minds. To conclude, if we find extraterrestrial life, we can be sure that this will change our thinking about how we perceive the world and our place in the living universe. It will change our science and culture forever.

11.1.3 EXTRATERRESTRIAL INTELLIGENCE

Perhaps, mused the philosopher in Bernard de Fontenelle’s *Entretiens sur la pluralité des mondes* (Fontenelle 1686), there are astronomers on Jupiter, and maybe, we cause them to engage in scientific quarrels, so that some Jovian philosophers must defend themselves when they put forward the ludicrous opinion that we exist. Their telescopes are directed toward us, as ours are toward them, “that mutual curiosity, with which the inhabitants of these Planets consider each other, and demand the one of the other, *What world is that? What people inhabit it?*” (Fontenelle 1701, p. 93, 1767, p. 207)

The search for extraterrestrial intelligence includes hypotheses and imaginations of foreign worlds and of the kind of creatures that might inhabit these worlds (Traphagan 2015b). The question is: What are we supposing when we human beings are searching for “extraterrestrial intelligence”? What are we searching for? Basically, there are four characteristics of possible extraterrestrial life-forms that we have in mind and that are presumed in our search. We assume that “they” are “intelligent,” “social,” and “communicative” and have “technology” (Dunér 2017). To some extent, we actually search for ourselves, for an intelligent life-form similar to us, and for something to which we can relate and establish a mutual understanding. We assume that they are social beings willing to and intelligent enough to be able to invent advanced technology for interstellar communication aimed for transferring information that would be possible to be decoded by the receiver. However, SETI research has mostly focused on the detection methods, especially radio and optical searches (Schuch 2011), rather than seriously addressing the questions of who and what extraterrestrial intelligence could be, which in its turn would direct us to where and how we should search for it (Cabrol 2016). The questions here are: How has intelligent life evolved? What are sociability, culture, and advanced technology? Why do we have these abilities? Why should we expect that the extraterrestrials have them?

11.1.3.1 EVOLUTION

Astrocognition starts from a fundamental, basic premise, *the evolutionary astrocognitive premise*: Cognition in the universe develops through evolutionary processes of adaption to a specific but changing environment and the challenges it presents. The search for life in the universe has, to a great extent, highlighted how strongly the evolution of life and environment are intertwined (Golding and Glikson 2011; Schulze-Makuch et al. 2015; Cabrol 2016) and that the coevolution of life and environment determines the uniqueness of an extraterrestrial life-form (Watson 1999; Irwin and Schulze-Makuch 2001; Kooijman 2004; Dietrich et al. 2006). The same could be said of cognition and environment. We should not only search for environmental habitability, but “environmental cogitability.”

Under certain conditions, which we are only beginning to understand, the environmental pressures force the cognitive agent to evolve toward more complex and flexible cognition. On Earth, we find that intelligence seems—in the same way as vision, aerial locomotion and other abilities—to have emerged several times, apparently independently, in the course of evolution and in separate evolutionary lines, that is, convergent or parallel evolution (Seed et al. 2009; Flores Martinez 2014). One might then argue that analogous planetary biospheres would lead to, through natural selection, the emergence of similarly adapted life-forms. Similar intelligent behavior could partly be an adaption to analogous biospheres. A certain biological convergence might be expected, but cultural convergence much less so, in respect to the arbitrary nature of symbolic thinking and communication.

Due to changing environmental pressures on other planets, sometimes similar and sometimes utterly different those that formed life on Earth, we cannot presume that extraterrestrial life would follow the same path as terrestrial life. Why a life-form evolves advanced cognition needs to be explained (Crowe 2015; Marino 2015a). One could bear in mind that complex cognitive skills are not necessary features of a living creature in order for it to sustain life. Advanced cognitive processing is costly and energy-consuming and not necessarily the most efficient way of securing continued survival of the genes of an organism. However, it is evident that cognitive flexibility has evolutionary benefits and is a good strategy for the adaptation to a changing environment. Intelligence or cognitive flexibility has thus emerged through a bio-cultural coevolution of the embodied mind, due to its benefits for survival, orientation, and adaptation to a variable environment in a Darwinian struggle for existence. Intelligence is thus the ability to respond to changes in the environment with flexibility and success, and a plasticity of learning, that is, to be able to learn from experience, of its own or others.

The more intelligent or cognitively flexible species on Earth, such as primates, dolphins, and corvids, share some important peculiarities. First, they are social animals and have a high degree of social complexity. Second, they are comparatively good at adapting to different environments and diets. If we could better understand the processes behind the rapid brain evolution that began a few million years ago on Earth—the encephalization in the Phanerozoic (Bogonovich 2011; Carter 2012), that is, the increased brain size relative to body size, over time—then we could use this knowledge to formulate astrocognitive theories on the evolution of intelligence in space (Osvath 2013).

Cognition has largely evolved as an adaptation to certain problems that the ancestors of a particular organism faced during the evolution of the species (see, e.g., Gärdenfors 2006). That is, the cognitive processor of the organism is adapted to, first, the physical and biological environment of their celestial body in order to understand and interpret, interact and deal with, and orientate itself in the particular physical and biological environment, in relation to its specific conditions, such as planetary orbit, gravitation, light conditions, atmosphere, radiation, temperature, chemistry, geology, ecology, and biota. Second, the cognition of an organism is also adapted to the minds and culture of its conspecifics, in order for it to understand and interact with other individuals, and to understand emotions, thoughts, and motives, etc., in a psychological and sociological interplay that forms that particular exoculture.

This bio-cultural coevolution of cognition is what can explain the emergence of advanced cognitive skills. Central here is the view of the mind as embodied, situated, enactive, and distributed, in other words, the coevolution of cognition and environment. Mind is thus a product of the interaction between the body and the surrounding environment, both the physical and cultural environments. And the very specific coevolution of cognition and environment, and the stochastic

events it is subdued to, forms the intelligent species of a particular exoplanet. This random nature of bio-cultural coevolution would most likely result in very distinct and unique forms of cognition in outer space. The stochastic events in the history of a species will give each intelligent life-form its unique fingerprint. The extraterrestrial intelligence and its thought processes that we might encounter one day would be completely alien to us. Extraterrestrial minds, like terrestrial minds, have adapted to their specific environment and the specific social interactions between the minds of their species. SETI research is, to a large extent, an endeavor to understand how intelligent life interacts with its environment and communicates information about its perspective on the surrounding world.

11.1.3.2 SOCIABILITY

The evolution of complex life on Earth is dependent on certain major evolutionary transitions, where a group of individuals that could replicate independently began to cooperate and formed a new, more complex form of life. Complexity is, in this context, commonly defined in terms of functional parts that take on more tasks and have more functional interactions (Smith and Szathmáry 1995; Corning and Szathmáry 2015; Levin 2017). One of the transitions on Earth was when individual insects began to collaborate for a common goal, in an alignment of interests, in a eusocial society. As Levin et al. (2017, p. 5) have stated, “Complexity requires different parts or units working together towards a common goal or purpose.” In order to unite for a shared goal, the group needs to decrease conflict between the individuals. A society of societies aligns interests and eliminates conflicts; here, different social colonies collaborate, with different specialized tasks, and finally become completely dependent on each other.

The evolution of cognition is not fully elucidated, but it seems that the orientation in the social environment has played a particularly important role in the encephalization. According to the social-brain hypothesis (Dunbar 1996, 1998), there is a correlation between the size of an animal’s social group and the size of its brain, leading to the conclusion that social behavior drives encephalization. The benefits of living in social groups, according to Dunbar, are that they provide defense against predators and enhance the defense of resources (Dunbar 2001; Chick 2014). A huge part of the brainpower will thus be used for handling social relations and mutual interactions within a group.

A congregation of a number of individuals, what we call a “social group” or “society,” has evolutionary benefits for the individuals as well as for the entire group. The efficiency in how social organisms manage to collaborate, or use their sociability skills, increases their chances for survival. In complex social systems, “individuals frequently interact in many different contexts with many different individuals, and often repeatedly interact with many of the same individuals over time” (Freeberg et al. 2012a, p. 1785, 2012b). The complex social structure of the group is probably a very important

drive for the emergence of intelligence, brain size, and communicative complexity. The brain has increased in capacity in order to tackle different kinds of social relations. Complex social worlds are like selective environments, driving species toward increased cognitive processing ability, which in its turn leads to higher social complexity, and when social complexity increases, it gives rise to a greater selection pressure on individuals for cognitive skills; that feedback produces even more social complexity, and so on (Bogonovich 2011).

In short, intelligent species are social species. Sociability and the social context enhance the adaption to the physical environment and make the individuals less vulnerable to a hostile environment. These social skills cannot subsist without a cognitive capacity to understand, feel, and share experiences of other minds. Beings, which we would recognize as intelligent in space, would be aware of themselves and of other minds and be able to share experiences, actions, information, and mental content. In other words, an extraterrestrial being technologically capable of transmitting and receiving interstellar messages would have intersubjective skills. In contemporary cognitive science, intersubjectivity has become a key concept for understanding not only empathy and altruism but also intelligence, sociability, and communication (Gärdenfors 2008a, 2008b; Gillespie 2009; Hrdy 2009; Gillespie and Cornish 2010; Tylén et al. 2010; Fusaroli et al. 2012; Gentilucci et al. 2012). In its most general definition, intersubjectivity can be explained as the “sharing of experiences about objects and events” (Brinck 2008, p. 116). To be more precise, Zlatev et al. (2008, p. 1) describe intersubjectivity as “the sharing of experiential content (e.g., feelings, perceptions, thoughts, and linguistic meanings) among a plurality of subjects.” Intersubjectivity is an indispensable requisite for the evolution of intelligence, sociability, communication, and advanced technology (Dunér 2014). An extraterrestrial life-form that we could recognize as “intelligent” is, in a way or another, social and able to handle complex social relations and would have intersubjective skills for interpretation, envision, and sharing the behavior and mind of others.

11.1.3.3 TECHNOLOGY

Within the SETI community, advanced technology has often been understood heuristically as “technology for interstellar communication” (Raulin Cerceau 2015; Shostak 2015; Frank and Sullivan 2016). Behind the SETI conception of technology is the tendency of viewing advanced technology as a sort of applied science, as a product of the rational, inventive mind. This is, of course, a very narrow definition of technology that does not fully explain what technology is, why we have it, and where it comes from. In a more general sense, I would rather describe technology as ways of manipulating the surrounding world, using objects in the environment outside the body, in order to strengthen the genetically given capacities, such as body strength, perception, and cognition. Technology gives the intelligent organism the capability to manipulate the environment, in order to make it easier to live in it and to adapt

the environment to fit the organism, instead of adapting the organism to the environment.

To answer the question of how advanced technology might evolve, we have to turn to studies in the evolution of cognition—how hominids began using and manipulating their environment—and to studies in the history of technology—how the cultural evolution of *Homo sapiens sapiens* led to higher technology (Donald 1991; Tomasello 1999; Steels 2004; Richerson and Boyd 2005; Dennett 2009; Rospars 2013). Characteristic of human social interaction is the ability to learn from others, that is, culture, the existence of intra-species group differences in behavioral patterns and repertoires, which has evolved through transmission of learned behavior and knowledge that are not biologically encoded, or in other words, the ability to transfer information from generation to generation that does not use the genetic code for the transfer but is learned, taught, and transferred by a multitude of communicative and cultural devices and artifacts, such as language, signs, pictures, sounds, and objects (Tomasello 1999; Sinha 2009, p. 292). Accordingly, culture presupposes enduring joint beliefs or common knowledge.

Technology, resting on specific cognitive abilities, is, to a large extent, a social phenomenon, a product of the cultural evolution. Without social interaction, joint beliefs, intersubjectivity, and information transfer—in one word, without culture—science and technology would not have arisen on this planet. The rise of civilization involved closeness, interaction of many individuals, and exchanges of ideas, products, and experiences that paved the way for a technological society. Culture, the ability to learn from others within a society of high social and communicational complexity, is what made advanced technology, as well as science, possible.

Thus, technology for interstellar communication is not just a form of advanced tool making that has its necessary conditions in physical or biological factors (cf. Casti 1989; Chick 2014). I would also maintain that there are three socio-cognitive capacities that characterize advanced complex technology and that are crucial for its development. First, a sustainable *complex social system*, with a regulated system for collaboration, such as ethics; second, *complex communication*, for collaboration and abstract conceptualization; and third, a high degree of *distributed cognition*. All these three capacities require intersubjective skills.

Cooperation within a complex social system is one of the reasons behind the emergence of higher technology. Cooperation, in turn, requires some fundamental cognitive and communicative functions. Cooperation regarding a striving for some detached non-present goal requires advanced coordination of the inner worlds of the individuals, that is, intersubjective skills. In order to achieve advanced technology within a civilization, the individuals have to cooperate in joint activities, where they are sharing goals and attentions. By coordinating their roles when working toward a specific goal, they achieve a joint intention. To this, we can add that they must be able to engage in prospective planning to anticipate the future, that is, have the capacity to represent future needs,

a prospective thinking, or “mental time travel” (Suddendorf and Corballis 1997; Roberts 2007).

A complex communicative system is needed in order to handle the social complexity, to facilitate collaboration, and to transfer information between the individuals, which are indispensable requisites for the innovation, development, and maintenance of complex technology. The communicative system must enable the users to construct abstract concepts and symbols and to generalize and discuss things and events not existent, that have ceased to exist, and have not yet come into being.

Important for the emergence of advanced technology is also the organisms’ degree of distributed cognition, that is, the ability to use external objects and/or other minds to enhance thinking (Hutchins 1995). As pointed earlier, the mind is extended to the environment, and the environment takes an active role in driving the cognitive processes (Clark and Chalmers 1998; Clark 2008). The ability to construct external cognitive artifacts is significant in human cognition (Norman 1991; Norman 1993; Malafouris and Renfrew 2010; Malafouris 2012). These organism-independent artifacts, in Donald’s terms, exograms, compensate for the limitations of the biological memory and could be regarded as an externalization and materialization of memory (Donald 1991, 2008, 2010). The distributed cognition strengthens the organism’s inborn sensory equipment and gives it a set of devices for thinking. An advanced technological civilization cannot rest on the cognitive flexibility of a few individuals but needs as many as possible sharing their knowledge, cooperating, and completing different specialized tasks.

A civilization with advanced technology is a complex social system, which entails a high degree of communicative complexity and high degree of cognitive flexibility. Such a socially complex extraterrestrial civilization would have many individuals rather than a few, a high rather than low density, many different member roles rather than a few roles, and many directional relations rather than a few. Many individuals entail greater collective brainpower. A high density entails more frequent and faster interactions between individuals. Many different member roles entail a distributed and specialized cognitive processing. And finally, complex societies have greater diversity of directional relations. These four characteristics of social complexity will enhance the emergence of advanced technology.

To conclude, if there were intelligent beings able to communicate with advanced technology, they would probably have a complex social system, complex communication, and a high degree of distributed cognition. A fundamental requisite for social and communicative complexity is intersubjectivity. A technologically advanced civilization could then be described as a social and communicative organization that facilitates cooperation and regulates and prevents conflicts in order to achieve specific joint intentions for the manipulation of its environment as an adaption of itself to the prevailing physical conditions or as a way of adapting its environment for its own purposes.

11.1.3.4 SUMMARY

Intelligence, regarded as a cognitive flexibility that enhances the chance of survival of a Darwinian creature, has evolved due to an adaptation to a changing environment, both the physical and social environments, through a bio-cultural coevolution. One of the most needed abilities of a cognitively flexible creature is intersubjectivity, the ability to understand other minds. The capability of intersubjectivity decides the degree of a society’s social and communicative complexities, which in turn are fundamental requisites for the emergence of advanced technology.

Then comes the question of the distribution of intelligence in space. We might confer that there are many habitable worlds in outer space that show cognitability. But the issue is connected to our chances to detect them, and this is a question of simultaneity. In the Drake equation, factor L , the length of time for which such civilizations release detectable signals into space (Chick 2015; Dunér 2015, 2017), has to do with survival, sustainability, and societal organization. It is about how an extraterrestrial intelligent life-form can create a sustainable society in equilibrium with the physical and biological environment, so that it can survive for a time period long enough to significantly increase the probability of detection. Another way of formulating L is as the number of Earth years that a cognitively flexible extraterrestrial life-form with advanced capability to manipulate its environment can manage to maintain a social organization that enables it to voluntary transmit electromagnetic radiation that we can detect. L is often regarded as the most difficult factor to estimate in the Drake equation (Shostak 2009; Denning 2011; Dominik and Zarnecki 2011; Penny 2011; Dunér 2015). We know only one global advanced technological civilization—our own—and we have not yet seen the end of it. The difficulty has to do not only with the fact that we lack empirical data about other technological civilizations, but also with the fact that we are dealing with very complex questions about how self-conscious beings organize their social structure.

The lifetime of an advanced technological civilization seems to be connected to how cognitively flexible creatures are able to control the power of their technology, find equilibrium with their environmental resources, and organize their society in order to prevent it from breaking down. In order to deal with destructive behavior within a society, an advanced technological civilization must have advanced intersubjective skills to understand other subjects; it must have a high degree of communicative complexity to sustain and strengthen the intersubjective interactions between its members, including long experience of communicating with a diversity of groups and species; and finally, it must have arrived at some sort of reliable regulation system for behavior, or what can be called “ethics.” L is, in other words, about how a congregation of cognitively flexible Darwinian organisms successfully manages the discrepancy between its capacity of manipulating its environment and its regulatory system for collaboration: L is a measure of this ratio.

11.1.4 TERRESTRIAL-EXTRATERRESTRIAL INTERACTION

11.1.4.1 COMMUNICATION

Communication can be regarded as a sharing of mental states, and the expression as information about a mental state (Østergaard 2012; cf. Gärdenfors 2013). Communication is a way of transferring mental content from mind to mind, where the encoding by the producer of a message is followed by a decoding by the recipient (Saint-Gelais 2014). As such, communication involves interpretation, where the interpreter endows meaning to the message. Communication is not about “things out there”; it is about our *conceptualization* of the things “out there” or rather our phenomenological experiences of the Lifeworld. According to the “social complexity hypothesis” for communication, “groups with complex social systems require more complex communicative systems to regulate interactions and relations among group members” (Freeberg et al. 2012a, p. 1785). Social complexity, in other words, leads to communicative complexity. Elsewhere, I have discussed the cognitive foundations of interstellar communication (Dunér 2011b) and maintained that communication is based on cognitive abilities embodied in an organism that has developed through an evolutionary and socio-cultural process by interacting with its specific environment (see also Arbib 2013; Holmer 2013). One of the most crucial cognitive abilities for language acquisition is, yet again, intersubjectivity. Communication presupposes shared knowledge or perhaps better, shared experiences.

If we extend communicational interactions beyond Earth, the question naturally arises: How could communication be possible between intelligent beings of different environments that differ physically, biologically, and culturally and have developed through separate evolutionary lines? This is the *cognitive-semiotic problem of interstellar communication* (Dunér 2011b). The circumstances in which we will have no kinship—that we will not likely share similar bodies or, even less, cultures—or even similar physical environments will have far-reaching consequences for how we will be able to construct and interpret messages from distant civilizations. The usual strategy to overcome the problem of interstellar communication has been to try to construct a message that is a universal symbolic information transfer, which is independent of context, time, and human nature (Sagan 1973; Vakoch 2011). This can be called the *universal-transcendental interstellar message objective*. However, this strategy and its requirements are not reconciled with what we presently know about cognition, communication, and evolution. Particularly, it presupposes the universality it is aimed at, and thereby ignores the facticity of evolution and symbolization as embodied and situated. It ignores the context that the living organisms, with their cognition and communication, are planet-bound and constrained by certain physical conditions. It leaves out time and history—the evolution, the phylogenetic, ontogenetic, and cultural-historical development—in which the organisms are evolving. Finally, it ignores the nature of the communicators—that they have bodies and brains evolved

in interaction with their environment. Building on the basic observation in cognitive science that our cognitive and communicational skills are embodied, situated in and adapted to our terrestrial environment, we cannot exclude the context, the situation, space, time, and human nature if we would like to construct comprehensible interstellar messages.

In order to solve the interstellar communication problem, we need the insights of cognitive science, evolutionary theory, semiotics, hermeneutics, and history. It could be argued that the problem of interstellar communication is not just a problem within natural science but a humanistic problem in its true sense, a human problem. It is we humans who will send and receive and code and decode the messages. The communicative problem also has to do with history, understood on the most basic level as the interaction of organisms with their environment over time. Cognition and communication are results of time and of history, both evolutionary history and socio-cultural history. Communication is thereby not something pre-given, but it rather evolves in interplay with the environment, in dialogue of agent with agent. In our case, this process took millions of years (Donald 1991; Christiansen and Kirby 1997; Deacon 1997; Donald 2001; Tomasello 2008).

Human communication, whether it consists of lingual, symbolic, or bodily expressions, is dependent on the inner workings of our brains and how humans interact with their physical, biological, and cultural environments. Accordingly, communication is a bio-cultural hybrid, a changing product of the genetic-cultural coevolution. Communication is therefore a situated practice. It is constrained by its surroundings and is adapted to specific circumstances. This means that we cannot exclude the situation where the message is performed and the physical, biological, and socio-cultural contexts of the communicators. We are planet-bound creatures.

Intelligence, as has been explained, could be seen as evolved mental gymnastics, which is required for a particular organism to survive and reproduce within its specific environment. This includes the capability of representing activities and being able to make inner models of reality. By using symbols, an intelligent creature could engage in abstract thinking detached from the environment. If the extraterrestrials are intelligent, then they probably have some kind of symbolization abilities and abstract thinking detached from the environment, with which they can reason about things that do not exist and things that are not right in front of them, facing their senses, in a specific moment in time. A very effective tool for symbolizing thought is our communicational devices. John Taylor describes language as a set of resources that are available to the language user for the symbolization of thought and the communication of those symbolizations (Taylor 2002). It facilitates thinking about the things and events that are not immediately in front of us, engaging with our senses, as well as about those things and events that, seemingly, could never exist outside of fiction. It frees us ever further from the here-and-now and lets us better contemplate the might-have-been. It allows us to share ideas and mental states. Yet, it rests on the cognitive abilities that are a result of bio-cultural coevolution here on Earth.

The cognition of an extraterrestrial life-form is likewise adapted to a specific environment, and the way this cognitively skilled organism expresses and communicates its thoughts, perspectives, and interpretations of its environment is a result of its specific bio-cultural coevolution. How we, and the aliens, transfer meaning in different ways, I would say, is the result of our dissimilar evolutions, bodily and cognitive constructions, and socio-cultural histories. The construction and interpretation of the symbols are dependent upon how our brains work, what our bodies are like, how we interact with our environment, how our sensations are processed, and the history of our culture. So, we can conclude that communication is based on cognitive abilities embodied in the organism that has developed through an evolutionary and socio-cultural process in interaction with its specific environment. In other words, our communication is adapted to an earthly environment and for communication with our conspecifics. Our communicational and symbolic skills have evolved through an evolutionary and cultural-historical process here on Earth and are thereby constrained by our human bodies, terrestrial environment, and the socio-cultural characteristics of our species. So, our human communication is, in fact, maladapted to interstellar communication. This understanding of human cognition is crucial for future interstellar communication and should be taken into account in order to be able to transfer messages to other minds in the universe.

11.1.4.2 SEMIOTICS

Inasmuch as interstellar communication is thought to be an exercise in coding and decoding signs, then the relevance of semiotics should be obvious (Vakoch 1998). In particular, cognitive semiotics studies the meaning-making structured by the use of different sign vehicles and the properties of meaningful interactions with the surrounding environment, both with the physical and social environments (Sonesson 2007, 2009; Zlatev 2012, 2015; Dunér and Sonesson 2016b). A key concept here is the bio-cultural coevolution, or in other words, meaning-making is a result of not only a natural, biological-genetic evolution, but also a cultural evolution, as well as the incessant interaction between the mind and its environment (Richerson and Boyd 2005). The interstellar communication problem is very much a semiotic problem: how meaning can be transferred and interpreted. The first problem that arises in a situation of interstellar communication is realizing that it really is a message at all (Sonesson 2013). Some regularity and order and finding a repetition in the pattern are not enough. We have to understand that someone has an intention with it that we should understand as a message. Next comes the problem of deciphering what the message means.

Some kind of vehicle for transferring the mental content is needed, that is, signs. The study of meaning-making, semiotics, concerns *signs*, which can be said to be something that we interpret as having meaning. According to Charles Sanders Peirce, one of the main figures in semiotics, “A sign,

or *representamen*, is something that stands to somebody for something in some respect or capacity” (Peirce 1932, p. 135; Saint-Gelais 2014). The sign, as *expression*, stands for something, its *object*. The sign does not include its meaning; rather, the meaning is attributed through elaboration of an *interpreter*. So, for something to be meaningful, an interpreter is needed, a human being (or other meaning-making creatures), who endows the sign a meaning. A physical phenomenon is meaningless so far as there is no one to recognize it as meaningful. For example, phenomena that we call biosignatures become meaningful phenomena when we interpret them as containing a meaning by making a connection between the expression and the object, in other words, between the “biosignature” and “the living organism” (Dunér 2019). With signs, we make sense of the world, approach it, get access to it, and differentiate things from each other. Correspondingly, the biosignatures we detect are one way among many other ways of making sense of the data we receive from outer space. And these biosignatures exist so far as we find them meaningful. In that perspective, the biosignatures are not solely “out there”; instead, they are, to a great extent, in our minds or rather in the interaction between our minds and the outer world. It is in our meaning-making practices that the “biosignatures” become biosignatures. The astrobiologist searching for biosignatures is a sort of semiotician, an astrobio-semiotician, trying to establish connections between expressions and objects in the universe. Semiotics of biosignatures concerns qualities and categories, as well as the search for rules and regularities within such a nomothetic science as astrobiology concerned with generalities. More generally, semiotics of biosignatures concerns the meaning-making processes of astrobiology.

The *semiosis* is the sign process, how the signs operate in the production of meaning. In that sense, when the astrobiologist is interpreting biosignatures, he or she is involved in a meaning-producing semiosis. This semiosis is triadic: it contains expression, object, and interpreter—which in our case respond to “biosignature,” “life,” and “astrobiologist,” respectively. Depending on how the interpreter makes or interprets the connection between the expression and the object, we have basically three types of sign relations, following Peirce, *icon*, *index*, and *symbol*. The meaning of the relation between expression and content that the interpreter experiences is based on similarity (iconicity); proximity (indexicality); or habits, rules, or conventions (symbolicity). An icon is a sign relation based on similarity, where the expression shares some of the object’s properties. An index is when the expression has some contiguity with the object. And finally, a symbol is when the connection between expression and object is just a mere convention.

The problem of interstellar communication lies not so much in the physical or technological constraints, even though they very much challenge our scientific and technological skills, but in the cognitive and semiotic problems that interstellar message decoding provokes (Vakoch 1998; Dunér 2011b, 2014; Sonesson 2013). It might be suggested that icons and indices would be easier to decode, depending on their respective similarity and contiguity. However, their decoding

rests on our biological sensory constraints and perceptual interpretations and our ability to recognize the connection between the expression and its object. The interpretation of indices requires empirical knowledge of the recurrent connection between the sign and what it refers to. The perceptual world consists of a profuse amount of potential indexicality, even though we do not yet recognize these indices as signs with meaning.

In order to reach more complex communication, a social organism not just needs attention, imitation, mimetic skills, and iconic and indexical signs, but it also needs to be able to use symbolic signs. If the extraterrestrials are intelligent, they probably have some kind of symbolization abilities and abstract thinking detached from the environment, with which they can reason about things not existent, non-present, senseless, timeless, and abstract. In other words, to reach a higher degree of communicative complexity, they need signs where the expression is separated from the content, that is, symbols. Icons and indices are signs that have some *non-arbitrary* similarity or contiguity with the signified, in contrast to the symbols' completely *arbitrary* relation. For example, the word "life" has no causal link to what it stands for, nor does it resemble what it signifies. There are no intrinsic relationships between the expression and the content whatsoever. It is the interpreters (the ones that construct the message and the ones that decode them, respectively) that join the expression and the content together and establish the connection between them. And the matching between the transmitters' and the receivers' interpretation of the symbols is by no means self-evident. We may figure out the reference of the signal but will probably have severe problems in understanding extraterrestrial symbols. It is the message's expression rather than its content that becomes the difficulty for the interpreter. In symbols, there is a gap between the sign and the meaning. Nothing in the physical appearance of the sign gives any clue to its object; they are instead linked by an arbitrary correlation.

The problem with symbols is that they are conventional, or arbitrary, as Ferdinand de Saussure called them (Saussure 1916). They are detached representations and, as such, dependent on cultural and social interactions that create some specific regularities that have their origin in more or less stochastic habits, conventions, etc., of the species (Sonesson and Dunér 2016). The sign (the expression) and the signified (the content) have no intrinsic connection. It is not impossible to imagine that the aliens would have certain knowledge about their environment that in its content is similar to our own knowledge of mathematics, physics, or chemistry. However, their expression of it would most likely be very different from ours. This basic semiotic distinction between expression and content is neglected in most human attempts at interstellar messaging. For all its ingenuity, Freudenthal's *Lingua Cosmica* is probably an effort in vain (Freudenthal 1960).

11.1.4.3 SUMMARY

Our communication and symbolization have evolved through an evolutionary and cultural-historical process here on Earth

and are thereby constrained by our human bodies, terrestrial environment, and the socio-cultural characteristics of our species. And likewise, a potential information transfer containing a symbolic message from an alien civilization would be constrained by the bio-cultural coevolution of the extraterrestrial intelligence that coded it. The semiosis of sign use, its triadic nature of expression, object, and interpreter, exposes the meaning-making processes behind biosignatures and interstellar communication.

11.1.5 CONCLUSION

In this chapter, I have discussed the question of mind in space, the thinking universe. We know for a fact that there are beings in the universe who think—the human species. But are there also other beings out there who cogitate about their own existence and perhaps even about our existence? And would it be possible to share and transfer mental content between various thinking beings in the universe? In order to answer these questions, I have suggested astrocognition as a new research field within astrobiology. Astrocognition explores the origin, evolution, and distribution of intelligent life in the universe, based on findings from cognitive science, linguistics, semiotics, history, philosophy, evolutionary theory, and allied sciences. This research will hopefully give us a better understanding of how the human mind interacts with unknown environments and phenomena, about the origin and evolution of intelligence, and what kind of environments intelligence needs in order to emerge on a planet and to what extent it might be distributed in outer space.

In the first section, concerning terrestrial intelligence, I discussed the cognitive phenomena involved in human exploration of the unknown, when humans search for extraterrestrial life and intelligence. First, I stated that intelligence is something more than a kind of logical, rational problem solving. Instead, I explained it as a cognitive flexibility, an ability to adjust to changes in the physical and socio-cultural environments, which include intersubjective skills. I highlighted three cognitive functions that are particularly prominent in the history of astrobiology, which says something about human cognition facing the unknown, that is, perception, conceptualization, and analogy. The sensory input is interpreted through our preconceived concepts, theories, and prior knowledge; that our concepts, categories, and definitions are challenged; and that we commonly engage in an analogical reasoning from what we know to what we do not know.

The next section, about extraterrestrial intelligence, dealt with the evolution of intelligence in outer space and the extent to which sociability and technology affect it. The starting point is that cognition evolves through an evolutionary process as an adaption to a changing physical and social environment. This bio-cultural coevolution of cognition explains the emergence of advanced cognitive skills. One of the most important drives for intelligence seems to be the organism's need to orientate itself in the social environment and to handle the increasing social complexity of the group. An indispensable requisite for the evolution of intelligence, sociability,

communication, and advanced technology is intersubjectivity, the ability to understand other minds. Technology is not a mere applied science; rather, it could be defined as ways of manipulating the surrounding world by using objects in the environment in order to strengthen the genetically given capacities and to adapt the environment to fit the organism, instead of the other way around. Resting on specific cognitive abilities, technology is, to a large extent, a social phenomenon, a product of the cultural evolution, that is, through the transmission of learned behavior and knowledge that are not biologically encoded. An intelligent being that has managed to develop advanced technology would likely have a complex social system, complex communication, and a high degree of distributed cognition.

In the final section, about terrestrial-extraterrestrial interaction, I discussed the question of whether two distinct creatures that share neither biology, environment, and evolution nor culture and history could be able to understand each other. The sharing of mental content, communication, is a product of a particular bio-cultural coevolution of a species, adapted to a specific physical and social environment. Cognitive semiotics, the study of meaning-making, is a key to understand the semiosis involved in astrobiology and astrocognition, such as biosignatures and interstellar communication. The problem of interstellar communication is, to a great extent, a semiotic problem, concerning how meaning is transferred and interpreted. Symbols, which are indispensable for abstract, complex reasoning, are particularly challenging due to their detached, arbitrary nature. To conclude, this chapter aimed to lay the ground for an emerging research field studying the origin, evolution, and distribution of intelligence in the universe. It concerned the thinking universe, what it means to think, why we think, and how we could understand other thinking beings, resting on the belief that the greatest discovery in a human's life is the encounter with the thoughts of another human being. Humankind's encounter with the thoughts of other thinking beings from another world would surely be the greatest discovery in the history of the human mind.

11.2.1 INTRODUCTION

Most of the effort in establishing the chances for the existence of life elsewhere in the universe has been put on evaluating the various astronomical and biological factors that may lead to the emergence of life on the surface of terrestrial-type exoplanets around other stars in the Milky Way. Twenty years after the discovery of the first exoplanet, we have now started to have sufficient data to allow us to think that such objects are relatively common in the Galaxy (Petigura et al. 2018). However, we do not yet have any evidence about the existence of other lifeforms, even at the microscopic level.

Historically, the main argument for the existence of life forms and intelligent beings beyond Earth has been formulated by Metrodorus, disciple of Epicurus, in the third century BC: *To consider the Earth as the only populated world in infinite space is as absurd as to assert that in an entire field sown with millet only one grain will grow.* The idea of space being infinite, with an infinite number of atoms populating it and composing its various objects, was a key ingredient of the atomistic philosophy of Leucippus, Democritus, and Epicurus (Furley 1987).

The argument is also invoked today by proponents of extraterrestrial intelligence (ETI), essentially unaltered; however, the concept of infinity is not used any more (because it is difficult to handle and it may lead to paradoxes, e.g., in an infinite universe, everything—including ourselves—could exist in an infinite number of copies). Our Galaxy contains about 100 billion stars, a number considered by some—mostly astronomers—to be large enough as to make Metrodorus' argument applicable to the Milky Way. Others, however—especially evolutionary

biologists—are not impressed by that number and remain skeptical concerning ETI (Simpson 1964, Mayr 1985).

In the second half of the twentieth century, the debate on ETI was largely shaped by the Drake equation and the Fermi paradox. The former was proposed in 1961 by American astronomer Frank Drake and became ever since the key quantitative tool to evaluate the probabilities for radio-communication with extraterrestrial intelligence (CETI), with the early evaluations being overly optimistic. The latter was formulated a decade earlier by Italian physicist Enrico Fermi, but it remained virtually unknown until 1975, when it was independently re-discovered twice (Hart 1975, Viewing 1975). In a concise form, it opposes a healthy skepticism to the optimistic views on ETI: (*if there are many of them*), *where are they?*

In this chapter, I discuss the physical meaning of the Drake equation and analyze it in a way revealing the implications of its last term, namely the lifetime of technologically evolved civilizations, the importance of which is often overlooked. The analysis allows us to define a region in the parameter space of the Drake equation, where the so-called “great silence” (Brin 1983) may be easily understood. The adopted framework is also applied to the analysis of the Fermi paradox, under the assumption of a simplified scheme for the colonization of the Galaxy. From the joint analysis of the Drake equation and the Fermi paradox, it appears that for sufficiently long-lived civilizations, colonization of the Galaxy appears to be the only reasonable option to gain knowledge about other life-forms. The analysis allows one to define a corresponding region in the parameter space of the Drake equation where the Fermi paradox holds.

11.2.2 INTRODUCING THE DRAKE EQUATION

Scientific study of the search for ETI has a short history, going back about half a century ago. In an article published in *Nature*, physicists Giuseppe Cocconi and Philip Morisson (1959) suggested that microwaves (high-frequency radio waves) are the best vector for interstellar communication. They can penetrate the terrestrial atmosphere and can pass through the dust and gas clouds of the Milky Way disk. In contrast, visible photons, our traditional window upon the universe, are absorbed by these clouds, limiting communication through optical telescopes to relatively short distances (of a few thousand light-years). In addition, radio telescopes can survey the skies 24 hours a day, even in broad daylight and under thick cloud cover. Another advantage of microwaves is that they carry little energy, implying that less energy would be expended using them for communication. Last but not least, our Galaxy emits little in the microwave region of the electromagnetic spectrum, compared with other radio frequencies; thus, the background noise would be reduced. While recognizing the difficulty of the enterprise, Cocconi and Morisson concluded: “Few will deny the profound importance, practical and philosophical, which the detection of interstellar communications would have. We therefore feel that a discriminating search for signals deserves a considerable effort. The probability of success is difficult to estimate; but if we never search the chance of success is zero.”

These considerations opened up the modern era in the plurality of worlds debate. The first to apply these ideas was Frank Drake, at the Green Bank National Astronomy Observatory in the USA (Drake 1960). He set up the first systematic search for extraterrestrial signals, called *Project Ozma*. The project was named after the queen of the imaginary land of Oz, a distant and inaccessible place in the story by Frank Baum. In 1960, the Green Bank telescope spent 4 months looking for radio signals from two nearby stars, ε Eridani and τ Ceti—both at about 12 light-years away—with no success (Drake 1961). The next year, Drake hosted a meeting on the Search for Extraterrestrial Intelligence (SETI) with 10 invitees, including Philip Morisson and Carl Sagan, and then 27. In preparing the agenda of the meeting, Drake established his famous equation, trying to evaluate the number of detectable civilizations in our Galaxy.

11.2.3 AN ANALYSIS OF THE DRAKE EQUATION

In its original formulation, the Drake equation reads

$$N = R_* f_p n_e f_l f_i f_T L \quad (11.2.1)$$

where R_* is the rate of star formation in the Galaxy (i.e., number of stars formed per unit time), f_p is the fraction of stars with planetary systems, n_e is the average number of planets around each star, f_l is the fraction of planets where life developed, f_i is the fraction of planets where intelligent life developed, and f_T is the fraction of planets with technological civilizations. Obviously, N and L are intimately connected:

if N is the number of radio-communicating civilizations—as in the original formulation by Drake—then L is the *average duration of the radio-communication phase* of such civilizations (and not their total lifetime, as sometimes incorrectly stated). On the other hand, if N is meant to be the number of technological or space-faring civilizations, then L represents the duration of the corresponding phase.

The Drake formula obviously corresponds to the equilibrium solution of an equation similar to the well-known equation of radioactivity for the decay rate D of a number N of radioactive nuclei: $D = dN/dt = -N/L$, where L is the lifetime of those nuclei. In the steady state, where the production rate P is equal to the decay rate D , one has $N = P L$. In a similar vein, the product of all the terms of the Drake formula, except L , can be interpreted as the production rate P of radio-communicating (or technological or space-faring) civilizations in the Galaxy.

It should be noticed that time does not appear explicitly in the terms of the Drake equation. This may be problematic, since we are interested in the present-day number of civilizations $N(t_0)$, while the stars harboring such civilizations were formed at time $t_0 - T$, where T is probably a substantial fraction of the age of the Galaxy ($T \sim 4.5$ Gy in the case of our civilization), that is, at a time where the rate of star formation $R(t_0 - T)$ was, perhaps, very different from the present-day star formation rate $R(t_0)$. However, in the case of the Milky Way, which is an Sbc-type spiral galaxy, there is evidence for a quiescent evolution at quasi-constant pace over billions of years (Kennicutt and Evans 2012). In that case, the average star formation rate $\langle R \rangle$ over the Galaxy age A~10 Gy can be considered as a fairly good approximation of $R(t)$ at any time t , and, consequently, the equilibrium solution approximates well the real situation. Notice that the solution $N < 1$ is acceptable in that case, meaning that the interval Δt between the occurrence of two such civilizations in the Galaxy is larger than their average duration L ; in other terms, there is just one civilization in the Galaxy emerging at time t and lasting for a duration L , but the next one emerges at $t + \Delta t$, where $\Delta t > L$. We shall discuss quantitatively that case in Section 11.2.5. On the other hand, if $R_*(t)$ varies widely in time, for example, in elliptical galaxies—which formed practically all their stars in the first couple of Gy—then the equilibrium solution does not apply, and instead of the Drake formula, one should use simply $N(t) = N_* \exp(-(t - T)/L)$, where N_* is the total number of stars in that galaxy, formed in the first couple of Gy.

In the 50 years since the formulation of the Drake equation, a fairly popular game consisted of attributing plausible numerical values to its various terms to estimate N . Unsurprisingly, estimates of different authors varied by many orders of magnitude: from a few million (Cameron 1963, Sagan 1963, Shklovskii and Sagan 1966), down to $N < 100$ (von Hoerner 1962, Jones 1981). It is significant to notice that typical values in the early years were substantially larger than those found in later times. In some cases, additional terms were added to the original ones to account for new astronomical factors (e.g., Ksanfomality 2004) or for intermediate steps in the development of a civilization, and even statistical

treatments were considered, to account for dispersion in the values of the relevant parameters (e.g., Maccone 2010b, Glade et al. 2012).

Despite the apparent sophistication of such efforts, the game is rather meaningless, because, until a few years ago, only $R_*(t_0)$ could be estimated from observations. Only in the past few years, statistics to estimate the second and third terms became available. The next four terms will remain unknown until we have a good theory on the emergence of life, intelligence, and technology or even better until such phenomena are detected beyond Earth (but then, very few will care about the Drake equation anymore, since the goal will have been achieved). However, despite its inability to help calculate N —which can have, in principle, any value between 1 and, say, 10^8 —the Drake equation has been extremely useful, as it provided a framework allowing us to formulate our knowledge/thoughts/educated guesses about a very complex phenomenon such as the development of life and intelligence in the astrophysical setting of the Milky Way.

11.2.4 REFORMULATING THE DRAKE EQUATION

In a recent study (Prantzos 2013), a different approach was adopted: instead of introducing additional terms in Equation 11.2.1, its seven terms were condensed to only three. The aim was twofold: (1) to illustrate quantitatively some implications of the number N for SETI and CETI, and (2) to use exactly the same framework for a quantitative assessment of the Fermi paradox (see [Section 11.2.7](#)).

The Drake equation is rewritten as

$$N = R_{ASTRO} f_{BIOTEC} L \quad (11.2.2)$$

where $R_{ASTRO} = R f_p n_e$ represents the production rate of habitable planets (determined through astrophysics) and $f_{BIOTEC} = f_l f_i f_T$ represents the product of all chemical, biological, and sociological factors leading to the development of a technological civilization. Obviously, $f_{BIOTEC} \leq 1$; its maximum possible value $f_{BIOTEC} = 1$ requires $f_l = f_i = f_T = 1$ (a rather implausibly optimistic combination), but there is no constrain on its lower value.

The astrophysical factor R_{ASTRO} is expected to be reasonably constrained in the foreseeable future. Indeed, its first term, R_* , is already constrained by observations in the Milky Way to be ~ 4 stars/year (Chomiuk and Povich 2011 give $\sim 1.9 M_\odot/\text{year}$ for the present-day star formation rate, and there are ~ 2 stars per M_\odot in a normal stellar initial mass function, like the one of Kroupa 2002). However, its average past value was probably higher by a factor of 2, and we shall adopt the value of $4 M_\odot/\text{year}$, which corresponds to an average star production rate of $R^* = \langle R \rangle \sim 8$ stars/year; this average star formation (SF) rate reproduces well the stellar mass of $\sim 4 \times 10^{10} M_\odot$ or the $\sim 10^{11}$ stars of the Milky Way if assumed to hold for the age of the Galaxy A ~ 10 Gy.

We shall assume that only 10% of those stars are appropriate for harboring habitable planets, because their mass has to

be smaller than $1.1 M_\odot$, that is, they have to be sufficiently long-lived (with main sequence lifetimes larger than 4.5 Gy as to give enough time for the development of intelligence and technology) and larger than $0.7 M_\odot$, to possess circumstellar habitable zones outside the tidally locked region (Selsis 2007). This leaves aside the most numerous class of stars, namely the low-mass red dwarfs: their intense and time-varying activity and their small circumstellar habitable zone largely balance the effect of their larger number with respect to solar-type stars. In any case, considering them would increase the planet numbers by a factor of 10–20, but this would change the conclusions little, given the extremely large uncertainties of the other factors of the Drake equation, as illustrated in a recent analysis (Wandel 2017).

A recent analysis of the Kepler satellite data (Petigura et al. 2018) finds that the statistics currently available on extra-solar planets around solar-type stars point to $\sim 20\%$ of the surveyed stars possessing super-Earths (planets in the ~ 2 – $10 M_\oplus$ range) with orbital periods $P = 10$ – 100 days. This fraction may be considered to describe the product $f_p n_e$ in the Drake equation, corresponding to *stars with continuously habitable Earth-like planets* (i.e., orbiting their star continuously within the circumstellar habitable zone). This is, admittedly, a fairly optimistic estimate, its only merit being that it imposes a plausible upper limit on the fraction of such solar-type stars. Combined with the aforementioned formation rate of 0.7 – $1.1 M_\odot$ stars, it leads to $R_{ASTRO} \sim 0.1$ habitable planet per year. We shall adopt this rounded value here, and we shall investigate the space of the remaining parameters f_{BIOTEC} and L , which are totally unknown at present.

In [Figure 11.2.1](#), the re-formulated Drake equation appears in a graphical form, after fixing $R_{ASTRO} = 0.1/\text{y}$ and putting L and f_{BIOTEC} in the ordinate and abscissa, respectively. In this log-log diagram, a given value of the product N of Equation 11.2.2 is represented by a straight quasi-diagonal line. For instance, $N = 1$ is obtained for both $f_{BIOTEC} = 0.1$ (high probability of appearance of a communicating civilization) and $L = 10^2$ year (short lifetime in that phase) or for $f_{BIOTEC} = 10^{-8}$ (small probability) and $L = 10^9$ year (extremely long lifetime). In both cases, $N = 1$ civilization exists permanently in the Galaxy, but in the former case, it is replaced by the next one every century, whereas in the latter, every Gy. It is interesting to notice the typical distances (appearing also in [Figure 11.2.1](#)) between such civilizations, assuming that they are uniformly distributed in the Milky Way, as discussed in [Section 11.2.6](#): even for a million civilizations, typical distances are of several hundred light-years, making contact—either by radio signals or space probes—difficult. This is the topic of [Sections 11.2.6](#) and [11.2.8](#).

Notice that these numbers assume that all civilizations have similar values of L , that is, the dispersion ΔL in L is much smaller than L itself. This need not be the case. Statistical treatments, considering $\Delta L \sim L$, and canonical distributions have been recently applied (Maccone 2010b, Glade et al. 2012). However, in any case, the unknown mean value of L plays a more important role than the equally unknown form of its distribution (see also Barlow 2013).

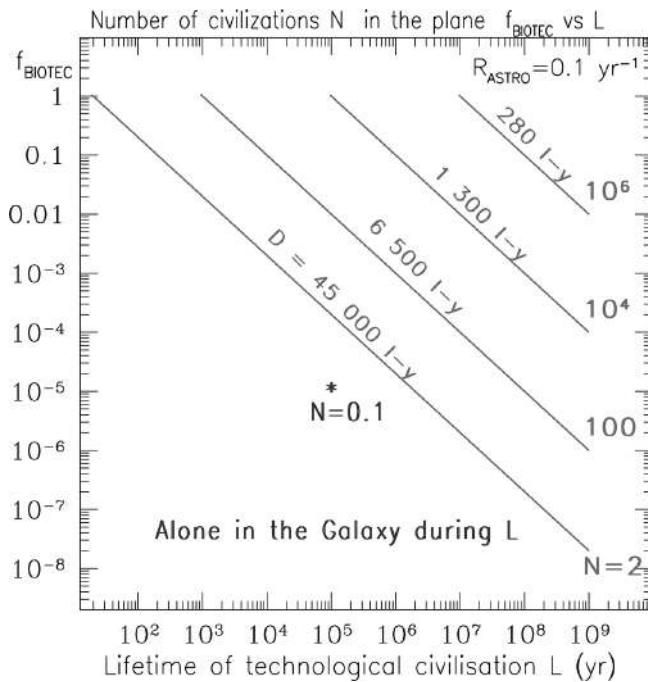

FIGURE 11.2.1 Number of civilizations N in the plane f versus L , assuming $R_{ASTRO} = 0.1/\text{year}$. A given number N is represented by a straight diagonal line. Typical distances D (in light-years) between civilizations for each N , obtained from the discussion of Section 11.2.6 (Figure 11.2.4), are indicated on the corresponding lines. The lower left region corresponds to $N < 1$. The potential meaning of that region (represented by the point $N = 0.1$) is illustrated in Figure 11.2.2 and discussed in Section 11.2.5.

11.2.5 LONELY HEARTS IN THE MILKY WAY?

The region below the line $N = 1$ is not necessarily void. In principle, it corresponds to values of $N < 1$, but such values may have a physical, albeit probabilistic, meaning, as illustrated in Figure 11.2.2: they may represent the fraction f of the time span T (between the appearance of two successive civilizations) that is occupied by the typical lifetime L : $f = L/T$. In Figure 11.2.2, this is illustrated by assuming arbitrarily that $L = 10^5$ year and $T = 10^6$ year. Ten civilizations appear within 10 million years, with an individual lifetime of 100,000 year: their summed lifetime is 1 My, that is, they exist for $1/10 = 0.1$ of that time span. For an external observer, the probability of finding a technological civilization anytime in the Galaxy is then 0.1.

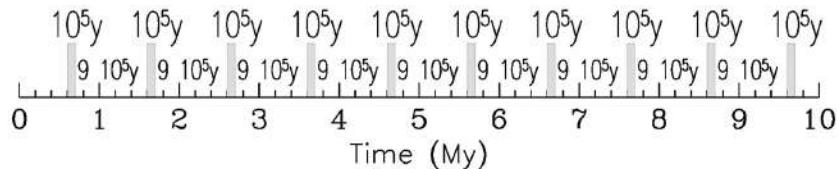

FIGURE 11.2.2 If $N < 1$, civilizations cannot coexist in the Galaxy. Still, the Drake equation has a meaning, albeit in a statistical sense only. Here is an example with $N = 0.1$, which may correspond to $\log(f) = -5 \log(L) = 5$ in Figure 11.2.1. A given technological civilization lives for $L = 10^5$ year and becomes extinct, leaving the Galaxy void from intelligent life for a period of $\Delta t = 9 L = 900,000$ year, until the appearance of the next civilization. In that case, the probability of finding a civilization in the Galaxy during any period $>> L$ is 0.1.

The case illustrated in Figure 11.2.2 is rather depressive: a technological civilization may emerge in the Galaxy and live as long as a hundred-thousand years (10 times more than the total human history and a thousand times longer than our technological era). Still, during its whole lifetime, the civilization would be alone in the Milky Way: a gap 10 times longer would separate it from both its predecessor and its successor. None of those civilizations would ever know of the existence of the others, especially if they remain confined to their planets (or within their solar systems).

Our own civilization may be such a lonely heart in the Milky Way. The implications of that situation are obvious: only a systematic research by unmanned probes or manned spaceships could provide evidence for or against the existence of other, perhaps now extinct, civilizations. Before discussing the connection of this conclusion with the Fermi paradox in Section 11.2.7, we shall consider another aspect of the Drake equation: the constraints it puts on some aspects of Galactic civilizations seeking communication, namely their probability of emergence and their lifetime.

11.2.6 CONSTRAINTS FROM CETI

The original intention of Frank Drake was to evaluate the chances for radio communication with ETI. However, his formula was mainly (or, rather, exclusively) used to evaluate the number of co-existing ETI in the Galaxy today, which is not exactly the same thing. The original task requires to take one more step and connect somehow the lifetime of the civilizations (last term in the formula) to the typical distances between such civilizations, to account for the finite speed of electromagnetic signals. As it turns out, those distances are related not only to the dimensions of the Galaxy but also to number N and, implicitly, to lifetime L . These relations then impose constraints on N and its components, f_{BIOTEC} and L .

To evaluate typical distances between Galactic civilizations, it may be assumed that, to a first approximation, the Galactic disk is described by a cylinder of radius $R_G = 10$ kpc and height $h = 1$ kpc, where the N civilizations of the Drake formula are distributed uniformly (Figure 11.2.3). A better approximation would be to consider the exponential profile of the stellar disk, but the conclusions depend little on such assumptions and much more on the unknown factors of the Drake formula.

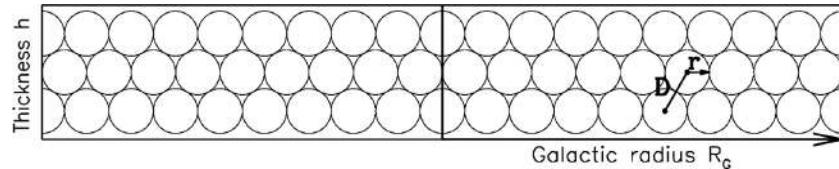

FIGURE 11.2.3 Filling the Galaxy with N civilizations located at average distances D from each other.

By equating the volume of the Galactic cylinder $V = \pi R_G^2 h$ with the sum of N volumes of spheres of average radius r occupied by each civilization, one obtains the average distance (D) between two civilizations as $D = 2r = 2(3V/4\pi N)^{1/3}$ for the case where $D < h$. In the case of a small number of civilizations (say $N < 1000$), it turns out that $D > h$, and a more appropriate expression is then $D = 2r = 2R_G/\sqrt{N}$.

The values of the average distances D as a function of the number of civilizations N appear in Figure 11.2.4, where the astronomical factor of the Drake formula is fixed to $R_{ASTRO} = 0.1/y$. One can appreciate the magnitude of the distances between civilizations, which plays an important role in the discussion (and understanding) of the great silence and the Fermi paradox. For less than a thousand civilizations, typical distances are larger than 3000 light-years, while for a million civilizations, they are of the order of 350 light-years (see also Figure 11.2.1). Notice that N is the number of civilizations co-existing in the Galaxy during their lifetime L .

For each number N , there is a minimum value L_{MIN} , corresponding to $f_{BIOTEC} = 1$ in Equation 11.2.2 for the adopted value of $R_{ASTRO} = 0.1/\text{year}$. Obviously, communication between neighboring civilizations requires their duration L to be larger than twice the travel time D/c (where c is the light speed) of radio waves. An inspection of Figure 11.2.4 shows that if there are less than a few hundred co-existing civilizations in the Galaxy, their radio-emission phase has to last longer than $\sim 10^4$ years to allow them to establish radio communication.

The analysis of the previous paragraph holds for the maximum possible value of the biotechnological factor $f_{BIOTEC} = 1$,

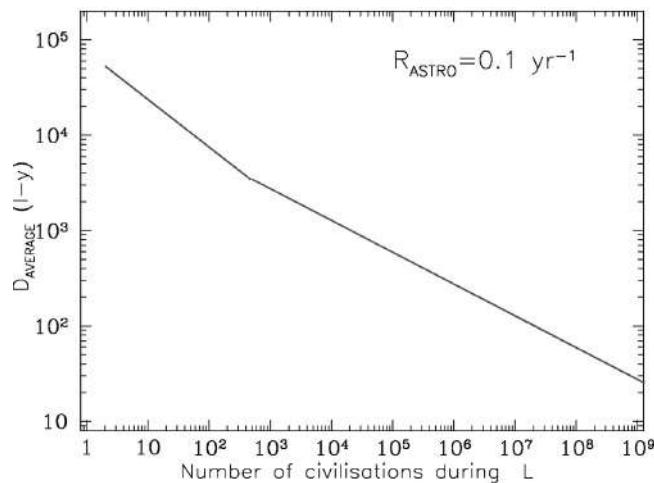

FIGURE 11.2.4 Average distances D (continuous curve) between civilizations as a function of their total number N in the Galaxy, assuming that they are uniformly distributed in the Milky Way disk.

which has a corresponding minimal value of L for a given N . In order to explore the whole range of possible values for f_{BIOTEC} and L , the diagram presented already in Figure 11.2.1 was used (Prantzos 2013), as shown in Figure 11.2.5: for the adopted value of R_{ASTRO} , a given value of N (and thus a corresponding value of D) represents a line in the f_{BIOTEC} versus L diagram, with $N = 2$ being a lower limit for communication.

The time required for such a communication, involving an exchange of radio signals, is $T = 2D/c$. Using the average distances D derived earlier, the condition for radio communication ($T < L$) is found to bound the f_{BIOTEC} versus L diagram from the left, according to

$$N > 48 R_G^2 h / (Lc)^3 \text{ for } D < h, \text{ and } N > 16 R_G^2 / (Lc)^2 \text{ for } D > h.$$

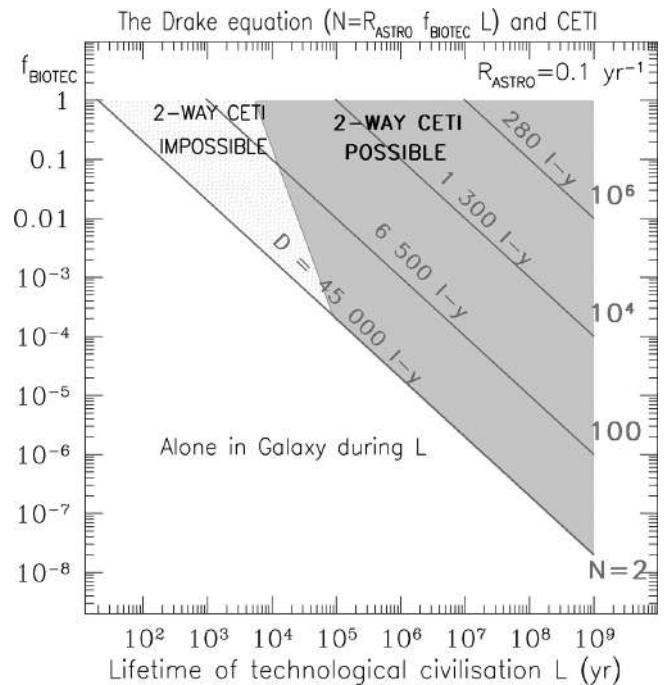

FIGURE 11.2.5 The parameter space of the bio-sociological factor $f_{BIOTEC} = f_L f_I f_C$ versus the average lifetime L of a technological civilization. Calculations are done by assuming a value $R_{ASTRO} = R_* f_P n_e = 0.1$ habitable planet per year for the astronomical factor (see text) in the Drake equation. This leads to values for the number N of technological civilizations indicated by the parallel diagonal lines. $N = 2$ is the minimum required for two-way communication during L . The shaded region allows for two-way communication between two civilizations during L ; that is, it satisfies the condition $L > 2D/c$, where D is the average distance between civilizations (see Figure 11.2.4) and c the velocity of light. (Adapted from Prantzos, N., *Int. J. Astrobiol.*, 12, 246–253, 2013. With permission.)

In those expressions, distances are expressed in light-years and durations are expressed in years, thus allowing one to omit the light speed of radio-signal propagation ($c = 1$ light-year per year). By replacing N through the Drake formula (Equation 11.2.2), the derived constraints can also be expressed as a relationship between the factors L and f_{BIOTEC} and the dimensions of the Galaxy $f_{BIOTEC} L^4 > 48 R_G^2 h / R_{ASTRO}$ for $D < h$ and $f_{BIOTEC} L^3 > 16 R_G^2 / R_{ASTRO}$ for $D > h$, respectively.

An inspection of Figure 11.2.5 shows that, for the adopted value of $R_{ASTRO} = 0.1$ habitable planets per year (an upper limit), communications are possible only for civilizations spending at least 10,000 years in the radio-communication phase. If $f_{BIOTEC} = 1$, there are about 1000 such civilizations in the Galaxy, and our chances of eavesdropping the communications of our closest neighbors are not negligible. But if $f_{BIOTEC} = 10^{-3}$, there are just a few civilizations in the Galaxy, and chances of eavesdropping appear insignificant. Of course, the larger the duration of the radio-communication phase, the larger the N (for the same value of f_{BIOTEC}), and chances improve considerably. However, it should be noticed that there is a large region of the considered log-log parameter space (for all $L < 10,000$ year, irrespectively of f_{BIOTEC}) for which communications are impossible or there is no second radio-emitting civilization in the Galaxy during L .

One may conclude then that it is improbable that we communicate with (or eavesdrop) civilizations of a level either similar to ours ($L \sim 100$ year of radio emission) or even radio-emitting for a few thousands of years. Only civilizations emitting for much longer timescales have chances to be detected by our SETI programs. On the other hand, it may well be that in the case of $f_{BIOTEC} < 10^{-2}$, we may spend thousands of years—and in the case of $f_{BIOTEC} < 10^{-5}$, even millions of years—searching for radio signals with no effect, since we would be alone in the Galaxy during that period. As already stressed, those numbers correspond to the optimistic case of $R_{ASTRO} = 0.1$ habitable planet per year. It seems obvious that such considerations will affect the strategy of any extraterrestrial civilizations searching their siblings.

At this point, it should be noticed that it is a rather futile exercise to try to imagine the kind of communications that technological civilizations older than a few centuries might have. In particular, the problem of understanding alien messages has been given serious attention by Soviet astronomers in the 1960s and 1970s—as properly emphasized in the monograph by Sheridan (2009)—but it appears to be virtually absent from the recent literature on the subject.

11.2.7 EARLY HISTORY AND ANALYSIS OF THE FERMI PARADOX

The origin of this famous paradox is documented by Eric Jones in his 1985 Los Alamos report (Jones 1985): it appears that Fermi formulated his question: Where is everybody? during a lunchtime conversation at Los Alamos in the summer of 1950 with colleagues Emil Konopinsky, Herbert York, and

Edward Teller. Its early history is related by Stephen Webb in his book *Where is everybody?* perhaps the most complete investigation today of the solutions proposed to solve the paradox (Webb 2014). Webb provides a detailed account of the early ideas on the paradox, including its earlier discovery by Russian father of astronautics K. Tsiolkovski in 1933, its independent re-discovery by M. Hart in 1975 and its identification as a paradox by D. Viewing in 1975. In recognition of those early contributions to the debate, Webb calls it the Tsiolkovski–Fermi–Hart–Viewing paradox. We shall keep the shorter term *Fermi paradox* here for convenience.

The basic idea of the “paradox” was already formulated more than three centuries ago, albeit in an inconclusive way. In 1666, French novelist Bernard le Bovier de Fontenelle (who later became secretary of the French Academy of Sciences) published his best-selling book *Entretiens sur la Pluralité des Mondes (Conversations on the Plurality of Worlds)*. It is often considered as the first popular science book, and it is written in the form of dialogues between the author and a charming and ingenuous marchioness. The marchioness counters the author’s assertion that “intelligent beings exist in other worlds, for instance the Moon” by the retort: “If this were the case, the Moon’s inhabitants would already have come to us before now.” Fontenelle can only argue that the time to master space travel is probably too long and that the Moon’s inhabitants “at this time are maybe exercising themselves; when they shall be more able and more experienced, we may see them... after all, the Europeans did not arrive in America till nearly at the end of six thousand years” (in Fontenelle’s days, the universe was thought to be 6000 years old, based on biblical accounts). Note that Fontenelle’s time argument is completely symmetric between Earth’s and Moon’s inhabitants; that is, they both have at most 6000 years to master space travel, but there is no hint as to whether one of the two civilizations is more advanced than the other; thus, the absence of people from the Moon on Earth could not really be considered as a surprise, since earthlings had not visited the Moon either. The modern argument by Fermi explicitly assumes, by virtue of the Copernican principle, that some of the extraterrestrial civilizations are (considerably) older than ours, and therefore, they have had enough time to spread into the Galaxy and reach our planet, while our own civilization is unable to do so at present.

For more than 10 years after the now famous lunchtime discussion at Los Alamos, there appears to be no written trace of Fermi’s question (at least to my knowledge). The earliest trace I am aware of is a footnote in a paper published by American astronomer Carl Sagan: This possibility has been seriously raised before, for example, by Enrico Fermi, in a now-rather-well-known dinner-table discussion at Los Alamos during the Second World War, when he introduced the problem with the words *Where are they?* (Sagan 1963). Sagan provides no information on his sources, making it difficult to know where he got such erroneous information about a dinner-table discussion during the Second World War. A few years later, the phrase *Where are they?*, attributed to Enrico Fermi but without any comment, appeared a few years later

in the book of I. Shklovskii and C. Sagan *Intelligent Life in the Universe* (Shklovskii and Sagan 1966). Obviously, Sagan realized that the question might have some profound implications for the CETI endeavor, but he could not or did not wish to brood over them.

Any paradox is based on at least one invalid assumption. The logical statement of Fermi's paradox may run as follows (Prantzos 2000):

- A. Our civilization is not the only technological civilization in the Galaxy.
- B. Our civilization is in every way “average” or typical. In particular, it is not the first to have appeared in the Galaxy, it is not the most technologically advanced, and it is not the only one seeking to explore the cosmos and communicate with other civilizations.
- C. Interstellar travel, although impossible for us today, is not too difficult for civilizations slightly more advanced than ours. Some extraterrestrial civilizations have mastered this kind of travel and undertaken a galactic colonization program, either with or without self-replicating robots (Tipler 1981).
- D. Galactic colonization is a relatively fast undertaking and could be achieved in a relatively small fraction of Galaxy's age (less than a few hundred million years).

If hypotheses A to D are valid, one clearly deduces that “they should be here.” Supporters of ETI reject at least one of the assumptions C and D, and some even go so far as to deny B, in order to save their key hypothesis A. In contrast, their opponents uphold the plausibility of C and D, whilst completely rejecting B. By virtue of the Copernican principle, hypothesis A should then be rejected as well. Of course, if the Copernican principle is inapplicable in case B, hypothesis A can still be saved (but at what a price!).

Most of the arguments in the debate on the Fermi paradox are of sociological nature (see Webb 2014 for a thorough, albeit not exhaustive, census) and concern assumptions B and D. Here, I will assume that assumptions A to C are valid, and I will explore the consequences of D, namely Galactic colonization by a technologically developed civilization.

The issue of the timescale for Galactic colonization in the context of the Fermi paradox has been quantitatively explored by various techniques using population dynamics (Hart 1975, Viewing 1975, Newman and Sagan 1981), percolation analysis (Landis 1998), or Monte Carlo methods (e.g., Jones 1981, Bjoerk 2011). Depending on the underlying assumptions, quite different results are found on the timescales of Galactic colonization. In most cases, timescales are found to be much smaller than the age of the Galaxy (e.g., Jones 1981), thus substantiating the Fermi paradox, while in a few cases, much larger values are found (e.g., Bjoerk 2011). In fact, it has been argued (Wiley 2011) that none of the assumptions underlying the aforementioned models is strong enough to render the conclusions robust.

11.2.8 THE FERMI PARADOX IN TERMS OF THE DRAKE FORMULA

The Fermi paradox may be illustrated in a fairly simple way (Prantzos 2013), by casting it into the same form as the Drake equation. It is assumed that once a civilization masters the techniques of interstellar travel, it starts a thorough colonization/exploration of its neighborhood for a period L . Colonization proceeds in a directed way, that is, it concerns only stars harboring nearby habitable planets, which are detected before the launching of the spaceships. According to the discussion in Section 11.2.2, an upper limit to the total number of such interesting stars in the Galaxy (i.e., by assuming $R_{ASTRO} = 0.1$ per year) is $n_I \sim 10^9$ stars, one hundredth of the total number of Galactic stars; their average density is then $\rho \sim 3 \times 10^{-5}$ stars per (l-year)³ and their average distances $D \sim 30$ l-year (from Figure 11.2.4).

The colonization front expands outward at an average velocity $v = \beta c$, where β is a fraction of light speed c . Ships are sent to new stars not from the mother planet but from the colonized planets in the wave front, and they are launched after a time interval t_{PREP} following colony foundation. This gives enough time to the colonizers to prepare the next colonizing mission after their installation on the planet. Notice that v is the *effective velocity of the colonization front* and not the velocity of the interstellar ships; the latter is given by $v_{SHIP} = D/(D/v - t_{PREP})$ and has to be larger than v . A quantitatively study of the above scheme (Prantzos 2013) finds that full exploration of the Galaxy by a single civilization and its offsprings would take approximately $\Delta T = 4 \times 10^5$, 4×10^6 , and 4×10^7 years for values of $\beta = 0.1$, 0.01 , and 0.001 , respectively (Prantzos 2013). And even if some of the colonies within the expanding spheres die out, the spheres need not remain partially hollow for a long time, since (some of) the active colonies could send new ships back and revive the dying colonies.

The model adopted here for the expansion of a civilization in the Galaxy corresponds to the so-called *Coral* model, describing how corals grow in the sea (Bennett and Shostak 2007), and has been used (Maccone 2010a) in an attempt to provide a statistical description of Galactic colonization. In both cases, a factor $k = 1/2$ is introduced in front of the fraction defining the ship speed to account for the zig-zag motion of the colonizing ships in space (sometimes colonizing back some stellar systems previously left behind or re-activating dying colonies). Introducing this factor should slightly change the numerical results presented here. Alternatively, the results should remain the same, under the assumption of a speed twice as large as the values originally adopted.

The analysis of the previous paragraphs concerns the colonization of the Galaxy in the case of a single colonizing civilization, starting from a single place in the Galaxy (a place close to the Galactic center was assumed here, but the results would not be very different if any other place was chosen). In Figure 11.2.6, the analysis is extended to the case of N independent civilizations—as given by the Drake formula—in a similar form as the one adopted for the analysis of CETI in

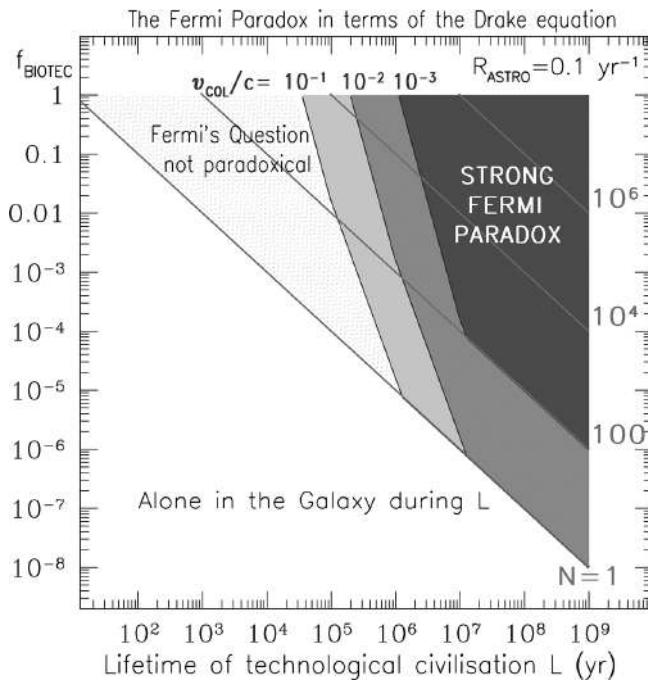

FIGURE 11.2.6 The Fermi paradox presented in the f_{BIOTEC} versus L plane, in terms of the factors appearing in the Drake formula. In the shaded region, space-faring civilizations may collectively explore/colonize the whole Galaxy within their average duration L , assuming that the colonization front expands with average velocity $v/c = 0.1, 0.01$, and 0.001 , respectively (thick blue lines). The Fermi paradox applies in the whole shaded region. The region of the “Strong Fermi Paradox” is discussed in the text. (Adapted from Prantzos, N., *Int. J. Astrobiol.*, 12, 246–253, 2013. With permission.)

Figure 11.2.5. It is checked whether the Galactic volume can be filled within time L by $N = R_{ASTRO} f_{BIOTEC} L$ spheres of radius $r = \beta cL$ for $\beta = 0.1, 0.01$, and 0.001 , respectively. If it can be filled, then every corner of the Galaxy should be visited by at least one of the N civilizations within its space-faring phase, and the Fermi paradox holds for the corresponding values of f_{BIOTEC} and L . Notice that here, the lifetime L corresponds to a single civilization and includes all its offspring colonies; in other terms, the colonies do not count as different civilizations, since they do not originate in an independent way.

Figure 11.2.6 shows that, depending on β and L , full colonization of the Galaxy by the N civilizations may or may not be possible during L . For instance, in the ultra-optimistic case of $f_{BIOTEC} = 1$, a thousand civilizations would need only a few tens of thousands of years to collectively colonize the Galaxy at $v/c = 0.1$, while a single civilization would need a hundred times longer. For values of f_{BIOTEC} and L outside the shaded region, the Fermi paradox is no more a paradox: civilizations are too rare or too short-lived to fully colonize the Galaxy within the duration L of their space-exploring phase. Within the shaded region, the Fermi paradox holds, since such civilizations can, in principle, colonize the galaxy, and they should have found us already.

In the case of a small number of civilizations, any one of the sociological ideas put forward to explain the Fermi paradox may be valid: indeed, some civilizations may never

master space travel or never wish to colonize or to perturb other, less mature, ones, or they may abandon their colonization effort shortly after they started it, etc. (see Webb 2014). However, such arguments appear hardly plausible in the case of a large number of independent civilizations (Prantzos 2000). It shall be assumed here, somewhat arbitrarily, that for $N > 100$, such sociological arguments can hold for some but not for the majority of civilizations. In an equally arbitrary way, it will be assumed that an expansion velocity of $v/c = 0.001$ for the colonization front is much more reasonable (less demanding) than $v/c = 0.1$. Those assumptions define a region in the f_{BIOTEC} versus L plane (bounded from below by $N = 100$ and from the left by $v/c = 0.001$), where the Fermi paradox is arguably on a solid basis (strong Fermi paradox), whereas the situation is less clear for the remaining shaded region (weak Fermi paradox).

It has been argued (Ostriker and Turner 1986) that, even if advanced technological civilizations are common, they are unlikely to fully occupy the Galaxy, because, at some point of their expansion, their mutual interactions could reduce the pace of colonization, leaving some portions of the Galaxy unoccupied for periods of the order of L . They base their arguments on a mathematical analysis, drawing from the ideas of theoretical ecology, and they suggest that the Earth may be found in such an unoccupied region, thus providing an(ther) explanation of the Fermi paradox. Somewhat counterintuitively, they claim that the complexity of the system describing population expansion allows one to predict its behavior with a reasonably high degree of confidence. Unfortunately, at the current stage of our knowledge, it is impossible to know whether Galactic colonization is better described by simple models (such as the Coral model adopted here) or by more sophisticated ones, such as theirs.

11.2.9 SUMMARY

For several decades, the Drake formula played an important role in the search for extraterrestrial life, providing a framework to formulate our current understanding about a very complex phenomenon such as the development of life and intelligence in the astrophysical setting of the Milky Way. However, in evaluating the number of technological civilizations N , emphasis was put mostly on the astrophysical and biotechnological factors describing the emergence of a civilization (R_{ASTRO} and f_{BIOTEC} , respectively) and much less on the lifetime L , which is related to its decline. In contrast, there has been no attempt to quantitatively evaluate the conditions where the Fermi paradox is indeed a paradox (although it is reported that Fermi had done so), while the role of factor L clearly appears to be important in that case.

The Drake formula and the Fermi paradox can be analyzed in the same framework, using a diagram of f_{BIOTEC} versus L (for a given value of R_{ASTRO}) in Figures 11.2.5 and 11.2.6. This type of analysis (first proposed in Prantzos 2013) leads—under some assumptions—to quantitative conclusions, emphasizing the role of the civilization lifetime L . The shaded regions in those figures—allowing CETI and full colonization of the Galaxy,

respectively—are of similar size; that is, they correspond to approximately the same range of values of f_{BIOTEC} and L . This occurs despite the fact that communication velocities are at light speed c , while maximum velocities of colonization fronts are $v = 0.1 c$ (in the most optimistic case). The reason is that CETI involves at least two signals exchanged over distances $D = 2r$, that is, a total distance of $4r$ crossed at light velocity c , which takes just 40% of the time required by the colonization front to cross radius r at velocity $v = 0.1 c$. This difference by a factor of ~ 2 between the effective velocities of the communication carriers (electromagnetic signals vs. starships) is barely visible in the shaded regions of Figures 11.2.5 and 11.2.6. Of course, $v = 0.1 c$ is a huge velocity for the colonization front; velocities hundreds of times smaller appear much more reasonable.

It should be noticed that, in this discussion, our own civilization is treated as a test particle rather than as a typical one. The lifetime L (~ 100 year) of our terrestrial technological civilization is far smaller than the typical values required either for CETI or for Galaxy colonization.

Although sending and receiving radio signals is certainly a much easier enterprise than launching starships, the latter should not be too difficult for a $>10^4$ -year-old technological civilization (minimum age to have reasonable chances for CETI according to Figure 11.2.5). Assuming that such civilizations wish to learn about other life-forms (intelligent or not), one may ask what kind of action they might adopt: just content themselves with a program of radio-signal emission/reception or undertake a serious effort of interstellar colonization? The former, although less demanding, might provide no results for several more 10^4 year (and even for millions of years, in case there are just a few such civilizations in the Galaxy at that period). The latter, even at the slow pace of $0.001 c$, would bring within their grasp, in that same period, thousands of stars, harboring perhaps interesting life-forms or even civilizations as advanced as the Egyptians or the Greeks, yet unable to radio-communicate. Obviously, the benefits would be far greater in the latter case, pushing most (if not all) technological civilizations older than a few 10^4 year to undertake a serious program of interstellar exploration. And even if some of them abandon the program for various reasons, the effort of their neighbors could compensate for that.

In summary, it appears that although radio communications constitute a natural means for SETI for civilizations younger than a few thousand years, older civilizations should rather develop extensive programs of interstellar colonization, because this is the only way to achieve undisputable evidence (either for or against the existence of ETI) within their lifetime L . In those conditions, the Fermi paradox appears all the more paradoxical: if, as the SETI proponents claim, there are literally thousands of such advanced civilizations wishing to establish contact, where are they?

Today, the *Plurality of worlds*, as the field was known in the antiquity, is as controversial as ever. Arguments on both sides (“It is unlikely that we are alone, in view of the Copernican principle and of such a large number of stars in the Galaxy” and “If there are so many of them, where are they?”) are of statistical kind. They are consequently of little importance, for

statistics cannot be based on the single case provided by life on Earth. Detection of life signatures on another planet would be a powerful reason to undertake interstellar travel, at first by sending unmanned probes. Detection of some extraterrestrial civilization would undoubtedly be one of the major landmarks in the history of mankind. On the other hand, non-detection of ETI signals, even after millennia of research, would never prove that there were no extraterrestrial civilizations. But it would be a reason to prepare ourselves for a life of cosmic solitude.

11.3.1 INTRODUCTION

The search for extraterrestrial intelligence, or SETI, has existed as a discipline since Cocconi and Morrison (1959) published a rationale for a search for narrow-band radio transmission from nearby stars.¹ The following year Drake (1961) performed initial observations of two nearby stars, Tau Ceti and Epsilon Eridani, using a 26-meter parabolic dish antenna tuned to 1.42 GHz. No extraterrestrial signals were detected. In the nearly six decades following, SETI endeavors have expanded in number of targets, sky coverage, and spectral coverage.

11.3.2 BASIC MOTIVATION: THE DRAKE EQUATION

The basic motivation for searching for extraterrestrial intelligence (ETI) often begins with an estimate of the number of

civilizations in the galaxy with whom we could communicate. The Drake equation is used to provide that estimate, using quantities that could, in principle, be determined. The standard Drake equation is given as:

$$N = R_* f_p n_e f_l f_i f_c L$$

where:

R_* is the average galactic star formation rate

f_p is the fraction of stars that have planets

n_e is the number of planets per star with planets that could support life

f_l is the fraction of planets that could support life that actually develops life

f_i is the fraction of planets that develops life where intelligence arises

f_c is the fraction of planets where intelligence arises and a communicating civilization arises

L is the average lifetime of a communicating civilization

In principle, we can simply determine those quantities and arrive at an estimate of the number of civilizations we could communicate with now. In practice, it is much more difficult than that. These values have significant uncertainty. For example, while the current value of the galactic star formation rate is well known, it is not the appropriate value to use for R_* . The appropriate value would be a weighted average of the galactic star formation rate, with the weighting based upon the likelihood that communicating intelligence would exist now on a planet around a star of a given age. This is, of course, unknown as the timescales for the origin of life and for biological evolution are unknown. It is entirely possible, and maybe even likely, that Earth is atypical in the time it took to reach those milestones (Korpela 2004). While some of the parameters are getting more certain (e.g., f_p and n_e), others have likelihood distributions that are more accurately expressed as roughly uniform between some limits in logarithmic space (f_l , f_i , f_c , and L). The values are uncertain enough that the value of N is relatively unconstrained, with little reason to prefer $N \sim 750,000$ over $N \sim 5 \times 10^{-7}$ (although the prior number is beginning to be approached by some SETI surveys for some definitions of “communicating”).

In essence, N is unconstrained. While some may find this to be discouraging, it is clear that the parameter space is very wide and that the most efficient way to obtain knowledge of the number of communicating civilizations is a direct search for communicating civilizations, hence SETI.

11.3.3 SETI, A DEFINITION

Before proceeding further, it is necessary to define SETI beyond the literal meaning. Intelligence is not something that can be detected directly. In nearby organisms (e.g., another human), it is identified by observing behavior that is presumed to require thought. Such behavior might be a complex set of operations requiring long-term planning. At interstellar distances, such behavior is more difficult to observe. We typically find ourselves limited to artifacts. Such artifacts could be signals encoded in electromagnetic or other radiation. They could be physical objects launched by an ETI. They could even be an object or set of objects so large that they effect the appearance of planets, stars, or even galaxies in their vicinity. At this point, I will attempt to dispense with terms such as civilization and species, as such terms presume, to some extent, that ETI will be like us: organized groups of independent biological organisms. While it is often the default assumption that is used by astrobiology researchers, the universe may surprise us. The most common type of “civilization” might consist of a single electronic intelligence. In cases where I use the term civilization, it will be associated with citations that use the term.

11.3.3.1 DISTINCTION FROM METI

It is important to distinguish SETI from messaging extra-terrestrial intelligence (METI). Also known as active SETI, METI involves beaming transmissions toward nearby stars thought likely to permit the evolution of life. SETI is a purely observational science, and many SETI proponents do not encourage directed messaging prior to a SETI detection (Azua-Bustos et al. 2015). The justification for this position stems from several bases. The primary concerns are that we have no way to predict the motivations or behaviors of an ETI apart from comparison to our own troubled history. Any ETI we do encounter is likely to be far more technologically advanced than our own. SETI is still in its infancy and has not even completed a systematic study of nearby stars across a wide range of electromagnetic frequencies; therefore, many SETI scientists feel that more study is necessary before directed transmissions are sent. There is also strong consensus among those opposed to directed transmissions that a small group of scientists should not take actions that could have significant consequences for future generations without at least getting explicit consent from intergovernmental groups such as the United Nations.

In response, proponents of METI often suggest that we have been sending signals for a significant time. As of this publication, omnidirectional radio signals from Earth have passed 0.008% of the stars in the galaxy, which implies we could have been detected through past radio emissions presuming $N \gtrsim 12,500$. However, omnidirectional signals are much weaker than the directional signals proposed for METI. A detection of the proverbial “I Love Lucy” rerun at this extreme range would require $\sim 700 \text{ km}^2$ of collecting area at the current extreme distances of these transmissions. For smaller values of N , the probability that our radio emissions have been detected is much smaller.

Radio emissions are not the only potentially detectable signatures of intelligent life on Earth.

Industrial activity has released anthropogenic chemicals such as chlorofluorocarbons (CFCs) into the atmosphere in quantities that might be detectable in the spectrum of the Earth; however, this signature is of more recent genesis than radio signals. Large terrestrial cities have thermal infrared (IR) and visible light signatures which may be detectable at interstellar distances given a large enough telescope.

11.3.4 DETECTABLE ASPECTS OF INTELLIGENCE

Let us consider the aspects of intelligence that can be detected. As we’ve mentioned, direct observation of behavior at interstellar distances is unlikely, and, therefore, any evidence of intelligence is likely to be transmitted. Transmitted, in this case, does not necessarily indicate electromagnetic radiation. A physical object can also be transmitted, albeit at a lower speed.

11.3.4.1 ENERGETICS OF DIRECTED TRANSMISSIONS, BEACONS, AND LEAKAGE

Transmissions are generally divided into three types. The first, directed transmissions, are transmitted toward one or more chosen targets. This conserves energy at the transmitter by concentrating the transmission in a small solid angle $\Omega_A = \int \Phi(\Omega) d\Omega$, where $\Phi(\Omega)$ is the emission pattern, oriented toward the target. The second, a beacon, is an omnidirectional transmission covering 4π steradians. It's easy to see that, for a given transmitted power P , the average power of the signal in the beam of a directed transmission is a factor of $\frac{4\pi}{\Omega_A}$ stronger. This gain (Γ) of a diffraction limited telescope can be approximated as:

$$\Gamma = \frac{4\pi}{\Omega_A} = \frac{4\pi A_e}{\lambda^2}$$

where A_e is the effective area, defined such that $A_e \Omega_A \equiv \lambda^2$.² For a perfectly efficient, diffraction-limited telescope, the effective area is approximately the geometric area. For a non-diffraction-limited telescope, telescopes with multiple apertures, or those with less-than-perfect optical efficiency, $A \Omega_A \neq \lambda^2$, a calculated value of Ω_A and efficiency must be used to determine gain. Because of the λ^{-2} dependence of gain, in general, the gain of optical telescopes of even moderate sizes is huge compared with that of single-dish radio telescopes.

Because of the energetics involved, it is often presumed that an ETI will send directed transmissions toward promising targets rather than utilizing omnidirectional beacons. This may be especially true if the transmitting intelligence has observational capabilities that allow them to detect biosignatures and weak technosignatures.

The final type of transmission, leakage, represents transmission of information as a by-product of activity of an intelligent being or beings, as opposed to intentional transmissions. Leakage transmissions can include omnidirectional signals used for local communication such as radio or television broadcasts. It should be noted, however, that current terrestrial telescopes would be unable to detect such transmissions at distances much larger than 1 parsec. More promising types of leakage transmissions would be directional signals, satellite communications, interplanetary communications within a planetary system, and radars. While these directed transmissions are expected to be stronger than the omnidirectional leakage transmissions, they are also expected to be intermittent, with duty cycles inversely proportional to the transmitter gain. That makes repeated detection of high-gain leakage transmissions unlikely, unless there is a geometrically favorable arrangement of transmitter, receiver, and the distant observer. For example, Siemion et al. (2014) suggest searches for signals be conducted for when exoplanets are in conjunction, as viewed from Earth. Large telescopes are still required for this type of search, as the extraterrestrials would

presumably use only as much signal power as is necessary for their short-range communication.

11.3.4.2 PHYSICAL ARTIFACTS VERSUS RADIATED TRANSMISSIONS

It has been suggested that it is energetically favorable to send physical artifacts rather than radiated emissions. Physical artifacts, if they can be decelerated at their destination, have the benefit of persisting, potentially for billions of years. No such method of decelerating radiated emissions exists, as far as our current technology is concerned. In addition, storage densities in physical structures can be large; 100 Gb per gram is easily achievable with current technologies. Transmission across interstellar distances can be achieved with non-relativistic velocities, resulting in low costs. The drawback is primarily higher latency between sending and receiving a reply due to slower carrier velocity. Because of the lower velocity and the persistence, it is common to conceive of physical artifact transmission as a one-way information transport, commonly carrying a near-complete encyclopedia of an ETI's knowledge. Others have conceived of a biological library capable of seeding life-forms on planets in the destination system. The typical behavior of such a physical message from an ETI upon reaching the destination system is difficult to predict. It could use stellar gravity to redirect its trajectory toward another star system. During such a flyby it might attract attention by directing electromagnetic signals toward planetary bodies. Alternatively, it could achieve a stable orbit within the destination system. If the purpose of the artifact is communication with other intelligences, it could sit idle for a long period of time, emitting a beacon only at specified intervals or when intelligent activity is detected. In either case, such a message might be difficult to detect for a civilization of limited technology.

People on Earth have deliberately transmitted four passive artifacts for the purpose of communication with extraterrestrials, although none is directed toward any specific star system. Pioneers 10 and 11 each contain a gold-anodized plaque etched with a description of the location of the solar system relative to galactic pulsars, a schematic of the solar system showing Earth as the origin, and scale images of male and female humans and the Pioneer spacecraft (Sagan et al. 1972).

Voyagers 1 and 2 each contain a gold-plated aluminum disk engraved in the style of an audio record. A stylus for playing the recording is provided. On one side is engraved a schematic description of the decoding method and the position of the solar system relative to pulsars. The record contains both audio and image data. There are greetings in multiple languages, music from many cultures, and sounds of nature and civilization. The images include diagrams explaining mathematical and scientific concepts, pictures of solar system objects, images of human anatomy and function, images of Earth landscapes, and images of culture and technology

(Sagan et al. 1978). Although not deliberate messages, to date, seven additional artifacts have been sent on escape trajectories from the solar system, where they may eventually confuse extraterrestrials as to their purpose. These include the New Horizons spacecraft, the third propulsion stages that propelled New Horizons, Pioneer 10, and both Voyagers, and two small de-spin weights from New Horizons. All are on escape trajectories from the solar system.

Our ability to detect equivalent artifacts is quite limited. An object as small as Voyager 2 would need to pass very close to (less than a few times the lunar distance [LD] from) Earth to be detected, unless it was an active source of optical or radio emission. The first detected object known to originate outside the solar system, A/2017 U1 ('Oumuamua) had a size of $230 \times 35 \times 35$ meters and was detected at a distance of 0.22 AU (85 LD) (Jewitt et al. 2017).

11.3.4.3 SENSITIVITY CONSTRAINTS FOR RADIATED SIGNALS

For a noise-limited system, the minimum detectable signal flux is given by the rather obvious relation

$$F_{\min} = n_{\text{thresh}} \sigma_F$$

where σ_F is the relative error in measurements due to noise within the instrument and internal and external backgrounds and n_{thresh} is chosen to limit the false alarm rate to a manageable level. The functional form of σ_F depends strongly on the instrumentation and its noise processes and the distribution of noise events. In general, it can include thermal noise processes, atmospheric and/or stellar backgrounds, and photon-counting statistics. The statistical form of these noise processes will also vary from instrument to instrument. Whereas a 5σ threshold may be adequate for a Gaussian noise distribution, a 25σ threshold might be necessary for an exponential distribution.

For future discussions of sensitivity in this article, we shall concentrate on integrated flux rather than spectral flux density, under the assumption that we are able to integrate across the entire spectral distribution of a signal.

11.3.4.4 DETECTION OF EXTRATERRESTRIAL INTELLIGENCE

To declare a detection of an extraterrestrial signal or artifact, it's important that the evidence points to an extraterrestrial intelligent origin and that natural origin be ruled out as much as possible. An extraterrestrial radiated signal must be repeatedly detected using multiple instruments, if possible at multiple telescopes. Single observations of short-duration events, such as the "Wow! signal" (Ehman 2011), should not be considered a detection until they are detected repeatedly. It's also important that a radiated signal be localized to a single source in the sky. The terrestrial environment is filled with sources of transient anthropogenic electromagnetic signals that appear to come from essentially random locations on the sky.

For any signal or artifact, intelligent extraterrestrial origin should be the final hypothesis rather than the first. When 'Oumuamua was detected, the media rapidly propagated the idea that it was an extraterrestrial spaceship, an idea that was even spurred on by some scientists. Yet, even a simple analysis would indicate that comets and asteroids that have been ejected from stellar systems are likely to outnumber extraterrestrial spaceships by factors of a billion. The media attention prompted SETI scientists to observe 'Oumuamua. Unsurprisingly, they detected no evidence of signals.

11.3.5 WHERE TO LOOK

11.3.5.1 A CHOICE OF CARRIER: PHOTONS, NEUTRINOS, AND GRAVITATIONAL WAVES

As humans, one of our most important sensory inputs, the eye, is based upon processing inputs of electromagnetic radiation (photons). As human technology has progressed, the use of the eye as an input for communications has increased. Some of our most important technological advances have been devices that turn information into visual stimuli that can be processed by the brain (i.e., writing) and devices that turn information into electromagnetic radiation that can be transmitted over long distances for later sensory processing (e.g., radio and television). Therefore, it's natural to conceive of interstellar data transmission using similar devices.

The benefit of using photons as a carrier is that photons interact electromagnetically with nearly all forms of normal matter. That makes it relatively easy to build devices that collect and measure photons and to build devices that deflect or guide photons into those devices. The drawback of using photons as a carrier is that photons interact electromagnetically with nearly all forms of normal matter. Atmospheres are opaque to many frequencies that would otherwise be useful for transmission. Interstellar matter can also block clear transmission because of opacity, dispersion, scintillation, refraction, and high natural backgrounds.

Because photon detectors are ubiquitous in astronomy, they will comprise the majority of the discussions in this chapter. We'll divert here into a short discussion of non-electromagnetic options for interstellar communications.

11.3.5.2 NEUTRINOS AND GRAVITATIONAL WAVES

Photons are not the only type of radiation that can travel interstellar distances and be detected; they are simply the easiest to create and detect. Other options include neutrinos. Neutrinos interact with normal matter through the weak nuclear force. As is implied in the name, the weak nuclear force is a weaker interaction than the electromagnetic interaction. That makes it difficult to build devices that create directed neutrinos (a particle accelerator) and very difficult to build devices that detect neutrinos (e.g., Super-Kamiokande) (Abe et al. 2011). It is virtually impossible to build devices that redirect or focus neutrinos (none known). Neutrino-detection efficiencies of these devices are of order 10^{-16} at

the low energies typical of solar neutrinos. At higher energies, neutrino detection can be significantly higher ($\sim 10^{-5}$). Silagadze (2008) postulates that a 200 TeV muon collider operating 6 parsecs from the Earth would be detectable with an existing neutrino detector, provided it created neutrinos at a rate of 10^{14} s^{-1} and was pointed within 50 milliarcsecond (mas) of the Earth. For random orientations, the probability of such an alignment is $P \sim 1.5 \times 10^{-14}$, which would imply purposeful targeting, should such a detection ever be made. Lacki (2015) postulates that extremely advanced civilizations might build particle accelerators to probe physical processes at the Plank scale. Such accelerators might emit 10^{24} eV neutrinos. Such a neutrino could interact in the upper atmosphere and be detected by existing cosmic ray detectors. No cosmic rays of such high energy have yet been detected. An additional possibility would be the use of gravitational waves as the information carrier. The interaction between gravitational waves and matter is very weak, and therefore, such waves are typically detected by measuring the distortion of spacetime between two points by using a laser interferometer many kilometers in size. The natural phenomena detected with gravitational wave detectors include merging black holes visible at hundreds of Mpc distance (Abbott et al. 2016) and merging neutron stars visible at tens of Mpc distance (Abbott et al. 2017).³ Although they are detectable with current technology, gravitational waves that can be detected at interstellar distances are difficult to generate. An interstellar gravitational wave transmitter might consist of a pair of closely orbiting neutron stars with some way of feeding energy into the orbits, in order to modulate the orbital period, and therefore the gravitational wave frequency. Such a transmitter is well beyond our current technology. As gravitational waves are additive in a manner similar to electromagnetic waves, it should be possible to build a directional transmitter array from synchronized orbiting masses. This does not remove the need for stellar mass neutron stars or black holes in the transmitter, as there are no known stable states of matter of lower mass that would provide the necessary densities to generate significant gravitational radiation. Gravitational wave generators that do not use mass to generate the waves require speculative extensions to physics and, for now, will remain science fiction.

11.3.5.3 TARGET CHOICES

Much consideration goes into target selection for SETI observations, with much of the preference going to nearby solar-type stars. There may be some validity to such a choice, as the only known technological civilization lives on a planet around such a star. Turnbull and Tarter (2003a,b) developed “HabCat: a Catalog of Nearby Habitable Stellar Systems” as a potential target list for SETI on the Allen Telescope Array (ATA). They selected for main sequence stars with low stellar activity and variability, stellar age greater than 3 Gyr, and luminosities less than 2.5 L. Because their choices depended upon *Hipparcos* parallaxes, the volume sampled in the catalog is strongly limited by stellar luminosity. Low-luminosity

K and M stars found in the catalog are very nearby. Most of the catalog consists of brighter late F and early G stars, thus their catalog is heavily biased toward solar-type stars.

For small values of Drake N , being limited to nearby stars is not necessarily appropriate. Other suggestions have been put forward. Some have suggested that faint cool M-dwarfs may have benefits for development of life (Tarter et al. 2007). They are abundant, representing more than 75% of the stars in the galaxy. They are long-lived, with lifetimes in the trillions of years for the lowest stellar masses. High stellar activity early in the life of the star, resulting in high ultraviolet (UV) and X-ray fluxes, could be a catalyst for generation of complex organic molecules necessary for the development of life. A potential disadvantage of these stars is the narrow width of the habitable zone, which may make it less likely that planets will be found in the habitable zone. The proximity of the habitable zone to the stars results in tidally locked planetary rotation for any planets in the habitable zone. This may result in conditions that make it difficult for life to thrive. The stellar activity of these stars early in their lifetimes is likely to be sufficient to strip atmospheres, which may deplete the planets of volatile elements (H, O, and N) necessary for terrestrial-type life.

It is possible that advanced life either has altered its environment to the point where we can't detect its star (see 11.3.9) or has no need to live near stars and planets, only visiting them to collect raw materials. In that case, concentrating solely on stars may be a mistake.

The Breakthrough Listen Green Bank Telescope survey (Isaacson et al. 2017) has chosen a more diverse sample of locations, although still concentrating on stars. Their target list includes all known stars within 5 pc, the 100 nearest giants, and main sequence stars between 5 and 50 pc with spectral types from A-M, with 100 chosen per unit 0.1 magnitude of B-V color, unless fewer were available. To this, they added 139 external galaxies.

Prior to Breakthrough Listen, most radio SETI observing by the Berkeley SETI team, through its projects *SERENDIP* (Search for Extraterrestrial Radio Emissions from Nearby Developed Intelligent Populations) and *SETI@home* (Korpela et al. 2011a; Bowyer et al. 2016), has been conducted in a commensal or piggyback mode, generally directed where other observers using the telescope have scheduled observations. At Arecibo, this has resulted in participating in both pointed observations of specific targets and surveys conducting observations of large regions of the sky.

11.3.6 RADIO AND MICROWAVE SETI

The earliest forms of serious SETI searched for radio-frequency transmissions by using instrumentation attached to radio telescopes. Because radio technology was one of the first methods of potential interstellar communications developed by humans, it seems a likely mechanism for extraterrestrials interested in communicating with developing species. In addition to being simple to deploy, it's quite easy to use radio to create signals that are easily distinguished from natural sources of radiation.

Natural sources of radiation are typically broadband, with signal bandwidths of tens of kilohertz to gigahertz. Since no known natural source of extremely narrow band (<1 Hz) emissions exists, if such a signal is found, it can be presumed to be artificial. Narrow bandwidth also economizes transmission power. The energy required to outshine background sources is narrower. Another way of outshining background sources is that, rather than putting energy into a narrow band, the transmitter could put lots of power into a pulse of short duration. This is less likely to be distinguishable from natural sources, however, as pulsars and fast radio bursts do give out short powerful bursts.

11.3.6.1 BASIC CONCEPTS: DETECTORS, BANDWIDTHS, AND CHANNELS

In its simplest form, a radio telescope consists of an antenna, a receiver system, and back-end instrumentation. The purpose of the antenna is to collect the radio waves, which are added in-phase and directed toward the receiver. The receiver system amplifies the weak RF signals and converts them into higher-amplitude electrical signals. Typically, a receiver processes two polarizations, either crossed linear polarizations or left and right circular polarization. These electrical signals may be converted into signals of lower frequency by mixing them with a sinusoidal oscillator. This prevents the need that the back-end instrumentation be able to process the RF signals directly at the Nyquist rate.⁴ A wide variety of back-end instrumentation is typically available. These back ends preserve differing amounts of the information that is received from the front end.

Direct digitization and recording of the down converted signal can preserve nearly all of the information present and, in principle, can reproduce the receiver voltages versus time to high precision. The drawback is that large amounts of data must be stored, typically four bytes (two per polarization) per unit time, with time being the inverse of the Nyquist rate. Therefore, a 100 MHz bandwidth will typically require 400 MB/s of recording capacity. Such recording techniques are used with very long baseline interferometry (VLBI), where preserving phase and timing relations is extremely important. It's also used in some SETI experiments. Breakthrough Listen (Enriquez et al. 2017) utilizes this method for its initial data capture, but processes the data quickly to a format that is thousands of times smaller. *SETI@home* (Korpela et al. 2001) utilizes this technique for recording data, but uses a recording technique that only requires 4 or 8 bits per complex sample.

The basic instrumentation for radio SETI is a spectrometer. Typically, these spectrometers generate spectra where the relationship between channel width and integration time is $\Delta\nu_{\text{chan}}\Delta t = 1$. There are few known natural processes that generate signals with that relationship; therefore, if one is seen, it could be a first indication of an artificial signal.

11.3.6.2 BACKGROUNDS AND OPACITIES

There are some issues that limit the sensitivity of radio observation by increasing the noise within a measurement. The first

is quantization noise, which is dependent upon the number of bits used to sample a signal. The easiest visualization is to imagine a sine wave sampled at 1 bit per sample. In essence, the sine wave is converted into a square wave by the sampling, which moves power out of the primary frequency and into the Fourier components of a square wave. For single-bit digitization, this results in a signal power loss of 36%. For 2-bit, the loss is 19% and drops rapidly to less than 1% for quantizations of 5 bits and higher (Vleck and Middleton 1966; Thompson et al. 2007).

Other limits are set by the noise processes present in interstellar and intergalactic spaces. At low frequencies, the noise processes are dominated by the emissions from energetic particles interacting with the galactic magnetic field. At higher frequencies, molecular rotational and vibrational transactions provide the dominant noise source. At frequencies between about 500 MHz and 20 GHz, there is a region known as the terrestrial microwave window. In this region, both the atmosphere and the galactic interstellar medium (ISM) are relatively transparent. Natural noise in this region is dominated by the 3K cosmic background radiation. However, thermal noise processes in telescope systems are often significantly larger than this, with receiver contributions of 20 to 40K. The sum of all the thermal noise sources is referred to as system temperature, T_{sys} . Figure 11.3.1 shows the microwave window in schematic form.

A portion of the microwave window known as the “water hole” has been the subject of significant interest among SETI scientists. It is bounded at the low-frequency end by the 1.42 GHz magnetic dipole transition of HI and at the high-frequency end by the 1.67 GHz transition of the OH radical. The HI transition is used by scientists to map the structure of the galaxy. The OH transition is similarly useful in studying molecular gas in the galaxy. It is presumed that ETI would utilize these transitions as well, and therefore, we would expect that a transmission on these frequencies is more likely to be

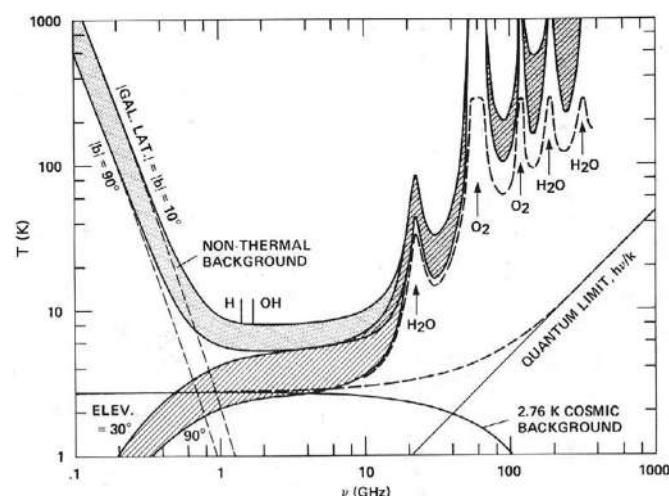

FIGURE 11.3.1 The terrestrial microwave window. (From Morrison, P. et al., *The Search for Extraterrestrial Intelligence, SETI*, NASA Special Publication, 419, 1977.)

seen by extraterrestrial scientists. In addition, the combination of H and OH results in water, which is an important compound for life, at least on Earth.

Sensitivity for detection of an extraterrestrial signal is dominated by the noise processes discussed previously. We define system equivalent flux density for a single dish as:

$$S_{\text{sys}} = \frac{2k_B T_{\text{sys}}}{A_e}$$

and the minimum detectable flux for a narrow signal as:

$$F_{\min} = n_{\text{thresh}} \sigma_F = n_{\text{thresh}} S_{\text{sys}} \sqrt{\frac{\Delta v_{\text{ch}}}{n_{\text{pol}} \Delta t}} \quad (11.3.1)$$

where:

Δv_{ch} is the spectral channel bandwidth.

Δt is the observation time.

n_{pol} is the number of polarizations measured.

A 100-meter telescope with a 30 K system temperature would have $S_{\text{sys}} \sim 10$ Jansky in 3 Hz channels, with 30-second dual polarization observations, and a 20σ threshold would have $F_{\min} \sim 5 \times 10^{-25} \text{ W m}^{-2}$. This is, coincidentally, about the spectral resolution and per-spectrum integration used by the Breakthrough Listen project for its high-resolution data product.

11.3.6.3 RADIO FREQUENCY INTERFERENCE

Perhaps an even larger problem for detecting ETI is that technosignatures surround us. Our radio telescopes are embedded in the middle of a technological civilization that uses radio frequencies, both narrow band and wide band, for communication and for object detection and ranging. A significant part of SETI science involves developing techniques to distinguish between local interference and potential extraterrestrial signals. This involves many techniques. On-source/off-source observation is one technique in which either a separate telescope or receiver is used simultaneously to gather data at a location away from a suspected ETI source or the telescope is moved between off source and on source positions. Any signal detected in both observations can be rejected as interference. Some of these techniques are discussed by Korpela et al. (2011b).

Signal properties can also be used to identify interference. The rotating Earth imparts a Doppler drift to a signal. If this drift is not seen, a signal can be presumed to be local. Satellites, on the other hand, pass overhead at a range of velocities and accelerations in a wide range of possible drift rates, which makes them more difficult to reject. An ETI would need to be aware of the exact distance to the Earth, the rotation rate of the Earth, and the location of the telescope on the Earth, in order to correct for this effect. The ISM is partially ionized, which results in a frequency-dependent delay in broadband pulses. If this delay is not

seen, a pulsed signal can be presumed to be local. We will discuss these effects further in the next sections. As interferometric arrays of radio telescopes are being used more frequently for SETI, new capabilities are being developed. Beamformers can produce nearly arbitrary beam shapes that allow null regions to be placed over radio frequency interference (RFI) sources (e.g., satellites) in the field of view. If multiple beamformers are available, both on target and off target observations can be conducted simultaneously. If a signal is seen from a target, a null can be placed over it to verify the signal disappears. See (Harp 2013) for further discussion of these methods.

11.3.6.4 THE DOPPLER DRIFT PROBLEM

There are some issues that limit the sensitivity of radio observation to narrow-band signals. One primary concern is the Doppler drift caused by accelerations of the transmitter or receiver. For a receiver located on the surface of the Earth, the dominant acceleration of the receiver is imparted by the rotation of the Earth. This acceleration is centripetal. The highest drift would occur for a receiver located at the equator, observing a target overhead. This acceleration of $3.4 \text{ cm s}^{-2} \sim 10^{-10} c \text{ s}^{-1}$ may not seem significant, and for most astronomical observations, it is not. But when dealing with channel widths near 1 Hz, the drifts become problematic. At L-band (1.4 GHz), this corresponds to a frequency drift in any received signal of 0.16 Hz s^{-1} . If uncorrected, this could cause a reduction in sensitivity by limiting the effective exposure time to no more than $\Delta t \leq \frac{\Delta v_{\text{ch}}}{v}$, or equivalently increasing channel bandwidth to $\Delta v_{\text{ch}} \geq v \Delta t$. Keeping in mind that the relation $\Delta v_{\text{chan}} \Delta t \geq 1$ still holds, the minimum channel width for an uncorrected L-band spectrometer is $\Delta v_{\text{ch}} \sim 0.4 \text{ Hz}$ and $\Delta t \sim 2.5 \text{ sec}$. Because of this, most SETI spectrometers have operated with channel bandwidths between 0.5 and 3 Hz. By Equation 11.3.1, this means that they are operating at sub-optimal sensitivity. It is possible to perform this correction coherently on the incoming signal to regain full sensitivity and allow for narrower channel widths. Unfortunately, because this process was not implemented with SETI in mind, at most observatories, the frequency steps implemented for the local oscillator are often too large ($\geq 10 \text{ Hz}$) to be useful.

There's a worse Doppler drift problem, the drift of the transmitter frequency due to its own motions. An extraterrestrial may take care of this problem for us. If the transmissions are directed specifically at Earth, they can be corrected by the sender for the motions of the transmitter. Omnidirectional beacons could be constructed from multiple antennas, each corrected for velocity changes along its direction of transmission (Korpela 2011). It's also possible that uncorrected transmitters are what an ETI may decide to build. Since the parameters of motion of the transmitter are unknown, SETI projects generally perform a blind search to likely Doppler drift rates.

There are two ways to perform this search. The most common method is to use an incoherent dechirp process, essentially shifting spectra by the drift rate to find drifting

signals. This can be implemented as a tree-search algorithm, which reduces the complexity to $O(n\log n)$ from the $O(n^2)$ of the naive implementation (Siemion et al. 2013). Because of the quantization of frequency and time, there is a sensitivity loss associated with this method, as the drift results in energy bleeding into adjacent frequency bins during the spectral integration. This results in an effective bin width of $\Delta v_{\text{eff}} \sim \Delta v_{\text{ch}}$ and a corresponding loss in sensitivity per Equation 11.3.1; in practice, this search looks through hundreds of potential drift rates.

The option is to use a coherent dechirp method on the time-domain (baseband) data. This method involves the complex multiplication of the data by a chirp function, effectively translating the data into an accelerating frame. Because this is done in the time domain, no loss of frequency resolution results, and the process can be performed for arbitrarily small differences in drift rate. For *SETI@home*, this is done for drift rate differentials as small as 10^{-3} Hz s $^{-1}$ over the range -100 Hz s $^{-1}$ to $+100$ Hz s $^{-1}$, which enables *SETI@home* to utilize 0.075 Hz spectral bin while still preserving sensitivity over the full Doppler drift range.

It is important to note that the behavior of a drifting signal is expected to vary over time. A signal not corrected at the source would have velocity components due to planetary rotation, due to orbital motions of the planet, and due to gravitational influences of other planets or satellites. These are likely to add up to 10 s to 100 s of km/s, which translates to long-term frequency shifts of 10 s or 100 s of kHz. This can add to the difficulty of detecting a signal.

11.3.6.5 THE DISPERSION PROBLEM

An equivalent problem to the Doppler drift problem exists when trying to detect pulsed radio emissions. The ISM is partially or fully ionized. A broadband radio pulse traveling through the ISM will interact with free electrons and will be delayed. The amount of this delay is dependent on frequency, such that:

$$\Delta t = 8.3 \mu\text{s} \frac{(\nu - \nu_o)[\text{MHz}]}{\nu_o^3[\text{GHz}]} DM[\text{pc cm}^{-3}]$$

where ν_o is a reference frequency and DM is the integrated electron density along the line of sight, given in units of pc cm $^{-3}$. So, a pulse coming from a distance of 10 pc through an electron density of 0.1 cm $^{-3}$ at a frequency of 1 GHz would have a dispersion of about 8.3 $\mu\text{s MHz}^{-1}$. Again, if the dispersion measure to a source is unknown, a tree search can be performed over a wide range of dispersions. This search can be performed incoherently, with the accompanying loss of sensitivity and a loss of potential time resolution, or coherently, requiring significantly more computation. Nearly every such SETI search is performed incoherently with time resolutions greater than 64 μs and spectral resolutions of megahertz. The only coherent search of note is the *Astropulse* search, which performed a search for pulses as short as 400 ns with the 305-meter Arecibo telescope (Von Korff et al. 2013).

11.3.7 OPTICAL AND INFRARED SETI

11.3.7.1 PHOTON-COUNTING INSTRUMENTS

Because the photon energies in the IR and optical are high enough to result in an electron being liberated via the photoelectric effect, most optical and IR SETI experiments use low-noise photon-counting detectors, such as charge coupled devices (CCDs), avalanche photodiodes (APDs), or photomultiplier tubes.

For an observation of a source with a photon flux integrated over the detection bandpass of F_{source} photons/cm 2 with a photon-counting detector of N_{total} counts with non-zero sky and/or stellar background (N_{sky}), detector background (N_{det}), and read noise (N_{read}), the measured flux can be expressed as:

$$F_{\text{source}} = \frac{1}{A_{\text{eff}}t} (N_{\text{total}} - N_{\text{sky}} - N_{\text{det}} - N_{\text{read}})$$

In the case where only shot noise is a significant error contribution and backgrounds levels can be determined with high precision:

$$\sigma_F = \sqrt{\frac{F_{\text{source}}}{A_{\text{eff}}t} + \Omega_r \frac{dF_b}{d\Omega} \frac{1}{A_{\text{eff}}t} + \frac{F_{\text{stellar}}}{A_{\text{eff}}t} + \frac{R_{\text{det}}}{A_{\text{eff}}^2 t} + \frac{N_{\text{read}}}{A_{\text{eff}}^2 t^2}}$$

where:

A_{eff} is the effective area of the telescope.

Ω_r is the solid angle of the integrated region.

$\frac{dF_b}{d\Omega}$ is the background surface brightness.

R_{det} is background count rate coincident with the signal.

F_{stellar} is coincident stellar flux.

Fluxes here are measured in units of ph m $^{-2}$ s $^{-1}$. Obvious take-aways are that (1) in general, the F_{min} will go as $(A_{\text{eff}} t)^{-\frac{1}{2}}$, and (2) angular resolution is important for reducing background, as are low-noise detectors.

In the case of a diffraction limited instrument, $A_{\text{eff}} = \pi R^2 \epsilon$, where R is the aperture radius and ϵ is the instrument's integrated efficiency, including optical and detector efficiency. When detector and readout noise are also low, σ_F becomes:

$$\sigma_F = \frac{1}{\sqrt{\pi \epsilon t R}} \sqrt{F_{\text{source}} + F_{\text{stellar}} + \frac{\pi}{2} \left(\frac{\lambda}{R} \right)^2 \frac{dF_b}{d\Omega}} \quad (11.3.2)$$

The basic types of detection systems are unchanged from the radio case. We can observe for a spectral signature: lots of power put into a single frequency (or a small number of frequencies), or for a transient signature: a detectable change in flux on short timescales.

11.3.7.2 THE PROBLEMS: THE ATMOSPHERE, DUST, AND BACKGROUNDS

Some of the difficulties involved in optical and IR SETI are the opacities of the media through which the radiation propagates. The Earth's atmosphere presents difficulties with

turbulence, which results in scintillation (twinkling) and blurring of stellar images. The total effect is known as “seeing” and is expressed as the angular blur in arcseconds that it adds to an image beyond what would be expected if the telescope were diffraction-limited. This can be combated with adaptive optics. However, at this time, those techniques are restricted to larger telescopes, which are not often made available for SETI observations.

The atmosphere is not entirely transparent at optical and IR wavelengths. Figure 11.3.2 shows the atmospheric transmittance from sea level in the optical and IR ranges. Significant spectral regions of high opacity are present. To avoid that opacity, it is necessary to get above the atmosphere. Some opacity can be avoided by locating observatories at high altitude. Others require balloon- or space-based observatories. Again, getting use of such observatories for SETI observations is problematic.

The opacity of the ISM is also a significant concern at X-ray, UV, and optical wavelengths. At photon energies above 13.6 eV, the opacity tends to be dominated by ionization of interstellar atoms, which leads to very high opacities near their ionization edges (Cruddace et al. 1974). Below 13.6 eV, the opacity tends to be dominated by interstellar dust. Dust opacities are highest in the UV and decrease rapidly in the IR, as wavelengths become larger than the size of the dust grains.

Given Equation 11.3.2, a 2-meter diameter telescope with 85% optical efficiency and a 75% efficiency noiseless detector would have:

$$\frac{F_{\text{source}}}{\sigma_F} \sim 140\sqrt{t[\text{sec}]F_{\text{source}}}$$

in the absence of background, as expected for Poisson statistics. For ground-based applications, sky backgrounds ($\sim 21.8 \text{ m}$ at V band, or equivalently $150 \text{ ph s}^{-1}\text{m}^{-2}$ integrated across the band, is considered a dark sky), combined with

seeing ($\sim 0.5\text{--}3''$) and/or aperture size (arcseconds to arc-minutes) and spectral resolution (fractions of an Å to 100s of nm), are often the dominant constraints. The sky background in a $3''$ circular aperture alone would result in a background rate of $\sim 2100 \text{ s}^{-1}$ in our hypothetical 2-meter telescope. Observations coincident with a star compound this rate, with even a 15th magnitude star providing a background count rate of $1.6 \times 10^5 \text{ s}^{-1}$. In this case, σ_F is dominated by the F_{stellar} term, and the signal-to-noise ratio is:

$$\frac{F_{\text{source}}}{\sigma_F} = \frac{F_{\text{source}}A_{\text{eff}}t}{\sqrt{F_{\text{stellar}}A_{\text{eff}}t}}$$

which, for our example, evaluates as $0.006F_{\text{stellar}}\sqrt{t[\text{s}]}$ and translates to the obvious statements that more intense signals and longer exposures increase signal to noise, and higher backgrounds decrease it. The less obvious conclusion is that emissions need to be intense (and, of course, variable) to be noticeable in a single broadband detector.

The means for combating these backgrounds on both the sending and receiving ends are similar to those used in radio SETI. If we are looking for bright laser lines, we would use a spectrograph to create a spectrum, and we would look for bright narrow lines in the spectrum, either within the stellar spectrum or adjacent to it. The V band has a spectral width of 880 Å (88 nm), so a spectral resolution of 0.1 Å essentially reduces the stellar background rate per bin by a factor of 8800.⁵ This technique is explored in more detail by Tellis and Marcy (2017).

11.3.7.3 PULSE AND COINCIDENCE AND ANTICOINCIDENCE DETECTORS

There are significant reasons to expect that pulsed lasers might be used for extraterrestrial communications. The

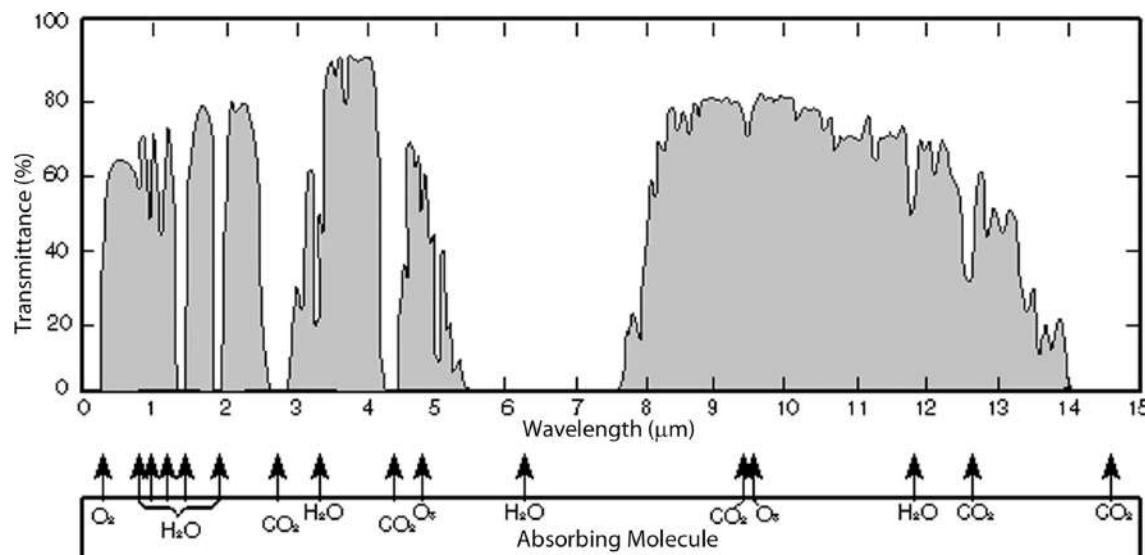

FIGURE 11.3.2 Optical and IR transmissions of the Earth's atmosphere versus wavelength.

largest existing terrestrial pulse laser, the National Ignition Facility, produces a pulse of 1.3 petawatt 1.053 μm IR light lasting a few nanoseconds, with total pulse energy of about 4 MJ. A similar laser attached to an astronomical telescope could be used to send a pulse of light that would outshine the Sun at interstellar distances. Even a moderate, 1" focus would illuminate a region 10 AU in diameter at a distance of 10 pc with a pulse consisting of 12 photons per square meter (Stoltz 2012). A pulse of that intensity could be detectable, even with current optical and IR detector technologies.

If we are looking for short-duration pulses, we look for bursts of photons on short timescales among the relatively constant rate backgrounds. Our hypothetical system, with its $1.6 \times 10^5 \text{ s}^{-1}$ count rate, results in a photon detection on average, every 6.25 μs . If we integrate for 100 ns, the probability of detecting photons is governed by Poisson statistics. The likelihood of detecting n or more photons in an exposure is $P(n, Rt)$, where $P()$ is the incomplete gamma function, R is the photon rate, and t is the integration time. Of course, in real photon-counting systems, some dead time is associated with each detection, which alters the statistics. Assuming zero dead time for our hypothetical system, the likelihood of detecting 10 photons in 100 ns is of order 3^{-25} , which would be one false alarm every 10 billion years. That would seem to be acceptable for detecting short-duration bright pulses from pulsed laser systems. Unfortunately, there are many instrumental, artificial, and natural sources of pulses that can be mistaken for extraterrestrial signals. These include cosmic rays hitting the detector, radiation from cosmic ray showers in the atmosphere, strobes, power line glitches, detector noise processes such as “after-pulsing,” and even RFI affecting the electronics. The false alarm rates of single detector systems are often dominated by these effects.

There are many ways of combating these effects. One way of combating cosmic rays is to surround the photodetector with an anticoincidence shield, often constructed of a plastic that scintillates and fluoresces when a cosmic ray passes through it. One or more photomultipliers detect cosmic ray signatures and veto any simultaneous photon events from the main detector. It's often less costly to build a coincidence detection system of two or three detectors to detect coincidence in the emission from the source being observed.

In a three-detector coincidence system, the light from the source passes through two beam splitters, dividing the light between the three photodetectors. The detection circuitry detects and counts coincidences between any two detectors and coincidences between all three detectors. Since the detectors are not colinear, it's unlikely that a cosmic ray could pass through all three. There is the potential of being triggered by light from the sky (cosmic ray Cerenkov radiation, strobes) that is not extraterrestrial. In the low rate ($Rt \ll 1$) limit, the probability of a false alarm in a coincidence system, given random photon arrival times, is simply $P(1, Rt/N)^N$, where N is the number of detectors. So, for our hypothetical telescope with triple detector and 100 ns

coincidence time, the false alarm probability per interval is 1.5×10^{-7} or about 1 per second. To adjust the false alarm rate, one could reduce the coincidence time, choose a fainter source, or increase the number of detectors. A 1-ns coincidence time would result in a false alarm rate of one every two hours. Such a system used in the optical is described in more detail by Wright et al. (2001). A similar IR system is described by Maire et al. (2016). The availability of arrays of photon-counting detectors such as APDs could allow the development of systems that use anticoincidence between different pixels in the detector array to reject any signal that impacts more than one location on the detector simultaneously.

11.3.8 THE MISSING BANDS: SPACE-BASED SETI

One of the biggest missing links in the electromagnetic spectrum for SETI are the bands to which the Earth's atmosphere is opaque. From the gamma rays to the near UV, no radiation penetrates the atmosphere. Similarly, in the IR, atmospheric molecules create broad absorption bands, through which no radiation penetrates. We can speculate that an ETI that wishes to communicate with other intelligences that have advanced to a spacefaring state might transmit on these frequencies.

While it is cost-prohibitive to place a telescope in space for the purpose of SETI, evidence of ETI might be hiding in the data of existing space telescopes. Many surveys in the UV and X-ray have sources that have not been identified with a known counterpart. For example, a combined analysis of the Extreme Ultraviolet Explorer (EUVE) extreme ultraviolet (EUV) and Röntgensatellit (ROSAT) soft X-ray surveys (Lampton et al. 1997) found 61 sources for which no obvious counterpart was identified. Some of these were later determined to be neutron stars, white dwarfs, or flare stars. It's unlikely that any are ETI sending X-ray messages, but we offer it as an example of the data sets that are available. Corbet (2016) provides a discussion of other types of X-ray SETI, using other existing X-ray facilities and data sets.

11.3.9 PHYSICAL ARTIFACT DETECTION AT INTERSTELLAR DISTANCE

Dyson (1960) suggested that an extraterrestrial civilization might build a giant structure to capture and utilize most or all of the visible emissions of a star, radiating only waste heat. A Dyson sphere would be detectable as a stellar-luminosity $\sim 300\text{K}$ featureless blackbody source if the structure completely encases the star, or as a star with a significant IR excess in the case of a partial sphere. If civilizations capable of such feats of engineering were common, we could likely detect them in IR surveys. Searches of the IR sky sensitive to both complete (Carrigan 2009) and partial (Conroy and Werthimer 2003, unpublished⁶; Globus et al. 2003, unpublished⁷; Jugaku and Nishimura 2004). Dyson spheres have been conducted by using the Infrared Astronomical Satellite (IRAS) data set. While these have detected a few interesting candidates, none have

been shown to indicate intelligent origin. Two high-sensitivity searches for Dyson spheres are ongoing, one searching for IR signatures of Dyson spheres in the *WISE* survey (Wright et al. 2014a,b; Griffith et al. 2015) and another examining *Kepler* light curves for unusual transit eclipses that could indicate a partial Dyson sphere (Marcy et al. 2014).

A civilization advanced enough to trap most of the available output of their host star ($\sim 4 \times 10^{33} \text{ ergs}^{-1}$) meets the definition of Kardashev Type II on the Kardashev (1964) scale of technological advancement of a civilization. A Type I civilization uses energy on the scale of current terrestrial civilization ($\sim 4 \times 10^{19} \text{ ergs}^{-1}$). Given the possibility of extinction, it seems likely that Kardashev Type II civilizations are much rarer than those capable of sending small spacecraft into orbit and that a continuum of possible engineering stages should exist. We might consider a civilization with significant ability to modify its planetary environment but not capable of building astronomical unit (AU) scale structures as Type I.5.

Carrigan (2012) recently summarized several other potential archaeological signatures for civilizations at various levels on the Kardashev scale, concluding that apart from electromagnetic communications, these are generally undetectable with current human technologies. Arnold (2005) suggests that an extraterrestrial civilization could deliberately create planetary-scale structures with unique shapes or periodicities that could be detected when the structure transits the star and could be distinguished from a planetary transit with current technology. Korpela et al. (2015) explored the possibility that even smaller structures could be detectable. They considered

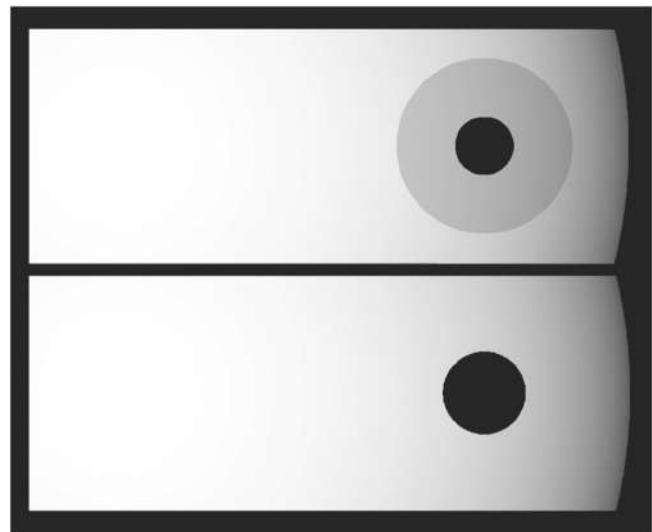

FIGURE 11.3.3 Top: simulated image of a planet surrounded with orbiting mirrors transiting in front of an M5 star. Bottom: same as above, but for an isolated planet large enough to produce a transit of the same depth.

the case where an ETI was using orbiting mirrors to illuminate the dark side of a tidally locked planet (see Figures 11.3.3 and 11.3.4). The differences in light curves between the case of a larger planet versus a smaller planet with orbiting mirrors could not be detected with existing instrument but would be detectable in some cases with the *James Webb Space Telescope (JWST)*.

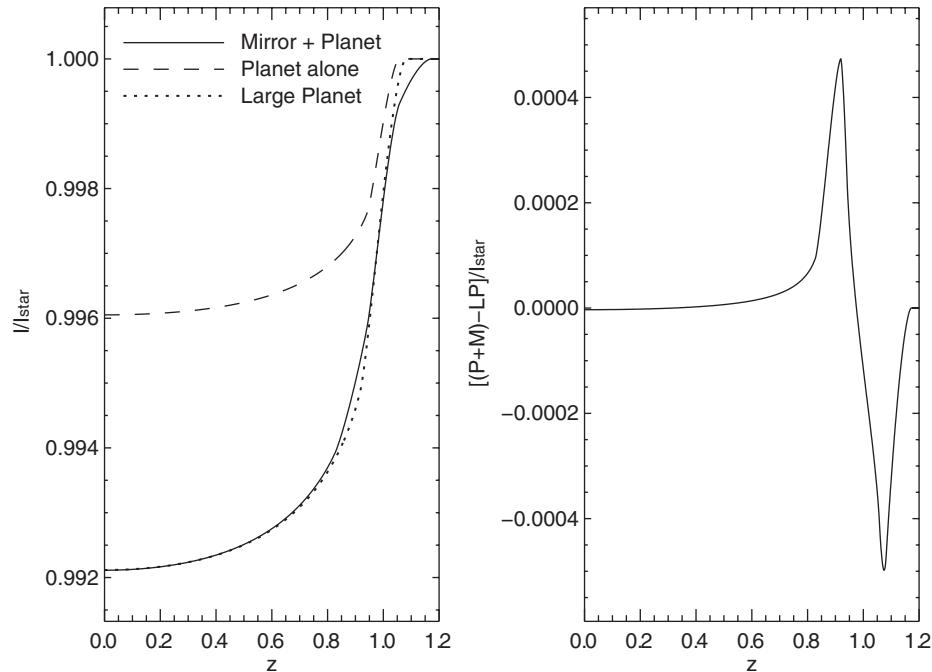

FIGURE 11.3.4 Left: transit light curves for a planet orbiting an M5 star (dashed line: P), the same planet surrounded by orbiting mirrors extending to three planetary radii (solid line: $P + M$), and a planet without mirrors that is large enough to produce a light curve with the same depth of transit (dotted line: large planet [LP]). Right: difference between transit light curve with mirrors ($P + M$) and the one for the solitary LP, relative to the stellar intensity.

11.3.10 THE FERMI PARADOX: A FINAL WORD?

The lack of any confirmed defections of ETI by SETI experiments is often described as a failure of SETI to produce results, rather than success in reducing the parameter space in which an ETI could remain hidden. Often this is mentioned in relation to the so-called “Fermi paradox,” which is neither a paradox nor a concept that originated with Fermi (Gray 2016). A typical statement of this “paradox” is: Since a civilization capable of interstellar travel could colonize the galaxy within a few million years and since the galaxy is 13 billion years old, why is there no evidence of a galaxy-wide civilization? The possible reasons for this have been discussed widely. Any of the Drake parameters could lead to $N \gg 1$, resulting in a galaxy where Earth is the first or only civilization. The probability of tool-using intelligence arising could be low. L could be small, resulting in civilizations that don’t last long enough for interstellar colonization. The end result of technological evolution could be machine intelligence that is not driven by biological desires to reproduce, expand, colonize, or even communicate. In the end, this is all speculation. The definition of success in science is not “Did I find what I was looking for?” but merely “Do I understand more than I did yesterday?”

ENDNOTES

- ¹ Earlier attempts to detect extraterrestrial transmissions originating within the solar system did occur; however, they were performed on radio frequencies that do not penetrate the Earth’s ionosphere. [NewYorkTimes 1920]
- ² This should be distinguished from the standard radio astronomy definition of gain, $G = \frac{A_e}{2k}$, usually given in units of K/Jy to provide a frequency-independent gain in units more appropriate for radio astronomers.
- ³ $Mpc = 10^6$ parsec (pc) = 3.1×10^{22} m.
- ⁴ The Nyquist sampling rate is equal to twice the sampled bandwidth for real valued data and equal to the bandwidth for complex valued data.
- ⁵ A spectrometer will also have a non-unity efficiency, typically of order 10% for an Echelle spectrograph, which will further reduce both the background and source rates.

11.4.1 INTRODUCTION

The remarkable discoveries in astrobiology in the last few decades, including extremophile life on Earth, ocean worlds such as Europa and Enceladus, and thousands of planets beyond our solar system, as well as ongoing programs searching for extraterrestrial intelligence, all raise an urgent question: what is the impact of discovering life beyond Earth on humanity? In this chapter, we discuss possible approaches to answering this question, as well as critical issues and potential impacts under a variety of discovery scenarios. The humanistic implications of astrobiology fall under the broad heading of astrobiology and society, a suite of issues raised already in NASA's first Astrobiology Roadmap (NASA 1998), elaborated in subsequent versions (NASA 2003; Des Marais et al. 2008), still present in its current Astrobiology Strategy document (Hays 2015), and recognized as well in other international documents that guide research in astrobiology (Horneck et al. 2006). In a more general sense, these humanistic questions are a subset of an important suite of issues in science and society. In the same way that social, ethical, and legal aspects are being studied for frontier areas of science and technology such as the Human Genome Project, nanotechnology, and artificial intelligence, the impact of the discovery of life beyond Earth deserves serious and systematic attention. Indeed, the World Economic Forum (2013) has declared the discovery of life beyond Earth as one of five X factors—emerging concerns for planet Earth of possible

future importance, but with unknown consequences. This research must be a combined effort encompassing the sciences, social sciences, and humanities and should become an integrated part of the astrobiological endeavor.

11.4.2 APPROACHES

At first thought, the problem of determining astrobiological impacts would seem to be intractable, and in one important sense, it is. We certainly cannot predict what the impacts will be, any more than we can predict with certainty other outcomes that involve human behavior. But this is no excuse: as in other areas such as economics, technology, and science, what we *can* do is provide guidelines for impact under certain scenarios by using systematic methods. In this section, we look at three approaches: history, discovery, and analogy, with the idea that these might be used to inform impact scenarios.

11.4.2.1 HISTORY

Numerous times in the last four centuries of telescopic astronomy, Earthlings believed that extraterrestrial life had been detected. Galileo's 1610 landmark telescopic lunar observations had barely been published when Kepler enthusiastically conjectured that one particularly circular crater must be an artificial construction of lunar inhabitants. Two centuries later, the famous "Moon Hoax" of 1835 placed lunarians on the Moon, supposedly based on the latest telescopic observations

of John Herschel. Sixty years further on, even as H. G. Wells was penning his *War of the Worlds*, the astronomer Percival Lowell argued that there were canals on Mars, built by a dying civilization managing its water resources. Though largely discredited by his death in 1916, the idea had not dimmed so much that when Orson Welles broadcast his radio version of *War of the Worlds* on Halloween eve, 1938, a considerable reaction ensued as some Americans believed that a real Martian invasion was underway. Thirty years later, when strange pulses were detected from the heavens (soon dubbed “pulsars”), astronomers briefly but seriously considered the “Little Green Men” hypothesis. Finally, in 1996, NASA announced that it had evidence of fossil life from Mars in the form of the now famous and infamous Mars rock dubbed ALH84001.

Each one of these episodes holds lessons (Dick 2018a), but perhaps, most relevant is the last and most recent: the reaction to the claimed discovery of nanofossils in the Mars rock ALH84001, discovered in the Antarctic in 1984. That episode reveals the public, media, and scientific reaction to even the most minimal claimed discovery: not a microbe or complex life or intelligence, but nanofossils so small that they could only be seen by a scanning electron microscope. From the time the rock was recognized as Martian in origin, almost 3 years of intense study had taken place before NASA scientists dared to make the announcement about potential fossil life in the summer of 1996 (McKay et al. 1996; Dick and Strick 2004). For fear of leaks, during that time, scientists at Johnson Space Center, where the work was being done, were circumspect about discussing their results even within NASA. By April 1996, they had enough confidence to submit an article to the prestigious journal *Science*, at which time NASA Headquarters began to play a role. The claim was closely held at the Headquarters’ level until mid-July, when peer review was complete and publication was scheduled for mid-August. On July 30, the NASA Administrator informed the White House, and NASA began receiving news inquiries on August 1. Although NASA had planned for the announcement to coincide with the publication of the *Science* article in mid-August, these news inquiries forced NASA to move the announcement forward to August 7. The timing of the announcement was also influenced by political events, since the Republican National Convention was scheduled to take place at about the time the announcement was originally scheduled.

In these days of social media, it is highly unlikely that such a discovery could be kept secret as long as the Mars rock claims were kept under wraps. And it is certain that political calculations will be factored into any decision to announce, or not announce. Already at the press conference, the claims were subject to skepticism from scientists. Within 5 weeks, Congressional hearings were held on life on Mars; within 4 months, symposia on the implications were being held, including a high-level meeting involving the vice president of the United States, the National Academy of Sciences, the NASA Administrator, and scholars from a wide array of disciplines. On the scale of months and years, the more technical and scholarly examination of the evidence and its

implications was carried out. The consensus today is that the putative nanofossils are not biogenic in origin, though some still hold to the original claim.

In short, the ALH84001 episode constitutes a real-life scenario of what might happen under even a minimal discovery scenario of fossilized life: reluctance about confirmation and announcement, attempts at secrecy whether because of uncertainty or competition, a media frenzy that would now be greatly accelerated by social media, scientific excitement and skepticism played out in the media, conferences and journals, the involvement of the government and high-level scientific institutions, and a general public clamoring for answers to one of the great questions of science—one with profound implications for humanity at the individual and global levels. While it is true the Mars rock announcement and subsequent events were relevant to a specific time, culture, and set of circumstances, in broad outline, these events are likely to be mimicked by any discovery of extraterrestrial life. The reaction of government institutions, the media, and the public will occur side by side with the reaction among scientists, who will subject the discovery to their exacting standards. Moreover, these events will likely take place over an extended period of time, a characteristic also reinforced by the nature of scientific discovery discussed in the next section. The point is that we can learn lessons from history: the study of this and other episodes of reaction to putative discoveries can inform what we might expect in the future, even if in the end it must be in the form of guidelines, not predictions.

11.4.2.2 DISCOVERY

The concept of discovery is important for at least two reasons when discussing the impact of astrobiology. First, the very nature of scientific discovery as a process provides insights into how the discovery of life beyond Earth and its consequences will play out; and second, the societal impact will very much depend on the discovery scenario. We therefore need to consider the nature of discovery and parse under what circumstances the discoveries may take place. The general question “What is the societal impact of discovering extraterrestrial life?” makes no sense unless we are talking about a specific discovery scenario and understand the nature of scientific discovery.

Contrary to common expectations, history shows that scientific discovery is far from the Eureka moment it is often thought to be. Rather, discovery is an extended process involving the efforts of many individuals across multiple stages of detection and interpretation, before true understanding finally dawns, perhaps years or decades later. “Discovery is a process and must take time,” scientist-philosopher Thomas Kuhn wrote already in 1962 in his famous *Structure of Scientific Revolutions*. In the half-century since Kuhn’s pronouncement (Kuhn 1962a, 1962b), scholars have repeatedly documented the truth of discovery’s extended and complex nature. It has been subjected to historical, psychological, and sociological analyses, and philosophers have parsed its conceptual meanings as well (Dick 2013). They have also insisted that discovery is not only a technical but also a social

process, involving real people with real emotions that have real effects on the final results—and their impacts on society.

The extended nature of discovery is evident, whether looking at the discovery of elementary particles such as the Higgs boson in physics, the elements in chemistry, or new classes of objects in astronomy, in short, in any area of science. To take only one example, in astronomy, Galileo is commonly credited with discovering the rings of Saturn. But when Galileo turned his telescope to Saturn on July 30, 1610, he was totally perplexed, thinking he had discovered some strange sort of satellite (van Helden 1974). It was only in March 1655 that Christiaan Huygens turned his large telescope toward Saturn and interpreted what Galileo had seen as handles or “anses” (we would say “rings”) that changed appearance depending on the angle of observation from Earth. Lacking knowledge of dynamics, Huygens in turn had no idea how such rings could physically exist and persist around Saturn. That understanding came only in the mid-nineteenth century, when James Clerk Maxwell provided a basic dynamical explanation. It would be most accurate to say that the full discovery of Saturn’s rings took centuries and that new discoveries about the rings continue to be made with spacecraft such as Cassini. The same can be said of comets, exoplanets, supernovae, spiral galaxies, or any of the other 82 classes of astronomical objects that have been identified (Dick 2013). Extended discovery applies as well to phenomena such as the expansion of the universe, the discovery of radio waves, and the three-degree cosmic background radiation. The discovery of extraterrestrial life will be no exception.

Moreover, the history of discovery indicates that there is very often a pre-discovery phase, during which the true nature of an object, signal, or phenomenon goes unrecognized or unreported or during which theory only indicates that the phenomenon *should* exist. This is true not only for pre-telescopic astronomy and pre-microscopic biology, but also after these technologies have reached advanced stages. We are perhaps not surprised that Galileo did not recognize his observations of the apparent protuberances of Saturn as rings or that the intriguing nebulous objects in the sky were not known to be external galaxies until the twentieth century. But the same is true today, as objects are not immediately recognized for what they truly are, or are theorized long before they are found (think black holes). The phenomenon of life beyond Earth is still in a pre-discovery phase. Whether anything has been observed that turns out to be an indication of life, or life itself, remains to be seen. The pre-discovery phase is bookended on the other side of discovery by a post-discovery phase, including short-term reaction and long-term impact. As seen in the Mars rock episode described previously, in this final phase, the media will play a crucial role, with all the complex interactions with scientists, government, and the general public.

The discovery of extraterrestrial life, whether microbial in our solar system or intelligent in our galaxy, will therefore be an extended process, with the general structure displayed in Figure 11.4.1. As in other astronomical discoveries, discovery will likely be preceded by a pre-discovery phase, in which the microbe, biosignature, or electromagnetic signal is at first

The Anatomy of Discovery: An Extended Process

FIGURE 11.4.1 The extended structure of discovery, showing its three stages of detection, interpretation, and basic understanding, as well as pre-discovery and post-discovery phases. Discovery also has a microstructure consisting of conceptual, technical, and social roles.

not recognized as extraterrestrial life. The discovery will then go through phases of detection and interpretation before understanding is achieved. These phases could be long or short, depending on the evidence, and might result in success or failure. How society reacts to the discovery will be affected by its extended nature, as evidence is presented, interpreted, and understood. This basic structure of discovery is essential to any understanding of its impact.

Just as essential is the insight that the reaction to the discovery of alien life in the post-discovery phase will be very much scenario-dependent. Table 11.4.1 summarizes possible discovery scenarios, showing direct and indirect encounters in terrestrial and extraterrestrial environments. In other words, we could encounter life *directly* here on Earth or in space, and we could find life *indirectly* here on Earth or in space. Indirect

TABLE 11.4.1
Discovery Scenarios for Contact with Extraterrestrial Life

	Terrestrial	Extraterrestrial
Direct	Encounter type 1 Accidental contamination by sample or astronaut return Panspermia or interplanetary matter transfer (ALH 84001) Alien space exploration UFOs	Encounter type 2 Human space exploration
Indirect	Encounter type 4 Shadow alien biosphere Unknown alien microbes Earth orbit or vicinity Artifact on Earth or vicinity	Encounter type 3 Robotic space exploration (Viking, Europa probes, etc) Biosignatures SETI—radio and Electromagnetic (EM) Spectrum Artifact in space

extraterrestrial contact—labeled encounter type 3 in [Table 11.4.1](#)—is where most of the action is found today, in the form of spacecraft observations, the detection of biosignatures on exoplanets, and search for extraterrestrial intelligence (SETI) programs. Direct encounters of types 1 (terrestrial) and 2 (extraterrestrial) are the most unlikely to occur in the near future, because they imply alien spaceflight to Earth or human spaceflight beyond the solar system. Unidentified flying objects (UFOs) as extraterrestrial spaceships remain a logical possibility, dependent on evidence, which is not yet very strong. A type 3 indirect encounter is the most likely, or at least the most anticipated, scenario, since remote detection of microbes beyond Earth by robotic space exploration is one of the main goals of NASA’s astrobiology program, the search for biosignatures is an active research goal, and several SETI programs are in progress. A type 4 encounter raises interesting possibilities not often discussed, including the discovery of an alien artifact on Earth or its vicinity. In its static form, [Table 11.4.1](#) lays out scenarios, but in its dynamic form, proceeding clockwise from encounter types 1 to 4, it arguably depicts impacts from their strongest to their weakest.

Each of these scenarios have triggered a large number of science fiction novels, beginning substantially with H. G. Wells’ *War of the Worlds* more than a century ago, accelerating in the second half of the twentieth century with the rise of the Space Age and continuing unabated today, in prototype novels and movies such as Arthur C. Clarke’s *2001: A Space Odyssey*, Carl Sagan’s *Contact*, and Stanislaw Lem’s *Solaris*. The best of science fiction literature lays out thoughtful scenarios about discovery and possible impacts, and this should not be forgotten as a source of ideas. In the more sober analysis of impacts, not only science but also numerous disciplines beyond science must become involved. Much more could be said about the nature of discovery and discovery scenarios for extraterrestrial life. Suffice to say here that it will be a large and daunting research project. But the essential point is that the reaction will be extended and will very much depend on the scenario.

11.4.2.3 ANALOGY

Analogy represents a third approach to studying the impact of discovering life beyond Earth. Far from its reputation as a “fuzzy way of thinking,” many scholars now see analogy as an essential and omnipresent mode of reasoning (Hesse 1966; Hofstadter 2001; Bartha 2010; Hofstadter and Sander 2013). Analogy has been defined as “a structural or functional similarity between two domains of knowledge,” more precisely “a mapping of knowledge from one domain (the base) into another (the target) such that a system of relations that holds among the base objects also holds among the target objects” (Gentner and Jeziorski 1993). At its best, analogy is a cognitive mechanism that allows us to learn and solve problems by drawing a map from the known to the unknown. In a broader sense, analogical reasoning is helpful in discovering, developing, explaining, or evaluating scientific theories. As philosopher Vidal (2014) summarizes its potential, “such reasoning enables us to propose new hypotheses, and thus discover new

phenomena. These new hypotheses trigger us to develop new experiments and theories.” All researchers on analogy caution that analogy is not a proof but a heuristic, a method that can serve and has served as an aid to learning and discovery. They also caution that the relation between any two systems needs to be examined in detail before an analogy or disanalogy can be tested. Scholars have also offered principles of analogical reasoning meant to avoid its many pitfalls; these principles include the structural consistency of what is being compared, the depth of any relation, avoidance of mixed analogies, and the realization that analogy is not causation (Gentner and Jeziorski 1993).

Four analogies, corresponding to different discovery scenarios and timescales, serve to illustrate the usefulness of this approach: the microbe analogy, the culture contact analogy, the transmission/translation analogy, and the worldview analogy. Because the discovery of microbes beyond Earth in any form potentially represents a revolution in biology, analogical candidates might include revolutionary ideas such as Darwinian evolution by natural selection, the role of DNA in genetics, and the discovery of extremophile microorganisms. But perhaps, no biological discovery closer approximates the potential fallout than the discovery of terrestrial microbes themselves, representing a new world of life on Earth, the microcosmos (Margulis and Sagan 1986). While Robert Hooke’s and Antony van Leeuwenhoek’s discovery of microbes in the second half of the seventeenth century excited considerable interest among both scientists and the public, they led nowhere during the lifetime of Hooke or Leeuwenhoek and for several generations thereafter (Gest 2004). Once microscopes had been considerably improved, however, the impact was swift and profound, spinning off the field of bacteriology. Today, the discovery of the microcosmos has greatly enlarged our view of life, carrying what had been a macro-science into the domain of the very small. Three centuries after Hooke and Leeuwenhoek, microbes once again radically changed biologist’s view of life with the discovery of extremophiles, micro-organisms functioning under conditions far beyond what had been considered the limits of life on Earth. These discoveries in turn led to something even more surprising—a complete reclassification of life (Sapp 2009). Surely, the discovery of life beyond Earth would do the same. A detailed look at this analogy and others may provide a more robust guide to the potential reaction to the discovery of microbes beyond Earth, taking into account the many cultural differences that now exist.

A very different scenario—the discovery of extraterrestrial intelligence—raises a very different set of analogies involving culture contacts. Again, one must distinguish between direct and indirect contacts. History abounds with direct contacts between cultures, usually with unhappy effects. The Western mind naturally goes to analogies such as the disastrous European contact with the Aztecs and Incas as part of the sixteenth-century Age of Discovery (Elliott 2006). But outside the tradition of Western expansionism, the less well-known great voyages of the fifteenth-century Ming China treasure fleets 50 years before Columbus, led by Admiral Zheng He, offer a very different scenario.

In contrast to the case of Cortes and the Aztecs, Chinese culture contacts resulted in new embassies in the Near East, deification (to this day) of Zheng He and his cult in South-East Asia, and the publication of works enlarging Chinese knowledge of the oceans and landmasses visited (Dreyer 2007). The point is that there are other models of culture contact than the destructive ones usually cited, including Jesuit models of culture contact that were not disastrous. Hoerder (2002) documents hundreds of culture contacts over the last thousand years; the sixteenth-century European exploits cover only a few of the book's 800 pages. Moreover, the contacts were arguably an equal mix of good, bad, and indifferent. Today, culture contacts under the name of globalism are also such a mix, as were the culture contacts in the first era of globalization dating from the fifteenth to the twelfth century BC in the Aegean, Egypt, and Near Eastern civilizations (Cline 2004). While it is understandable for Westerners to focus on our own recent history from the Age of Discovery, to use the Aztecs and Incas as the sole or chief analogies for contact with extraterrestrial intelligence is to ignore the bulk of history. While we cannot draw definitive conclusions even based on a small sample of culture contacts, an analysis by historians and anthropologists of characteristics common to all culture contacts is a respectable research program that could pay significant dividends. Beyond physical culture clashes, these contacts illustrate the difficulties among cultures of communication and even grasping certain concepts such as the “soul” and “immortality” (Kuznicki 2011).

A third analogy for the discovery of life beyond Earth is the “decipherment/translation” analogy (Dick 1995; Finney and Bentley 2014). If, as is widely assumed, first contact with intelligence beyond Earth turns out to be indirect, in the form of an electromagnetic signal that is deciphered with significant information transmitted, the flow of information between civilizations across time is a more appropriate analog. Particularly compelling is the transmission of Greek knowledge to the Latin West by way of the Arabs in the twelfth and thirteenth centuries, only one example of what Arnold Toynbee (1957) has called in the terrestrial context “encounters between civilizations in time.” Others have pointed out that a better analogy might be decipherment of the Mayan glyphs, since we will not know the alien language (Finney and Bentley 2014). The two analogies might profitably be combined into a more robust decipherment/translation analogy, since both are likely to be phases in the same process.

Even if an extraterrestrial message is not deciphered, and perhaps even in the case that “only” microbial life is discovered constituting a second genesis, a change in worldview would likely gradually take place. In the long term, the discovery of microbial or intelligent life beyond Earth might be analogous to grand changes in scientific worldviews, exemplified in the Copernican worldview originated in the sixteenth century, the Darwinian worldview of the nineteenth century, or the Shapley-Hubble worldview of the galactic universe in the twentieth century. The gradual construction of worldviews, and their influence on our thinking, is a deep philosophical problem requiring more research (Vidal 2007, 2014). The impact of scientific worldviews has been studied

extensively (Smith 1982; Blumenberg 1987; Bowler 1989), and the rich literature on worldviews cannot help but illuminate the problem of the impact of discovering extraterrestrial life.

Despite the obvious need for caution and the lack of predictive value, analogies can indeed serve as solid guidelines to cosmic encounters with alien life. In sorting good analogies from bad, the guiding principle should be what I call the “Goldilocks principle of Analogy”: *Analogy must not be so general as to be meaningless, nor so specific as to be misleading. The middle “Goldilocks” ground is where analogies may serve as useful guideposts.* On the one hand, it does little good to argue that both science and religion are searching for our place in the universe, when one addresses the natural world and the other invokes the supernatural—differences so great as to swamp any comparison whatsoever. And it does little good to argue that because there is life on Earth, there is life out there—the very thing we seek to demonstrate. On the other hand, it is hopelessly naïve to expect that contact with extraterrestrial intelligence will change our worldviews in ways precisely mirroring past discoveries, culture contacts, decipherment efforts, or revolutions in thought, leading us to reiterate that under no circumstances will analogy predict the future.

11.4.3 CRITICAL ISSUES

In order to address seriously the impact of astrobiology, we must not assume that life beyond Earth will be similar to ours, whether microbial or intelligent. Nor when it comes to SETI strategy can we assume that human knowledge is universal, even in the realm of mathematics and science. Envisioning impact requires us to act locally but think universally. In this section, we address some of these issues to indicate how important it is to take these problems into account if we are going to discover life and deal with its impact in a realistic way.

11.4.3.1 TRANSCENDING ANTHROPOCENTRISM

Transcending anthropocentrism is easily recognized as an important issue. But how do we move beyond our own preconceptions and “get out of our heads” to study concepts in astrobiology that are perhaps entirely divorced from our everyday experience on Earth? The question is far from academic and indeed becomes very practical when searches for extraterrestrial life and intelligence require a specific idea of the object of the search. The 100-million-dollar Viking Mars lander biology package could not have been built without some specific strategy and technology to search for a preconceived type of life (in this case life that metabolizes). Search for extraterrestrial intelligence (SETI) and messaging extra-terrestrial intelligence (METI) programs assume a certain mode of intelligence that involves technology, usually technology that will reveal itself in the electromagnetic spectrum. High technology in turn assumes a culture and civilization sophisticated enough to produce it, which assumes in turn that aliens have a social organization in some way similar to ours.

And communication with such intelligence makes assumptions about technology, language, metaphysics, universals, and the nature of knowledge. Our conception of life and intelligence, culture and civilization, and technology and communication are exemplars of foundational concepts that need to be critically examined in an extraterrestrial context.

Among the most basic concepts is life itself. Attempts to define life have a long and checkered history, with some concluding that such a definition is impossible in the absence of a general theory of living systems (Cleland and Chyba 2007) and others arguing that this is definitional pessimism (Smith 2016). These conclusions are important but theoretical. A more practical way forward is to begin with life on Earth and speculate how life beyond Earth might differ in specific respects, especially in its biochemical scaffolding, genetics, solvents, and metabolism. One widely accepted definition of life is a “self-sustaining chemical system capable of Darwinian evolution,” where Darwinian evolution at the molecular level refers to descent with modification by natural selection in a replicating genetic system such as RNA or DNA on Earth (Joyce 1994). The “scaffolding” for this replication system on Earth is based on carbon, hydrogen, oxygen, and nitrogen (CHON), with carbon as the anchor and water as the solvent. But what if the environmentally available biochemical scaffolding is silicon or ammonia? What if the genetic system involves proteins instead of DNA? And what if the solvent is nitrogen or methane? All of these possibilities have been considered, with conclusions that are still controversial (Bains 2004; Ward and Benner 2007).

Moreover, with the decades-ago discovery of microbes thriving under extreme conditions of temperature, pressure, acidity, radioactivity, and other parameters, our conception of the environment in which life might emerge has significantly broadened. New views of the diversity of metabolism, such as chemosynthetic ecosystems like hydrothermal vents deep in the ocean, have broadened our conceptions of life even more.

These questions regarding the origin and evolution of life are multiplied when it comes to the evolution and nature of intelligence. Our usual concept of intelligence in the context of SETI is dominated by the Drake paradigm, whose central icon is the Drake equation, including the crucial term representing the fraction of planets on which intelligence arises (Vakoch and Dowd 2015). Because the equation goes on to winnow this down to the number of technologically communicative civilizations, we normally think of intelligence as an entity that can conceive and build the requisite technology for such communication. This, however, is a very restricted concept of intelligence, even if a practical one in terms of our ability to detect it. In short, at the outset, we need to distinguish intelligence from technologically communicative intelligence.

The difficulties with the slippery concept of intelligence are immediately revealed by posing the simple question “when did intelligence arise on Earth?” Even if posed to biological or paleontological experts, the answers would wildly diverge, because the story of the evolution of intelligence on Earth depends entirely on how broadly one defines intelligence. Is it hominid intelligence, mammalian intelligence, or some earlier

ancestor that is the first “real” intelligence? The only reasonable answer is that there was no one day, year, or even period in the history of life where intelligence was lacking and then suddenly it appeared. Because it is not a binary choice, it follows that there was no one life-form that suddenly possessed the quality we call intelligence. It was part of the evolutionary process, just as physical morphology was part of that process; indeed, the two are inextricably intertwined (Marino 2015).

Such an expansive concept of intelligence opens the way to much broader investigations. While most research has focused on the evolution of intelligence in hominids on Earth over the last 5 to 7 million years, for astrobiology, the evolution of intelligence in a more general sense is of primary importance. Here, broader definitions of intelligence apply, such as “the ability to respond flexibly and successfully to one’s environment and to learn from experience,” or, put another way, “the ability to respond with an appropriate behavior in a given context” (Bogonovich 2011; Rospars 2013). Such broad definitions clearly apply to a wide range of animals. Accordingly, research has been undertaken, especially on dolphins and other mammals, and has even extended to cephalopods such as octopuses. Issues such as dolphin communication, brain encephalization, convergent brain evolution, and progressive trends in the history of life have all been studied in the context of astrobiology. By some definitions, there is a good deal of consensus that the higher primates and some cetaceans such as dolphins and whales share some of our reasoning abilities.

Thus, the landscapes of life and intelligence may extend far beyond our normal anthropocentric views of terrestrial life. Table 11.4.2 summarizes some general principles for life, namely biochemistry, morphology, and cognitive capacity, all of which may operate through evolution according to physical conditions much broader than we now realize, just as the extremophiles on Earth have expanded our view of the possibilities of life. In addition to taking into account the scaffolding, genetic material, and solvents available at any given location, for more complex life, we need to consider body patterns in terms of size, shape, and mass such as

TABLE 11.4.2
Principles for Possible Types of Life Beyond Earth

Mathematics	Consciousness
Sense of time	Cognition
	Biological intelligence
	Postbiological intelligence
	Collective “Hive” or “Swarm” intelligence

originated in the Cambrian explosion, all closely associated with issues of chance, necessity, and evolutionary convergence. For intelligence, we need to consider scientific issues about what constitutes intelligence, as well as age-old philosophical issues of mind, body, and consciousness, and again issues of convergence.

Arguably, we should think even further out of the box of intelligence by emphasizing that the universe may be postbiological, given the timescales involved (Dick 2003; Schneider 2015). The key realization here is that cultural evolution is not often taken seriously enough in imagining what extraterrestrial intelligence might be like. Beyond extrapolations from Earth (Moravec 1988; Kurzweil 2005), there are evolutionary reasons for believing the universe may already have transitioned from biologicals to postbiologicals, possibly in the form of artificial intelligence. I have formalized this concept in what I call the Intelligence Principle: *The maintenance, improvement and perpetuation of knowledge and intelligence is the central driving force of cultural evolution, and to the extent intelligence can be improved, it will be improved.* Failure to do so may cause cultural evolution to cease to exist in the presence of competing forces (Dick 2003). **Table 11.4.2** also lists another form of intelligence sometimes associated with social insects, a collective or distributed form often known as hive, or swarm intelligence. Finally, **Table 11.4.2** lists “space-time filters” as one of the principles for cognitive life. We discuss this in the next section on the universality of knowledge.

In the same way, our concepts of life and intelligence should be scrutinized and our ideas of culture, civilization, technology and communication should be subjected to critical analysis, with an eye toward what is universal and what is contingent. Are there cultural universals? (Ashkenazi 2017; Traphagan 2015). Does technology converge? (Basalla 2006). Would aliens communicate in the same way as we do? (Traphagan 2011, 2015; Vakoch 2011). Tackling these questions is a serious task for historians, anthropologists, and the social sciences, and these issues have sometimes already been addressed in fields such as the philosophy of technology (Kelly 2010) and the philosophy of the social sciences (Rosenberg 2016). This is not an academic exercise but an effort that will increase our chances of discovering life and evaluating its impact.

11.4.3.2 THE UNIVERSALITY OF HUMAN KNOWLEDGE

The contemplation of extraterrestrial intelligence almost immediately raises an even broader set of questions about the validity and universality of human knowledge itself. The crucial question is how much of our knowledge—especially our seemingly “objective” natural science and mathematics—is contingent on the history of evolution on planet Earth and how much is universal? Even more problematic is: would our approaches to the social sciences and humanities—the “human sciences”—be recognizable to aliens? These questions inform two practical matters: how much of our knowledge would actually be useful in assessing the alien

in the event of a discovery? And how might our knowledge be universalized if we find life beyond Earth, in the sense of placing our possibly parochial ideas in a much broader and perhaps more objective context?

In asking whether human knowledge, in general, is universal, we can draw on research from at least three fields: philosophy of knowledge, cognitive science, and evolutionary biology. The philosophy of knowledge, also known as epistemology in one of its many aspects, normally proceeds with a discussion of the relative merits of the schools of rationalism and empiricism, realism and idealism, and their variations and elaborations by philosophers over time. Most relevant here is the eighteenth-century German philosopher Immanuel Kant, who posited a category of knowledge he termed synthetic *a priori* judgments (Kuehn 2002). He claimed that these judgments, which include mathematics, geometry, and God, depend on our cognitive apparatus, so that these claims are about reality “only as it is experienced by beings such as we are... these claims cannot be claims about the world as it is independent of our conceptual apparatus.” In other words, in Kant’s view, our experiential knowledge must first pass through a set of *a priori* “forms” or filters. Space and time (**Table 11.4.2**) are forms of our “sensibilities,” without which we cannot view the world of our experience. They are objective for us but not for all beings. While few philosophers today would accept the details of Kant’s epistemology, almost all would endorse his conclusion that our knowledge of the external world is compromised by the human filters through which our perceptions must pass. In short, just as in the sixteenth century, Copernicus placed the Sun in the center of the world rather than the Earth, already, in the eighteenth century, Kant placed the human mind at the center of reality only *as we perceive it*. So, the human mind may not be the center of reality, as perceived by extraterrestrials.

Cognitive science brings to bear on the problem of universal knowledge disciplines such as neuroscience, animal cognition, and artificial intelligence in an attempt to understand the nature of the human mind. The idea of embodied cognition (Lakoff 2003) proposes that cognition is evolutionarily related to the body it inhabits, a claim that seems to be validated by some studies in animal cognition (Griffin 2001). Such embodied cognition in turn relates directly to knowledge in the epistemological sense of how we know things. When extended to extraterrestrials, David Dunér has coined the term “astrocognition” to study the origin and evolution of cognitive abilities in extraterrestrial environments, as well as a variety of other issues related to space (Dunér 2011, 2013). In the context of the evolution of cognition, the basic premise is that cognitive abilities are adapted to “the physical and biological environment of their celestial body in order to understand and interpret, interact and deal with, and orientate itself in the particular physical and biological environment, in relation to its specific conditions.” Embodied cognition and its extension to astrocognition are also in keeping with the similar idea of “situated cognition.” Thus, an argument can be made that the search for intelligence beyond Earth is meaningless, unless we understand the underlying cognitive basis of intelligence.

If the body shapes mind, it also shapes thought, and extraterrestrials will have knowledge of the external world very different from us—just as Kant suspected on different grounds. Whatever term is used, whether embodied mind theory, situated cognition, or astrocognition, this is a field wide open for future development based on real data.

Finally, evolutionary biology, along with everything else it encompasses, sheds light on the evolution of the mind. Whereas embodied mind theory states that cognition depends on the body in which it is embedded, evolutionary epistemology now claims that since the body is a product of evolution and cognition is related to the body, cognition will also depend on the environment in which it evolves. In the words of philosopher of biology Michael Ruse (1998), it means “taking Darwin seriously,” not only for biology but also for all of its by-products. In this view, all the tools of evolutionary biology not only can but must be applied to cognition, and epistemology itself is a product of evolution. Epistemology without evolution is seen as bankrupt. The evolution of cognitive processes during the long history of life on Earth can now be studied. Just as some see evolutionary biology as the starting point for an entire suite of cultural evolution, possibilities such as evolutionary psychology—the commonsense but controversial idea that our psychology and behavior have evolved over time according to natural selection—so also for epistemology.

The implications of evolutionary epistemology for astrobiology are clear: as an evolutionary product of its environment, not only the mind but also its ways of knowing will be different, depending on the long history of life under any given planetary conditions. Whether Kant or embodied cognition or the extension of evolutionary biology, the conclusion is the same for extraterrestrials: if all minds are embodied and Darwinian factors are at work in epistemology, then it is at least possible that our knowledge is not their knowledge, our science is not their science, and our mathematics is not their mathematics.

Science and mathematics are good tests for our ideas of the universality of human knowledge, since most people would consider them the most objective and universal aspects of all our knowledge. But even their objectivity has been called into question. The philosopher Rescher (1985), for example, has emphasized the potential diversity of science in a universal context: the *mathematics* used for alien science might be very different; the *orientation* of alien science might be different in the sense that any particular extraterrestrial intelligence might concentrate on social science rather than natural science, or their natural science might be very different; and the alien *conceptualization* of science might be different, embracing radically different cognitive points of view, just as our conceptual apparatus (think relativity and quantum mechanics) is radically different from a century ago.

While we can easily see why an Earth-bound and locally invented system like theology might not be the same among extraterrestrials as among Earthlings—diverse as theologies are even here on Earth—the non-universality of science and mathematics is a more difficult pill to swallow. But the

philosophy of knowledge, cognitive science, and evolutionary biology all suggest the same conclusion: the different cognitive structures bound to exist among extraterrestrials leave open the real possibility that human knowledge, including even science and mathematics, might not be the same as theirs. And these differences might be enough to affect SETI programs in terms of both discovery and communications—perhaps another solution of the Fermi paradox of why we have not yet found extraterrestrials, and perhaps cannot, unless we find a way to transcend our anthropocentrism.

11.4.3.3 ENVISIONING IMPACT

Another critical issue is how to frame the societal impact of discovering of life beyond Earth, who should be involved in this framing, and how to make it systematic rather than sporadic. The question of impact has received increasing attention in the last two decades, since John Billingham, the head of NASA’s SETI program at the time, convened a series of workshops on “The Cultural Aspects of SETI” (CASETI) on the eve of the inauguration of NASA SETI observations in 1992 (Billingham et al. 1999). For its time, this was an admirable effort, and the following decades saw additional sporadic efforts, both individual and in group settings. During the formulation and initiation of the first Astrobiology Roadmap in 1998 (Des Marais et al. 2008), calls were made for the study of cultural impacts of astrobiology (Dick 2000a), and in 1999, NASA Ames Research Center organized a workshop on the societal implications of astrobiology (Harrison and Connell 2001). Other organizations, including the John Templeton Foundation and the Foundation for the Future, organized meetings on the subject at about the same time (Dick 2000b; Harrison and Dick 2000; Tough 2000). Interest has increased in the last decade, notably with the American Association for the Advancement of Science (AAAS) series of workshops sponsored by its program on Dialogue on Science, Ethics, and Religion (Bertka 2009); several meetings at the Royal Society of London (Dominik and Zarnecki 2011); and a series of sessions at the American Anthropological Association (Vakoch 2009). While most of the attention has focused on the impact of the discovery of extraterrestrial intelligence, the AAAS volume also addresses the quite different scenario of the impact of discovery of microbial life. Race et al. (2012) has taken the lead in marshalling the astrobiology, social sciences, and humanities communities to address these issues in the context of the Astrobiology Roadmap, with the support of the NASA Astrobiology Institute. NASA has also advanced the study of the humanistic aspects of astrobiology by establishing the Baruch S. Blumberg NASA/Library of Congress Chair in Astrobiology, which held an international symposium on the impact of astrobiology at the Library of Congress in 2014 (Dick 2015). Individual efforts have also concentrated on different aspects of the problem (Davies 1995; Harrison 1997; Achenbach 1999; Harrison and Dick 2000; Michaud 2007; Impey et al. 2013; Vakoch 2013; Dick 2015, 2018b; Race 2015), including a comparison to the impact of other scientific endeavors such as biotechnology (Race 2007).

The results of these studies have been to demonstrate the serious impact that the discovery of extraterrestrial life could have on society, especially in the case of extraterrestrial intelligence. There is no consensus among these disparate studies. What is needed is a general framework within which these studies might be incorporated. One such framework was suggested almost a half-century ago in the much broader context of the impact of science and technology (Ladrière 1977), though it has received little attention. In the most basic sense, just as we have distinguished pre-discovery, discovery, and post-discovery stages in the discovery process, the Belgian philosopher and scientist Jean Ladrière demonstrated that we should distinguish pre-impact, impact, and post-impact phases, making explicit the simple but undeniable fact that any impact scenario consists of a past, present, and future. Before impact, a certain set of assumptions, ideas, and values (we would also say worldviews) is in place. These are then in flux for an extended period, before the assimilation of new assumptions, ideas, and values is completed. During this period of flux, reinforcing and competing worldviews are also in play. In Ladrière's rather unwieldy terminology, the process of impact involves a "destruction" phase, during which the old order is torn down, and a "reconstruction" phase, during which the new order is built up. We refer to these simply as deconstructing and restructuring stages, each of which will have political, economic, and cultural components (Table 11.4.3).

During the deconstructing phase, a new discovery of large-enough magnitude affects all three components of society (political, economic, and cultural) and either challenges or confirms them. This is followed by growing acceptance of the new information and its implications for the future, which feeds into society's values and meanings. Finally, a new idea of the future is established, a future that may be rich in possibility and transformable by human activity or, alternatively, threatening and out of our control. In short, a critical mass of novelty is reached, bursting with potential that begs to be

TABLE 11.4.3
The Anatomy of Impact

Impact	Pre-Impact	Established assumptions, ideas, and values	
	Impact	Destructuring phase (Disruption of cultural elements)	Political economic cultural proportional to magnitude of discovery
		<ul style="list-style-type: none"> • Challenge or confirm values • Growing acceptance • New vision of future Restructuring phase (Rebuilding cultural elements) <ul style="list-style-type: none"> • Acceptance or rejection of new elements • Criticism and move toward resolution • Unity of vision restored 	
Post-impact		Acceptance of new assumptions, ideas, and values	Over decades and centuries

reintegrated. This triggers the restructuring phase, in which there is a reintegration and reunification of culture and its subsystems based on the new meanings and values. Some aspects of culture may accept the new system of values and meanings, while others reject it. This is followed by criticism and resolution of conflicting views. And finally, in the post-impact, there is restoration of a unity of vision—to the extent that such unity can ever exist in a multicultural world.

The Jesuit astronomer Stoeger (1996) has proposed that Ladrière's ideas may be useful as a way of understanding astronomy's impact on culture. This seemingly simple schema of deconstructing and restructuring, which may apply to large and small impacts over the long and short terms, also provides a potentially powerful framework within which we can discuss the impact of discovering life beyond Earth under whatever scenario. It resonates with the rise and fall of worldviews that we will discuss in the next chapter, including stages in worldview development ranging from presentation based on observation to elaboration, opposition, exploration of implications outside the field, general acceptance, and final confirmation. It also parallels in some ways Thomas Kuhn's paradigms, though the latter are now so laden with baggage that it is perhaps best to avoid the complications of that comparison. Finally, the deconstructing and restructuring process is arguably inherent at a very practical level in the long-term cycles of the global world order (Kissinger 2014). It is obviously an idealized view, bound to be complicated by the messiness of human behavior, not to mention the problem of overlapping discoveries.

11.4.4 SOCIETAL IMPACTS OF DISCOVERING EXTRATERRESTRIAL INTELLIGENCE

In this section, we explore possible impacts on humanity of finding life beyond Earth, using the concept of worldviews as our framework (Vidal 2014). For our purposes here, we use worldview in the sense of the German *Weltanschauung*, defined as how we see the world from a variety of perspectives and carrying with it the implication that worldviews have impact on our daily lives. Each of us sees the world in a different way; our individual worldviews are a mix of political, cultural, religious, philosophical, and scientific components, among others. Given this framework, our task of exploring the impact of discovering life beyond Earth then becomes an exploration of its impact on current worldviews and the generation of new worldviews. The three worldview levels in Figure 11.4.2 thus provide the organizing principle for this section: the cosmological, the theological, and the cultural.

11.4.4.1 COSMOLOGICAL WORLDVIEWS: THE RISE OF THE BIOLOGICAL UNIVERSE

Cosmological worldviews have always affected the human mind. The ordered geocentric universe in Dante's *Divine Comedy*, with its moral lessons played out in a cosmological worldview of nested spheres, with the Earth at the center and

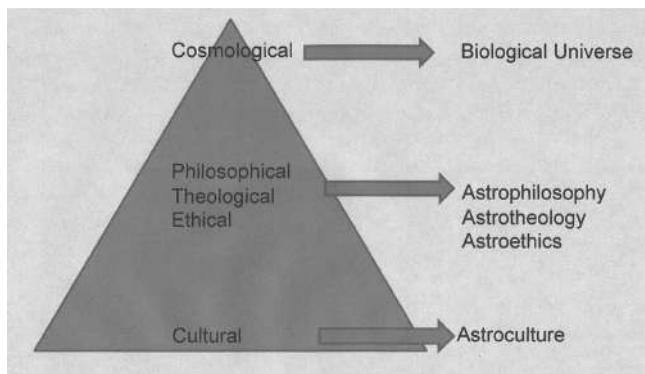

FIGURE 11.4.2 A hierarchy of worldviews, in which cosmological worldviews trickle down and profoundly affect various levels of human culture. The discovery of life beyond Earth may result in a transition from our current physical cosmology to one based on a biological universe. Philosophical, religious, and ethical worldviews may be generalized and transformed into astrophilosophy, astrotheology, and astroethics. And the transformation of human culture to astroculture may be accelerated beyond the initial thrust of the Space Age.

the sphere of fixed stars at the periphery, provided the backdrop for medieval life. The heliocentric universe upended that framework, prompting John Donne to say that “Tis all in peeces, all cohaerence gone.” We are now at a turning point similar to that of the sixteenth and seventeenth centuries. Over the last four centuries since Copernicus, the idea of a purely physical universe has gradually given way to the idea of a universe filled with life, what I have termed “the biological universe” (Dick 1996). Those championing this idea hold that planetary systems are common; that wherever conditions are favorable, life will originate and evolve, and in its strongest form; and that this evolution will likely culminate in intelligence. In its most robust form, the biological universe makes claims about the large-scale nature of the universe, especially that life is one of its basic properties. It is therefore more than an idea, more than another theory or hypothesis. It is sufficiently fundamental and comprehensive to qualify as a worldview of its own, one that has implications for all humanity. Moreover, because it is testable, it is a scientific worldview, perhaps best described as a cosmology. And because it combines the biological with the physical, it may accurately be termed “the biophysical cosmology” (Dick 1989).

The potential impact of this biological universe is best approached by distinguishing several possibilities. As many scientists have argued, it is entirely possible that the universe is full of microbes but lacks complex life or intelligence. Such a *microbial biological universe* would be a fundamental discovery in the history of science. If found to be of independent origin, the discovery of such microbes would open the possibility of a universal biology in the same way we now believe we have a universal physics. It is tempting to say that the impact of a microbial biological universe would be primarily scientific. But the reaction in 1996, when nanofossils were claimed in the Mars rock ALH84001, clearly indicates that the impact will be much broader than that, at least over the

short term. If microbial life is common, it may indicate that, given enough time as we have had on Earth, intelligence may develop. But the discovery of microbial life in itself would be the greatest discovery in the history of science.

An *intelligent biological universe* is one where intelligent life is a common feature. We can argue about the meaning of “common,” or in its reverse “rare Earth,” formulation, about the meaning of “rare” (Ward and Brownlee 2000). But in a universe so large that even if one in a million planets have intelligence, millions of planets with intelligence would still occur even in our own galaxy, the semantic argument over the definition of common or rare does seem rather pointless. More urgent is a discussion of what it means to be sentient, intelligent, or superintelligent (Bostrom 2014); what interaction with such entities implies in terms of ethical standards; and, beyond that, what issues of law and diplomacy might be expanded into space law and metalaw (Haley 1963).

The *anthropic biological universe* holds that life and mind are intimately connected with the physical universe (Barrow and Tipler 1986). The physical and biological universes that are obviously already connected in the sense biology cannot exist without a prior physical substrate. But scientists and philosophers alike are increasingly aware of possible deep connections between the physical universe of planets, stars, and galaxies and the biological universe of life, mind, and intelligence. The more we learn about the universe, the more we find that it is even more mysterious than we thought—that the universe is not only subject to mathematical laws, but also finely tuned for life. In its deepest structure and most fundamental properties such as the physical constants, the universe seems tailor-made for life. Or, to put it another way, the universe is “biofriendly,” as witnessed by our existence and the possible existence of other life beyond Earth (Davies 2007).

The microbial, intelligent, and anthropic versions of the biological universe, and the postbiological universe as well, each represents different worldviews with different implications for humanity. They can also be viewed in terms of human destiny, usually seen in theological terms, but also in more secular terms. In a microbial biological universe, aside from its scientific value, we may be dealing primarily with the instrumental rather than intrinsic value of life. Instrumental value in this case implies that humans might be mainly interested in the utility of extraterrestrial microbes for medicines and other purposes, just as has been the case with newly discovered extremophile organisms on Earth. That would be a subject of major ethical and practical discussion. In such a microbial biological universe, human destiny would be to explore the universe as the Lords of creation—at least until sentience or intelligence was discovered near or far.

In an intelligent biological universe, by contrast, human destiny is to interact with extraterrestrials, whether in struggle or to join the galactic club. This is the stuff of science fiction, but in case of an actual discovery, it would very quickly become a practical problem. As we have emphasized earlier, the outcome would very much depend on the scenario. In an anthropic biological universe, the questions turn more to the philosophical. The obvious question is why is the universe so

biofriendly? Could it be just a coincidence? For most people who have thought deeply about the problem, this seems too good to be true. Could it be that a supernatural intelligence fine-tuned the universe, the God hypothesis? Many would say so, but it depends on whether the supernatural is part of your metaphysics. Could a highly evolved *natural* intelligence have fine-tuned the universe? This possibility has received some attention, but is difficult to prove. Or perhaps, a “multiverse” exists, an ensemble of universes, and we happen to live in a universe that is suitable for life. Whatever version of the anthropic universe we except, and whatever is the explanation for it, the anthropic biological universe is a cosmological worldview, as new and expansive as any in the past. Finally, the postbiological universe (Dick 2003) has barely been discussed in the terrestrial context, much less the extraterrestrial.

If after many centuries, it turns out that we find none of these versions of the biological or postbiological universe, then we will have determined that we live in a physical universe in which humans are unique or nearly unique. In that case, human destiny will be to explore this universe and perhaps to spread humanity throughout its vast spaces. We need not invoke or repeat the sins of manifest destiny in doing so. If we are indeed alone, we need not worry about harming the “natives.” But there will be many questions about exploiting and harming the space environment for human purposes.

In summary, the impact of actually discovering life—as opposed to conjecturing and theorizing about it based on preconceptions—will be to strengthen and consolidate the new worldview called the biological universe, or its cultural extension the postbiological universe, all as a part of the epic of cosmic evolution. Whether it is microbial, biological, anthropic, or postbiological, or whether some mix of these or something yet to be discovered, remains to be seen. But in any case, with the discovery of alien life, our cosmological worldviews will have been transformed in proportion to the complexity of life discovered and in proportion to the degree to which the universe is anthropic or biocentric.

11.4.4.2 THEOLOGICAL WORLDVIEWS: FROM THEOLOGY TO ASTROTHEOLOGY

Below the cosmological level in our framework of Figure 11.4.2 looms a perplexing variety of theological worldviews, a dominating feature of human cultures. Whatever the other effects on cultural elements at a level below the theological, the impact of the discovery of life beyond Earth on these theologies is likely to be pervasive, foundational, and personal. Such impacts will vary depending on the nature of the discovery and the particular religion involved. Because theological worldviews are so deeply held by such a large part of the population, changes in worldviews at this level—whether those worldviews are objectively true or not—are sure to have profound effects. Conversely, however, they also have the potential to help Earthlings cope with the discovery in whatever form it takes.

The effect of what we have called the intelligent biological universe on theologies, particularly Christian theology, has long been the subject of sporadic debate since Copernicus

made the Earth a planet and the planets potential Earths (Dick 1996). In subsequent centuries, three choices were logically open to Christians, who pondered the question of other worlds: they could reject other worlds, reject Christianity, or attempt to reconcile the two. Historically, all three of these possibilities came to pass in the eighteenth and nineteenth centuries (Crowe 1986). In the twentieth century, the relation of alien life to theology—most often Christian theology—has also been discussed, as events have unfolded in the SETI and as new discoveries or reputed discoveries have been made in NASA’s astrobiology program. Debate has centered around Christian doctrines such as incarnation and redemption, Christian practices such as baptism (Consolmagno and Mueller 2014; Consolmagno 2015), and the nature of God. The subject has been debated in books (O’Meara 2012; Wilkinson 2013; Weintraub 2014; Peters et al. 2018), articles (Bertka 2013; Peters 2011, 2013a, 2013b), and meetings (Bertka 2009; Dick 2000b), with no consensus. Some argue for an expansion of Christian doctrine and practice, while others conclude that the discovery of life beyond Earth would be fatal to the one-to-one relationship between God and humanity inherent in most Western religions.

Unlike Christianity, no substantial historical tradition exists in Judaism or Islam, the other two “Adamist” religions analogous to the Christian tradition on this subject. In his “Jewish exotheology,” Rabbi Norman Lamm (1978) did point to some historical precedents and express his viewpoint that extraterrestrials would not be problematic, much less fatal, for the Jewish religion. In the Islamic tradition, second only to Christianity, with its 1.5 billion adherents, scholars have pointed out that some particulars of Islam would prove problematic in their geocentric and anthropocentric aspects: the importance of Mecca for prayer and travel; praying five times per day on worlds with potentially vastly different day lengths; and, in general, following the teachings of Muhammad, who was born and lived on Earth. Thus, while Muslims do not have to deal with incarnation, they still have some of the same problems brought about by the anthropocentric nature of their religion.

Beyond the Adamist traditions, there has been even less discussion, but one ambitious overview touching on more than a dozen religions (Weintraub 2014) indicates that Eastern religions might have less trouble adapting than Western religions. Weintraub finds that the least impact on these would be to Hinduism (900 million members) and Buddhism (400 million members), which do not posit a single godhead with a relationship to humanity. Each of these religions might absorb, and even welcome, the discovery of extraterrestrial life. Indeed, some religions such as Mormonism already have extraterrestrials as part of their doctrine, an artifact of the time of their founding. Belying the seemingly simple question of the effect of astrobiology on theology, these findings point to one main conclusion, in some ways obvious from the outset: each religion will have to deal with the discovery of extraterrestrial life in its own way. There will not be one effect, but many.

It is also possible that the discovery of life beyond Earth will result in new theologies. One of these, known as cosmotheology (Dick 2000c, 2018b), is in its most general sense

a theology that takes into account what we know about the universe based on science. It is therefore a naturalistic cosmotheology, but it is not coextensive with scientism, because it does not imply that science is the only way to understand the world. Cosmotheology has six bedrock principles: (1) humanity is in no way physically central in the universe; (2) humanity is not central biologically, mentally, or morally in the universe; (3) we must take into account the probability that humanity is near the bottom in the great chain of beings in the universe; (4) cosmotheology must be open to radically new conceptions of God, not necessarily the God of the ancient near East or the God of the human imagination, but a natural God grounded in cosmic evolution; (5) cosmotheology must have a moral dimension, extended to embrace all species in the universe—a reverence and respect for life in any form; and (6) cosmotheology can and should transform our ideas about human destiny. With regard to the latter, although human destiny has most often been couched in divine terms, as in Reinhold Niebuhr's *The Nature and Destiny of Man* (1941) or Pierre Lecomte du Nouy's best-selling *Human Destiny* (1947), or, indeed, as in the entire Christian theology, it need not be linked to the supernatural. Rather, it can be linked to the process and endpoint of cosmic evolution. Taken as a whole, this version of astrotheology can also be seen in the tradition of religious naturalism, but specifically formulated to take into account the realities of cosmic evolution and the many possibilities inherent in life in the universe.

All of these streams of thought have resulted in what is now a considerable scholarly discussion of the subject, known variously as exotheology (Peters 1995), astrotheology (Peters 2014; Peters et al. 2018), and cosmotheology (Dick 2000c, 2018b). Such terminological diversity is not unusual in the early stages of a new intellectual endeavor.

11.4.4.3 CULTURAL WORLDVIEWS: FROM CULTURE TO ASTROCULTURE

At the broad base of the pyramid of worldviews of Figure 11.4.2, culture is being transformed into astroculture at an ever-accelerating pace, in its broadest sense an increasing awareness of our place in the universe. “Astroculture” is a relatively new umbrella concept used to describe the array of images, events, and media reactions that “ascribe meaning to outer space while stirring both the individual and the collective imagination” (Geppert 2012). The concept may be expanded to argue that, while different perspectives on space may exist in different cultures, humanity as a whole is increasingly creating and immersed in an overarching astroculture that transcends national boundaries, a kind of *global astroculture*. While this transformation is much broader than the possibility of life beyond Earth, the idea of alien life has, for some time, been a major component of culture (at least Western culture) and is sure to accelerate if a discovery of life beyond Earth is made.

Over the last 50 years, the idea that Carl Sagan embodied in the phrase “the cosmic connection” (Sagan 1973, 2000) has become more and more a part of our daily lives and will even more in the future, as our cosmic consciousness increases.

The cosmic connection of which Sagan spoke in 1973 not only embraced cosmic evolution, life beyond Earth, and the exploration of space in a hundred different forms, it also emphasized the most intimate connection of all: that we are made of stardust. The cosmic connection has only increased over the last several decades, as we have viewed spectacular imagery from the Hubble Space Telescope and other observatories, as well as absorbed the results of other spacecraft that have revealed our place in space and time. Within this grand context of cosmic evolution, the search for life in the universe finds its place, becoming in the process a dominant part of astroculture.

The discovery of life in any form will also impact broader aspects of culture. Given the impact that even the possibility of alien life has had on science fiction, the effect on literature in general will likely be enormous if extraterrestrial life is discovered. In the same way as literature was affected in the wake of the Copernican theory with John Donne and other writers, surely, the biological universe in any of its forms will do the same in ever more expressive form. The discipline of history will be affected, as our attempts at “universal history” in the tradition of Spengler, Toynbee, and Fukuyama will become only subsets of a much larger and truly universal history. Beyond theological-philosophical worldviews, philosophy will also change, as venerable questions such as the nature of objective knowledge are finally answered, or at least advanced or expanded. In short, the transformation of culture to global astroculture will witness the slow dismantling of one worldview and the reconstruction of a new one, in accordance with the Ladrierean framework discussed previously. In the process, new values will also emerge, feeding into established ethical systems and even giving rise to new ones.

11.4.5 ASTROETHICS: INTERACTING WITH ALIEN LIFE

The Space Age has required the contemplation and development of ethical standards for a variety of issues, including terraforming of planets, resource utilization, near-Earth asteroid threats, space exploration, and planetary protection. The discovery of extraterrestrial life would certainly raise these concerns to a new level, giving rise to a new discipline, sometimes termed astroethics (Impey et al. 2013; Peters 2013a, 2013b). Does Mars belong to the Martians, even if the Martians are only microbes? What do we say in response to an alien message, and who speaks for Earth? How do we treat an alien in a “close encounter of the third kind?” In short, whether we discover alien microbes or advanced alien life, we will immediately be faced with the problem of how to interact.

Before we can act in any situation that involves life, it is first important to assess the moral status of the organisms involved (Cleland and Wilson 2015). This is no easy task, since we are ambiguous even about relations with animals on Earth. But over the last few centuries, a good deal of thought has been given to the subject of moral status of Earth organisms and the idea of intrinsic value on which it is often based. This has resulted in an entire spectrum of frameworks or theories

for moral status, an ethical landscape that has been presented with broad brushstrokes by the Swedish philosopher Persson (2012). He distinguishes four ethical theories of moral status, in order of increasing inclusivity: *anthropocentrism*, in which only humans have moral status; *sentientism*, in which all and only sentient beings have moral status; *biocentrism* in which all and only living beings have moral status; and *ecocentrism*, in which all living beings, species, and ecosystems, and perhaps even nonliving matter, have moral status. Which of these frameworks we accept will determine how we treat alien life.

Contemplating encounters with alien life tremendously expands our ethical horizons. In the case of intelligent aliens, it also encompasses not just the problem of how we might treat them but also how aliens might act or react. In other words, it is not just a question of our ethics. What about their ethics? Is there any basis for inferring whether alien intelligence might be good or bad? Might there be such a thing as a universal ethics, perhaps in the form of the Golden Rule, as Rolston (2014) suggests, or simply a reverence for life, as Albert Schweitzer famously taught? Or is Star Trek's "Prime Directive" of non-intervention a naive one-way street, a recipe for our own extinction? In short, to expand one of the best-known statements of Martin Luther King to an extraterrestrial context, does the arc of the moral universe indeed bend toward justice? Or perhaps, more precisely, does the moral arc of the universe bend toward justice? This is the domain of altruism, which surprisingly has also been the subject of considerable thought in an extraterrestrial context, though with no decisive conclusions (Vakoch 2014b).

As with theories of moral status, the answers to these questions about altruism will inform our actions in real-world contacts with alien life under different scenarios. By contemplating these issues, and certainly by putting them into practice in the event of the discovery of life beyond Earth, we will not only address an important "wild card" problem in our near or far future but also transform our thinking by moving from an anthropocentric ethic toward a "cosmocentric" ethic, one that establishes the universe and all of its life as a priority in a value system, rather than just humans or even terrestrial life in general (Lupisella and Logsdon 1997; Lupisella 2009, 2016, in press). This is compatible with certain brands of astrotheology such as cosmotheology, which includes as its fifth principle a moral dimension, extended to include all species in the universe—a reverence and respect for life that we find difficult enough to foster on Earth. For both our Earthly and celestial concerns, a cosmocentric ethic will surely be a shift in worldview as radical as any of those we discussed in the last chapter.

The need for a basic cosmocentric ethic is already growing in proportion to the growth of our cosmic consciousness and the development of astroculture, as discussed previously. At one level, the novel ethical challenges that arise as we explore the extraterrestrial environment argue for a cosmos-wide ethical view. At another level, we need such an ethic because the cosmos potentially grounds our ethics in some objective way, or at least serves as a shared frame of reference with other intelligent beings, or even because the cosmos and

life are intimately entwined. The answer turns on how constrained we consider our terrestrial ethics, but a cosmic perspective is surely in order as we expand our views of the space environment, including (and especially) life. Such a view will not happen overnight, but perhaps, humanity will increase its awareness in stages, as we encounter the universe in increasingly intimate ways that will become a basic part of what it means to be human, or post-human.

11.4.6 THE ROAD AHEAD: PREPARING FOR DISCOVERY

Two practical questions remain: how do we prepare for the discovery of life, and what should we do if we find it? These questions have been sporadically raised at the highest levels of government, usually in the context of astrobiology programs at NASA, but also at other space agencies such as the European Space Agency. Arguably, preparing for astrobiological discovery and its aftermath is no less urgent than other science policy issues with the potential to impact all of society.

The questions here are legion, and potentially Earth-shaking. Who should take the lead in preparing for discovery? What do we do if life is actually discovered, microbial or intelligent, near or far? Should national governments be in charge or international political and scientific institutions, scientists and social scientists, ethicists and theologians, or some mix thereof? How do we prevent contamination of potential microbes on Mars, Europa, Enceladus, or other habitable sites in the solar system, and (more perhaps more urgently from most Earthlings' point of view), how do we protect our planet from back-contamination in the event of the discovery of microbial life? If a message is received as a result of a successful SETI program, should we answer? If so, who speaks for Earth? Should we initiate messages as part of a METI program? If so, what should we say, and who, if anyone, should control what is said? These questions are only the leading edge of the many decisions that will have to be made once alien life is actually discovered. And each discovery scenario will have its own unique problems and solutions.

While we can debate how likely any extraterrestrial life discovery scenario might be, in the last few decades, developments in astrobiology have made the discovery of life beyond Earth more and more feasible. Clearly, the time is ripe for serious discussion of strategies and policies in the event of discovery. Any analysis needs to keep in mind the two primary scenarios we distinguished earlier: the discovery of microbial life and intelligent life, each with its multiple modes of near and remote discovery and direct or indirect impacts. While policies do not always survive contact with the actual events, it is indisputably prudent to contemplate them in advance, especially when the implications for Earth are so all encompassing as in the discovery of alien life. We need not only to "look forward," but also to develop policies to achieve the goal of being fully proactive—and to have the best chance of having a positive impact on society when and if alien life is discovered under a variety of scenarios. Scientists and scholars in the humanities and social sciences can and do

play a major role in formulating policy (Michaud 2007; Race 2010, 2015; Lupisella 2015). Because there are many other stakeholders in society, they may not be the final arbiters of policy, much less the major players in implementing it. This highlights the importance of not only of continuing to develop strategies and policies, but also of having the political mandate to implement them when the time comes.

12.1.1 INTRODUCTION

Extrasolar planets, or exoplanets, are planetary-mass bodies in orbit around stars other than the Sun. To date, we have confirmed detections of more than 3700 exoplanets, ranging from objects with masses more than 10 times that of Jupiter to ones with masses, and radii, less than that of the Earth.

Discovering what are very faint objects around very bright host stars is, of course, challenging. As an illustration, [Figure 12.1.1](#) shows the 2M1207 system. It consists of a planetary-mass object (red object in lower-left region) in orbit around what is known as a brown dwarf (see, e.g., Chauvin et al. 2005). A brown dwarf is an object that does not become massive enough to ignite nuclear fusion in its core and, therefore, does not become a star.

In this case (Biller and Close 2007), the brown dwarf host has a mass 25 times that of Jupiter and a luminosity 500 times less than that of the Sun. The planetary companion has a mass of about 4 Jupiter masses and, because it is still young, is considerably brighter than Jupiter. The separation between the planet and its host is also more than 10 times greater than the separation between Jupiter and the Sun.

Now imagine trying to detect a planet that is fainter than that shown in [Figure 12.1.1](#) and more than 10 times closer to a host that is 500 times brighter. It is clearly hugely challenging, and although it is sometimes possible to directly image an exoplanet around a Sun-like star, most of the exoplanets detected to date have been detected using indirect, rather than direct, methods.

In the rest of this chapter, we will focus on the various methods that have been used to detect exoplanets and also

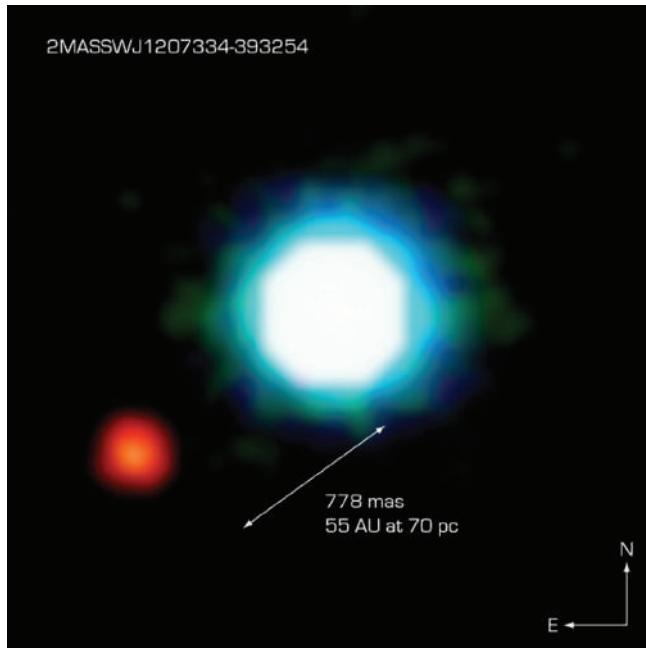

FIGURE 12.1.1 Image showing the 2MASS J12073346-3932539 system, which includes a planetary-mass body (red object in the lower-left region of the figure) and a brown dwarf host. (Courtesy of European Southern Observatory [ESO].)

what we can learn about these planets from these different methods. We'll focus, initially, on methods that indirectly detect exoplanets but will also explore direct detection, which is becoming more and more successful. We will also discuss what we now know about the properties and characteristics of exoplanets and what we may expect to discover in the coming years and will examine the prospects for detecting planets that may potentially be habitable.

12.1.2 DETECTION METHODS

12.1.2.1 PULSAR TIMING

Even though we often talk in terms of planets orbiting their parent stars, in reality, the star and planets all orbit the common center of mass of the system. In most planetary systems, the star has, by far, the most mass, and so, the center of mass will be located near, or sometimes inside, the star. The motion of the star around the center of mass is a consequence of the gravitational influence of the planets on their parent star. Therefore, one way to detect exoplanets is to observe stars to see if they are moving in a way consistent with them having planetary companions.

The first known exoplanets were detected in this way but were not actually detected around a Sun-like star; they were detected around a pulsar. A pulsar is a rapidly spinning compact object, typically the remnant core of a dead, high-mass star, a star that originally had a mass at least eight times that of the Sun.

Pulsars are highly magnetized and can emit a beam of electromagnetic radiation. Because the radiation beam is

not aligned with the spin axis, the beam can sweep past the Earth, producing what we observe as pulses, hence the name.

If the pulsar is an isolated object, then the interval between these pulses will be very regular. If, however, it is the host to a planet, or planets, then because it will also be in orbit around the center of mass of the system, it will sometimes be slightly further from the Earth than at other times. Consequently, there will be variations in the pulse timings that can then be used to infer the presence of a planetary companion.

The first such detection was announced in 1992 (Wolszczan and Frail 1992) and was a planetary system composed of three planets orbiting a 1.4 solar-mass pulsar. The innermost planet has a mass only slightly larger than that of the Earth's moon, while the other two have masses a few times that of the Earth. They orbit the pulsar with orbital periods of 25, 66, and 98 days.

In this case, however, the pulsar likely formed from the merger of two white dwarfs, the remnant cores of stars with masses similar to that of the Sun. Therefore, rather than the planets being primordial, they probably formed from a disc of material generated during the merger of these two white dwarfs (Podsaidlowski 1993).

So, not only was this detection not of planets around a star like the Sun, these planets were also probably never in orbit around a main-sequence star, having formed well after the death of the stars that later became their pulsar host. Such planets also turn out to be rare, with very few others having been found. They are, however, still the first planets to be found outside our solar system and demonstrate how they can be detected via their influence on their parent object.

12.1.2.2 ASTROMETRY

Given that, in a planetary system, both the planets and the host star orbit the common center of mass, one way we might expect to be able to detect planets would be to actually observe the motion of the star around the center of mass of the system. Doing so would require the measuring the angular motion of a planetary host star by using high-precision astrometry.

However, the angular motion of a planetary host star is typically very small. For example, the Sun executes an orbit about the center of mass (due to the gravitational influence of the planets in the solar system), with a radius of about 0.005 AU. When viewed from a distance of 10 parsecs (1 parsec being 206,265 times the distance from the Sun to the Earth), the Sun would appear to have an angular motion of about 0.001 arcsecs, or 2.8×10^{-7} degrees. We have not yet been able to make such measurements. However, European Space Agency (ESA's) *Gaia* mission, which launched in 2013, will soon have collected enough data that it will be possible to detect planets via astrometric measurements of the motion of their host stars.

12.1.2.3 RADIAL VELOCITY/DOPPLER WOBBLE

The first exoplanet found in orbit around a Sun-like star was announced in Mayor and Queloz (1995). The method used to detect this planet is known as the radial velocity, or Doppler

wobble, method. Stars have a spectrum with absorption lines that depend on the various atomic, and molecular, species in their atmospheres.

If a star is moving relative to us, then the wavelengths of these spectral lines shift in a way that depends on the relative line-of-sight velocity of the star. This is known as the Doppler effect. If the star is moving away from us, the lines will shift to longer wavelengths (red-shifted). If the star is moving toward us, they will shift to shorter wavelengths (blue-shifted).

However, if a star has a companion—such as a planet—it will orbit the common center of mass of the system. This means that at some times, it will be coming toward us, while at other times, it will be moving away. As illustrated in [Figure 12.1.2](#), the spectral lines will, therefore, be red-shifted when the star is moving away from us and blue-shifted when it is moving toward us.

This effect can then be used to determine the radial (or line-of-sight) velocity of the star. If measurements are taken at different times, then one can determine how this radial velocity varies with time and can plot a radial velocity curve, as shown in [Figure 12.1.3](#) (taken from Rowan et al. 2016).

[Figure 12.1.3](#) shows the radial velocity of the Sun-like star HD32963 in meters per second (m/s), plotted against time, in days. It shows an amplitude of just over 10 m/s, with a period of 2372 days (6.5 years). In this case, the observations were taken over a period of more than 6.5 years, but the data has been phase-folded, so as to represent it as a single orbital period.

[Figure 12.1.3](#) clearly shows that the star is executing some kind of orbit and indicates that there must be a companion. The period of the orbit can be determined directly from the radial velocity curve. The radial velocity measurements are also estimated using the spectrum of the star itself. Hence, we can also use the stellar spectra to determine what type of star it is and its mass. From the mass of the star, and the

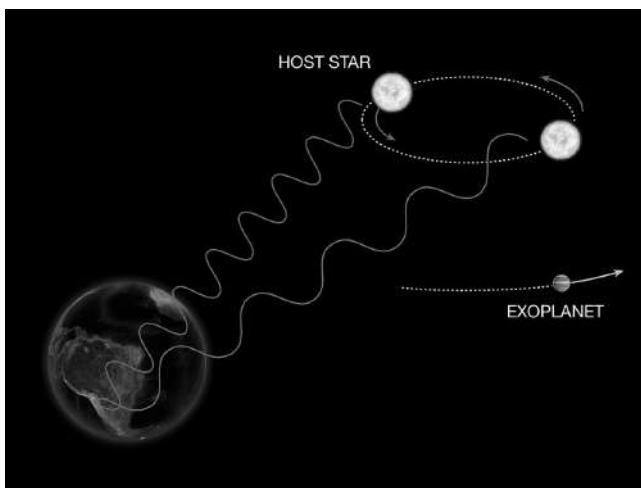

FIGURE 12.1.2 Illustration showing how the spectral lines of a star with a planetary companion will shift toward the blue side when the star is moving toward us and then toward the red side when it is moving away. (Courtesy of ESO.)

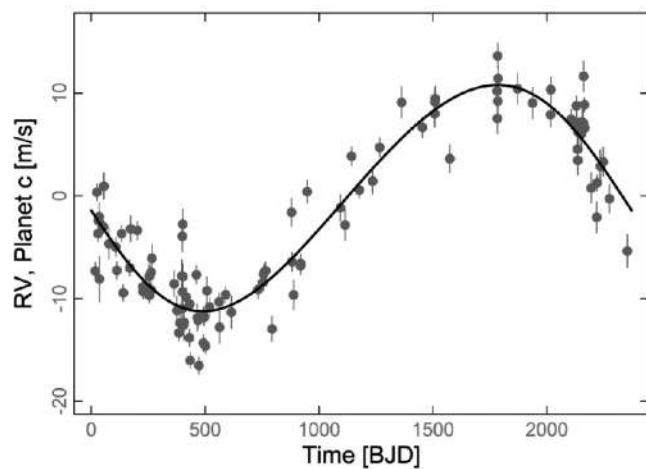

FIGURE 12.1.3 Radial velocity curve for the star HD32963 showing a radial velocity variation, with an amplitude of just over 10 m/s and a period of 6.5 years. (From Rowan, D., *Astrophys. J.*, 817: 104, 2016.)

period of the orbit, we can use Kepler's laws to infer the orbital radius of the planet, typically called the semimajor axis.

We can also determine the mass of the companion by using conservation of linear momentum. The radial velocity measurements give the line-of-sight velocity of the star. The companion's orbital radius and orbital period can be used to determine its velocity. Combining this with the mass of the star can be used to estimate the companion's mass.

As already noted, [Figure 12.1.3](#) shows a system with an orbital period of 6.5 years. The central star has a mass of 1.03 solar masses, which indicates that the companion must have orbital radius (semimajor axis) of 3.4 AU, where 1 AU is an astronomical unit, the average distance from the Sun to the Earth. This means that this planet orbits its parent star in between where Mars and Jupiter orbit the Sun. The amplitude of the radial velocity curve indicates that the mass of the companion is around 0.7 Jupiter masses.

There is, however, one caveat. The radial velocity method only allows us to determine the radial, or line-of-sight, velocity of the star. We do not know the actual inclination of the orbit. If it is inclined relative to our line of sight, then the radial velocity we measure will be smaller than the actual orbital velocity of the star. The mass we estimate for the companion will therefore be smaller than its actual mass, and so, this estimate is typically taken to be a lower limit to the mass of the companion. However, it doesn't depend very strongly on inclination. Hence, the estimated mass will often be reasonably close to the actual mass.

One final thing that can be determined using radial velocity measurements is the eccentricity of the orbit. The eccentricity indicates how circular, or non-circular, the orbit is. An eccentricity close to 0 would indicate an almost circular orbit, while an eccentricity close to 1 would indicate an extremely eccentric orbit.

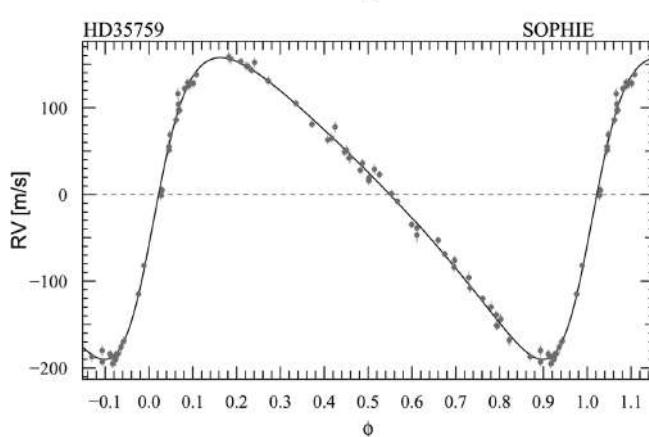

FIGURE 12.1.4 Radial velocity curve for the star HD35759. The non-symmetric nature of the light curve indicates that the orbit is eccentric, rather than circular. In this case, $e = 0.389$. (From Hebrard, G. et al., *Astron. Astrophys.*, 588, A145, 2016.)

The radial velocity curve shown in Figure 12.1.3 is quite symmetric and indicates that this system has a reasonably circular orbit ($e = 0.07$). Figure 12.1.4, however, shows the radial velocity curve for HD35759 (Hebrard et al. 2016) and indicates that the star is moving faster at some points in its orbit than in others. In this case, the orbit of the planet is quite eccentric ($e = 0.389$).

12.1.2.3.1 “Hot” Jupiters—the Case of 51 Pegasi B

The system illustrated in Figure 12.1.3 was announced in 2015 and comprises a roughly Sun-like star, with a roughly Jupiter-like planet that has an orbital period of 6.5 years—a bit smaller than the orbital period of Jupiter around the Sun (11 years). To a certain extent, it is a Jupiter analogue.

However, the first exoplanet detected via the radial velocity method around a Sun-like star was actually announced in Mayor and Queloz (1995) and was found around the star 51 Pegasus (hence the name, 51 Pegasi b). What was somewhat astonishing about this planet is that, although the mass estimate suggested a mass similar to that of Jupiter, the orbital period was only 4.23 days. In other words, this Jupiter-like planet is orbiting its parent star closer than Mercury is to the Sun.

Part of this is simply that it is easier to find planets that are closer to their parent stars than planets, of a similar mass, that are further out. This is partly a consequence of having to wait for at least an orbital period to be confident of a detection; orbital periods increase with orbital distance, and so, it takes longer to detect a planet on a wider orbit. Also, close-in planets induce larger radial velocities on their parent stars than planets that are further out and, hence, are easier to detect.

However, despite this selection effect, a reasonable number of such close-in planets—now known as “hot” Jupiters—have been found, with about 1% of all solar-like stars hosting such companions (Wang et al. 2015). Their origin is still not completely clear, but we currently think that they probably formed further from their star and then migrated through the

planet-forming disc, or were scattered via dynamical interactions with other bodies, onto the orbits they now occupy.

12.1.2.3.2 Some Relevant Numbers

A Jupiter-mass planet orbiting a Sun-like star at 5 AU will induce a stellar velocity of 13 m/s. The most accurate radial velocity spectrometers today, such as the High Accuracy Radial velocity Planet Searcher North (HARPS-N) on the 3.6-m Telescopio Nazionale Galileo (TNG) on La Palma, can accurately measure stellar radial velocities down to about 1 m/s (Cosentino et al. 2014).

This means that we can quite easily detect Jupiter analogues, the only complication being that such planets take about 11 years to complete an orbit. Planets with similar masses, but with closer-in orbits, induce even larger radial velocities and have shorter orbital periods. Such planets are, therefore, now reasonably easy to detect.

If we consider Earth-mass planets, then current instruments can only detect radial velocity signatures from Earth-mass planets if they orbit very close to their parent stars. For example, to induce a radial velocity of 1 m/s on a Sun-like star will require an Earth-mass planet orbiting 100 times closer to its star than the Earth is to the Sun. To detect a true Earth-analogue (1 Earth mass orbiting a Sun-like star, with an orbital period of 1 year) will require measuring a radial velocity signature of only 10 cm/s. This is currently not possible, and so, confirming a true Earth analogue will have to wait for future instruments and methods. This will require to be able to detect such a small radial velocity signature and will also require to be able to extract this signal from data that will include stellar noise of comparable amplitude.

12.1.2.4 THE TRANSIT METHOD

The radial velocity method (discussed in Section 12.1.2.2) can be used to determine a number of properties of a planetary system, in particular, orbital period, orbital radius, planetary mass, and orbital eccentricity. Another method for detecting, and characterizing, exoplanets is the transit method. This involves observing a large number of stars, with the goal of measuring small dips in brightness caused by something passing between us and the star being observed.

Figure 12.1.5 illustrates the basics of the transit method. Most stars have a reasonably constant brightness. Hence, if there is a small dip in brightness, this may indicate that something has passed between the star and us. If this dip repeats periodically, then it can indicate that something is in orbit around the star, potentially a planetary-mass companion.

One might expect that it is pretty straightforward to detect planetary companions by using the transit method. It turns out, however, that there are various complications. As mentioned in Section 12.1.1, a brown dwarf is an object that is more massive than something regarded as a planet but isn’t massive enough to become a star. Its radius, however, is very similar to Jupiter’s radius. Therefore, a transit of a brown dwarf can look similar to that of a massive planet. Similarly, a grazing eclipse by a stellar companion can block as much

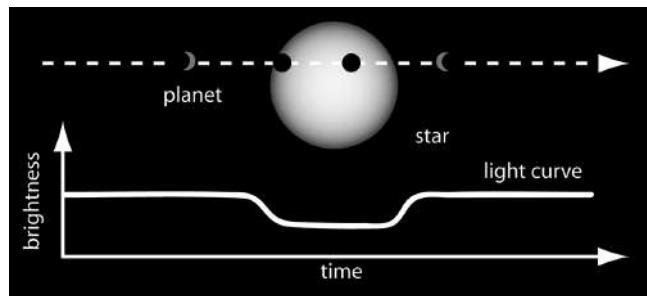

FIGURE 12.1.5 Illustration showing the transit method for detecting exoplanets. If a planet passes in front of its parent star, it will block some of the star's light, which we will measure as a small dip in brightness. (Courtesy of NASA AMES, Mountain View, CA.)

light as a full planetary transit. Very distant binary stars that happen to almost align with the star being observed can also produce apparent periodic dips of the target star.

However, it is possible to eliminate these false positives, and the transit method has become the most successful of the exoplanet detection methods, accounting for more than 2500 of the 3700 known exoplanets.

12.1.2.4.1 What Can the Transit Method Tell Us?

As with the radial velocity method, the transit method can tell us the orbital period of the companion. If we know the type of star, then we can also estimate its mass and radius. Using Kepler's laws, the orbital period can be used to estimate the orbital distance. The amount of light blocked also tells us the ratio of the cross-sectional area of the planet to the cross-sectional area of the star. From this, given the radius of the star, we can determine the radius of the planet.

Figure 12.1.6 shows a transit lightcurve for the HD209458 system (Brown et al. 2001), the first planet detected transiting its parent star (Charbonneau et al. 2000). It was generated by combining lightcurves from four different

transits. In this case, the planet (HD209458b) is found to have an orbital period of 3.52 days. The transit of the planet across the face of its parent star takes just under 3 hours and blocks about 1.7% of the starlight. Given that the star has a radius 1.146 times that of the Sun means that the companion has a radius 1.347 times that of Jupiter.

As mentioned earlier, a radius similar to that of Jupiter does not mean that the companion is of planetary mass; brown dwarfs can have similar radii. However, HD209458b was actually first detected via the radial velocity method, which means that there was already a mass estimate.

Normally, this would be a minimum mass, since the inclination of the orbit would be unknown. However, this planet also transits its host star, which means that the planet orbits in a plane that is very close to our line of sight. The mass estimate is therefore going to be very close to the actual mass of the companion. In this case, the radial velocity measurements indicate a mass of about 0.7 Jupiter masses.

Therefore, from the transit observations, we have an object with a radius slightly bigger than that of Jupiter, while the radial velocity measurements indicate a mass slightly below that of Jupiter. Clearly, this is what we would normally call a gas giant: a planet like Jupiter that is primarily composed of a hydrogen-rich, gaseous envelope/atmosphere. As we will discuss later in this chapter, combining different detection methods can provide additional information about the systems being observed.

12.1.2.4.2 Some Relevant Numbers

A Jupiter-like planet has a radius about 10 times less than that of a Sun-like star. The transit of a Jupiter-like planet will therefore block about 1% of the starlight from a Sun-like star (see, e.g., Figure 12.1.6). Detecting such signals is quite possible, even from the ground. In fact, one of the most successful transit projects is the Wide-Angle Search for Planets (WASP—Street et al. 2003), which uses camera lenses. This allows the WASP team to survey a reasonably large patch of the sky containing many stars. Just over 150 exoplanets have been detected by the WASP team, mostly exoplanets with radii similar to that of Jupiter.

An Earth-like planet has a radius about 10 times less than that of Jupiter and would therefore only block 0.01% of the starlight from a Sun-like star. This isn't really possible from the ground but is possible from space. NASA's Kepler satellite has now detected more than 1500 exoplanets via the transit method, in excess of 200 of which have sizes similar to that of the Earth.

Figure 12.1.7 shows the known planets by size (as of January 2018) and goes from planets slightly larger than Jupiter to those smaller than the Earth (data taken from <http://exoplanets.eu>). What it indicates is that we now have quite a large number of planets similar to, and even smaller than, the Earth. What is also interesting is that Figure 12.1.7 indicates that the most common type of exoplanet is probably one with a size between that of the Earth and Neptune (super-Earths and sub-Neptunes), a type of planet that we do not find in our solar system.

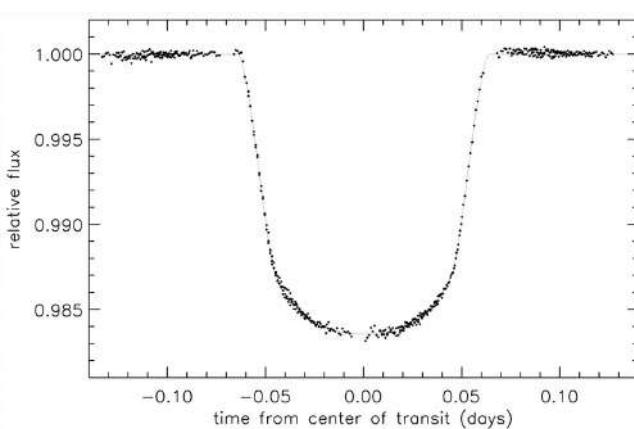

FIGURE 12.1.6 Transit lightcurve for HD209458. The transiting planet (HD209458b) has an orbital period of 3.52 days, and, when it transits, it blocks about 1.7% of the starlight. Given the radius of the star (1.146 Solar radii), this indicates that the planet has a radius of 1.347 Jupiter radii. (From Brown, T.M. et al., *Astrophys. J.*, 552, 699–709, 2001.)

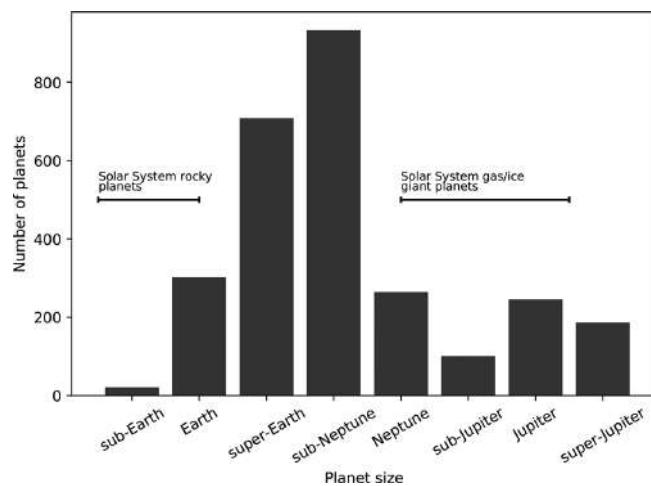

FIGURE 12.1.7 Bar chart showing the number of exoplanets of various sizes, from ones smaller than the Earth (sub-Earth) to those larger than Jupiter (super-Jupiter). What this indicates is that we have now found quite a large number with sizes similar to, or even smaller than, the Earth. Also, the most common exoplanet appears to have a size between that of the Earth and Neptune (super-Earths and sub-Neptunes). There are no such planets in our solar system. (Data from <http://exoplanet.eu/>.)

One final thing to consider here is that a planet will only transit if it happens to pass between us (the observer) and its parent star. The probability of a transit depends on the radius of the star and on the distance of the planet from the star; the further a planet is from a star, the less likely it is to transit. Detecting transits therefore requires observing many stars. The first phase of NASA's Kepler mission, for example, observed more than 100,000 stars (Borucki et al. 2006) and detected just over 2500 planets.

This does not, however, mean that only 2500 of Kepler's target stars host planets. Given that the transit probably decreases with increasing planet orbital radius, it is very unlikely that a planet with an orbital radius greater than about 1 AU will be detected. Similarly, a large number of closer-in planets may simply not transit, because their orbit means that they will not pass between their parent star and us. As we will discuss in a later section, this can be used to infer the planet occurrence rate.

12.1.2.5 GRAVITATIONAL MICROLENSING

The final indirect detection method that we will briefly discuss is based on Einstein's Theory of General Relativity. Gravity is the force between two objects that depends on their masses and on the distance between them. The original formulation, presented by Isaac Newton, essentially suggested that this force acted instantaneously. This violates Einstein's Theory of Special Relativity, which suggests that nothing can travel faster than the speed of light.

Einstein's Theory of General Relativity proposed that objects with mass act to distort spacetime (which is really just the fusion of the three spatial dimensions with the time dimension) and that gravity is simply a manifestation of this

curved spacetime. Essentially, massive objects in the universe will tend to "fall" toward other massive objects because of this curvature of spacetime.

Similarly, light will also be affected by this curvature of spacetime. Light follows a path that takes the least time and, as a consequence of the curvature of spacetime, will appear to be bent if it passes near an object that has mass. We can then use this to detect planets around stars.

This is illustrated in the diagram in [Figure 12.1.8](#). If a distant star happens to pass behind a nearer star, when viewed from the Earth, the nearer star can act like a lens, focusing some of the more distant star's light onto the Earth. In principle, this will produce two images of the more distant (source) star. However, telescopes today do not have the resolution to actually observe this. What actually happens is that as the source star moves behind the lens star, more and more of its light will be focused onto the Earth and it will appear to get much brighter. As it passes out from behind the lens star, it will then get fainter and fainter, until it returns to its original brightness. This can take many days, potentially even a few months.

If, however, the lens star happens to have a planet and this planet happens to be in the right place, it can provide an additional magnification that will last for a relatively short amount of time, typically a few hours to a day.

For example, [Figure 12.1.9](#) shows the lightcurve for the OGLE-2005-BLG-390 microlensing event, which occurred in 2005 (Beaulieu et al. 2006). The event lasted for about 50 days and was due to the light from the distant star being magnified by a closer star (as illustrated in [Figure 12.1.8](#)). In this case, the lens star does have a planet, which causes the additional magnification—lasting for approximately 1 day—about 10 days after July 31, 2005. This event was analyzed, and it indicated that the planet has a mass of about 5.5 Earth masses and an orbital radius of about 2.6 AU (i.e., about 2.6 times further from its parent star than the Earth is from the Sun).

What makes this an interesting method is that it is able to detect planets with masses similar to that of the Earth. However, because such alignments are very rare, we typically search in the direction of the center of our galaxy (the Milky Way), because there are lots of stars in that direction and therefore

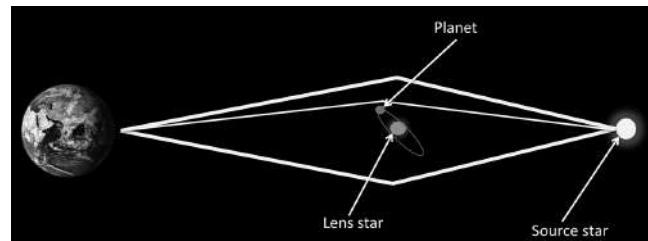

FIGURE 12.1.8 Diagram illustrating how we can use gravitational microlensing to detect planets around other stars. If two stars line up, when viewed from the Earth, the nearer star (lens star) can focus the light from the further star (source star), making it appear to get brighter. If the lens star also hosts a planet, the planet can provide an additional magnification that can then be used to infer its presence and some of its properties.

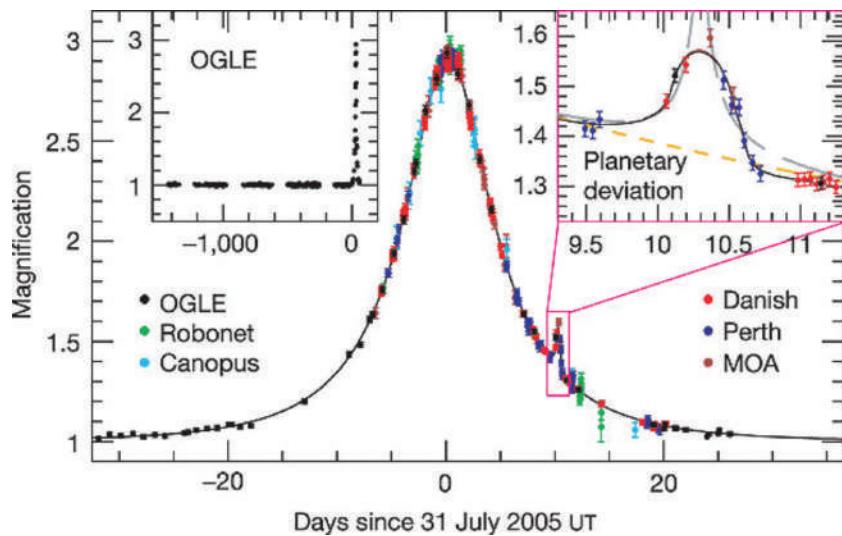

FIGURE 12.1.9 Lightcurve for the OGLE-2005-BLG-390 microlensing event. This shows the overall magnification event, lasting about 50 days, and the additional magnification, about 10 days after July 31, 2005, which is indicative of the lens star hosting a planet with a mass of about 5.5 Earth masses and orbiting at about 2.6 AU. (From Beaulieu, J.-P. et al., *Nature* 439: 437–440, 2006.)

such chance alignments become more likely. A consequence of this, however, is that such events will typically show a planetary signature only if the planet lies a few astronomical units from its host star (i.e., if the orbital radius is greater than that of the Earth around the Sun). Hence, this method can potentially find Earth-mass planets that are cool.

A downside of this method, though, is that such an event will at most happen once for a particular system, and these stars are faint, so there is not really any possibility of doing follow-up observations. So, we can get estimates for the planet's mass and orbital radius but cannot really characterize the system any further. However, they do provide an additional sample of exoplanets and also probe a region of parameter space (cool, low-mass planets) that cannot currently be probed by other methods.

12.1.2.6 DIRECT IMAGING

The previous sections have discussed indirect methods for detecting exoplanets. Here, we will discuss their direct detection. An advantage of this is that rather than inferring the planets' properties from their influence on their parent stars, we can infer them through direct observations. In particular, we can make direct observations that will help us understand the properties of their atmospheres. As we will discuss later, we can also infer some atmospheric properties by using spectroscopic observations of transiting exoplanets. However, the direct observation is likely to play a key role in the characterization of exoplanet atmospheres.

Directly imaging exoplanets involves surveying nearby young (<200 million years old) stars to look for faint companions. Typically, observations are taken at different times to establish if the star and its potential companion are moving together and also to establish if the companion appears to be orbiting the star.

Typically, when making observations with a telescope, the telescope is rotated so as to fix the orientation of what is being observed in the resulting image. However, when trying to directly detect planets, rotation is often turned off. If the star is placed in the center of the image, any other sources in the image will appear to move as the telescope tracks the target star. However, the noise, which comes from the structure, and optics, of the telescope itself, will remain fixed. The star, and this noise, can then be removed, enhancing any other real objects in the image. These can then be analyzed to see if they are planets in orbit around the target star. This process is known as angular differential imaging (ADI).

The HR8799 planetary system (shown in Figure 12.1.10) was one of the first to be directly detected (Marois et al. 2008). It was found to initially have three and then four (Marois et al. 2010) planetary companions with masses of between 5 and 7 Jupiter masses. The closest orbits at about 14.5 AU, while the furthest orbits at about 68 AU. The central star has a mass about 1.5 times that of the Sun and is probably about 30 million years old.

This quite nicely illustrates the constraints associated with directly imaging extrasolar planets. Currently, it can only really detect relatively massive planets (masses above that of Jupiter) on wide orbits (orbital radii greater than about 10 AU) and that are still quite young. This is because we typically observe in the infrared, where we detect thermal emission from the planet itself, rather than reflected light from the parent star. Planets with masses below that of Jupiter are simply not bright enough to be detected. Also, these planets tend to cool as they age and hence become fainter. Therefore, we can only detect them when they are relatively young (younger than a few hundred million years). Also, even though we can remove much of the bright central star from the resulting images, it is still difficult to find planetary companions that are closer than about 10 AU.

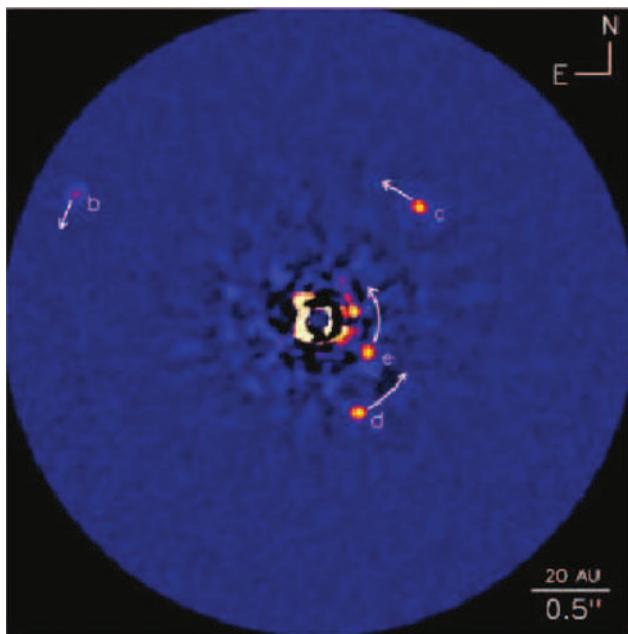

FIGURE 12.1.10 Image showing the HR8799 system. It has four planets (HR8799b, c, d, and e). The closest (e) orbits at about 14.5 AU, while the furthest orbits at about 68 AU. The planets' masses are estimated to be between 5 and 7 Jupiter masses. (From NRC-HIA, C. Marois, and Keck Observatory.)

12.1.2.6.1 Some Relevant Numbers

The direct search for companions to stellar bodies has already uncovered a reasonable number of objects. If we restrict it to those with planetary mass (typically less than about 13 Jupiter masses) and in orbit around a star (rather than having a brown dwarf host), the numbers are quite modest. We now know of about 10 such objects. As mentioned, they typically have masses above a few Jupiter masses and orbit at radii beyond about 10 AU.

The above, however, is mostly a selection effect; we simply don't have the ability to detect lower-mass planets on orbits that are closer to their parent star. Given that directly imaging a planet allows us to potentially characterize its atmospheric properties, we would like to be able to do so for smaller planets on closer-in orbits. This would allow us to directly probe their potential habitability. This, however, will have to wait for another generation of telescopes and instruments, some of which, such as 30-m class, ground-based telescopes, will become available within the next decade.

12.1.3 WHERE HAVE WE EXPLORERED?

We have now covered the main exoplanet detection methods. In most cases, exoplanets are detected via indirect methods (astrometry, radial velocity, transits, timing, and microlensing), but we are starting to be able to directly image some planetary-mass objects. Each method, however, typically works in some circumstances but not in others.

Figure 12.1.11 illustrates the different detection methods and the regions in which they can detect exoplanets (Dominik 2010). The y-axis represents the planet's mass, while the x-axis is the planet's temperature, increasing as it gets closer to its host star. Orange shows the region accessible by the transit technique. It is possible to detect planets with small radii (and, hence, low masses). However, the probability of a transit occurring decreases with increasing orbital radius, and, therefore, it becomes increasingly unlikely that we will observe a transit as the planet's orbital radius increases. Therefore, the transit method might be able to detect small planets, but it can currently only really do so for planets with orbital radii inside about 1 AU.

The yellow shows the region accessible by the radial velocity/Doppler wobble method. It can detect relatively low-mass planets but not quite as low as is possible with the transit method. However, the influence of the planet on the star decreases as the planet's orbital radius increases. Therefore, the mass of a planet that can be detected by the Doppler wobble method increases as the planet's orbital radius increases.

The light blue shows the region in which gravitational microlensing can detect exoplanets. It can detect quite-low-mass planets (down to masses similar to that of the Earth). However, because of the geometry of these microlensing events, it typically finds exoplanets with orbital radii greater than that of the Earth (cool low-mass planets). Finally, purple shows where direct imaging can detect exoplanets. As discussed earlier, this method preferentially finds massive planets on wide orbits.

The red circle illustrates the region around a Sun-like star in which we would find something analogous to the Earth, a rocky planet on which liquid water could exist on its surface. It is, however, a region of parameter space that we currently

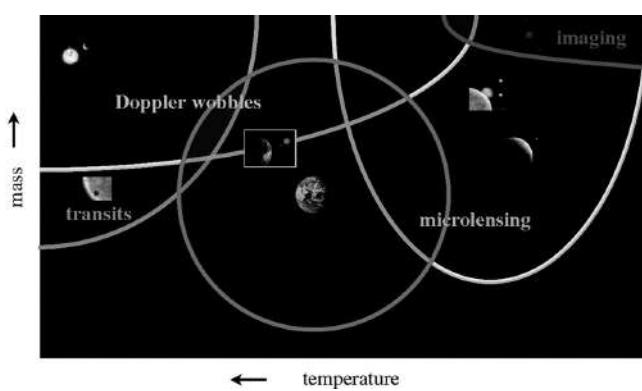

FIGURE 12.1.11 Diagram illustrating the different regions of planet mass-orbital radius space accessible to the various exoplanet detection methods. In the diagram, orbital radius is expressed as Temperature, since the closer a planet orbits to its host star, the higher its temperature. The region of parameter space that is still not accessible is exoplanets with Earth-like masses orbiting a Sun-like star at an orbital radius similar to that of the Earth. (From Dominik, M., *Gen. Relativ. Grav.*, 42: 2075–2100, 2010.)

can't easily explore. We can find planets more massive than the Earth with similar orbital radii, and we can find planets of a similar mass, either closer to their parent star or further from their parent star. Finding a true Earth analogue will, however, probably have to wait for the next generation of telescopes and instruments. On the other hand, as we will discuss later, it is already possible to find (using radial velocity and transit measurements) planets around stars less massive than the Sun that orbit in a zone where liquid water could exist on their surface.

Figure 12.1.12 shows the actual exoplanet data and also illustrates what is shown in **Figure 12.1.11**. It shows planet mass (in Jupiter masses) against orbital separation (in AU). The red circles are those exoplanets detected via the transit method. They can go down to quite low masses but show few detections beyond 1 AU. The blue circles are the radial velocity exoplanets, which show some exoplanets with low masses at small separations but only shows the more massive planets at larger separations. The green triangles are the microlensing exoplanets, which tend to be found beyond 1 AU, while the yellow squares are the massive, wide-orbit planets detected via direct imaging. As also illustrated in **Figure 12.1.11**, a region that we cannot yet explore is Earth-mass planets ($M = 0.0032$ Jupiter masses) at about the same distance as the Earth is from the Sun (~ 1 AU).

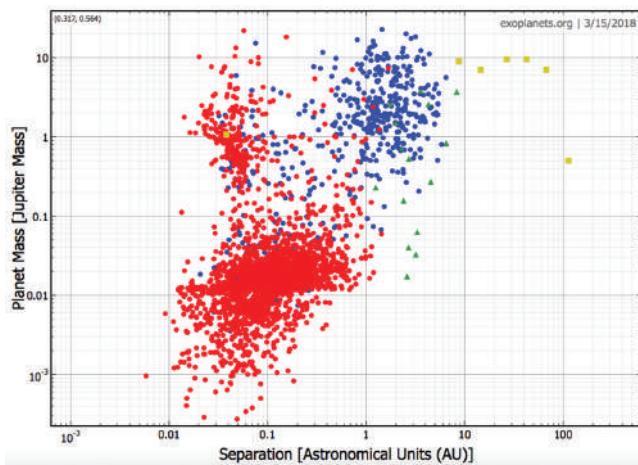

FIGURE 12.1.12 Planet mass (in Jupiter masses) against orbital separation (in astronomical units, or AU) for all known exoplanets. The different colors are for the different detection methods: red circles (transit), blue circles (radial velocity), green triangles (microlensing), and yellow squares (direct imaging). This illustrates, as discussed in the text, what type of planets each method can uncover and also illustrates that we are not yet able to detect true Earth analogues—a ~ 0.003 Jupiter mass planet at ~ 1 AU around a Sun-like star. (From NASA Exoplanet Archive. This research has made use of the NASA Exoplanet Archive, which is operated by the California Institute of Technology, under contract with the National Aeronautics and Space Administration under the Exoplanet Exploration Program. With permission.)

12.1.4 EXOPLANET CHARACTERISTICS

As discussed previously, the different detection methods provide different information about the planets that they detect. For example, both the transit and radial velocity methods can determine the planet's orbital period (and, hence, orbital radius), but the former also determines the planet's physical radius, while the latter can be used to estimate the planet's mass. If you combine the two, you can then get an estimate for the planet's density and, hence, internal composition.

There are now many exoplanets for which we have both mass and radius estimates. Initially, these were mostly planets that had masses and radii consistent with them being gas giants, like Jupiter or Saturn. In some cases, however, these turned out to have radii somewhat bigger than expected (Bodenheimer et al. 2001), with some having radii almost twice that of Jupiter (Hebb et al. 2009). In the absence of any additional energy sources, gas giant planets more than a few billion years old should not have radii more than 1.2 times that of Jupiter (Fortney et al. 2007).

However, most of these inflated gas giant exoplanets are very close to their parent stars and, hence, are heavily irradiated. Being so strongly irradiated might either reduce the rate at which these planets cool and, hence, shrink, or actually deposit energy in the planetary interior, inflating their radii (Lopez and Fortney 2016).

With the advent of NASA's Kepler mission, we now also know of numerous planets with radii very similar to that of the Earth. In some cases, we have been able, using ground-based radial velocity measurements, to estimate their masses. **Figure 12.1.13** shows a mass radius plot for all exoplanets with masses below 20 Earth masses and with a mass precision of better than 20% (Lopez-Morales et al. 2016).

The curves in **Figure 12.1.13** show different possible internal compositions, from a fully iron planet (100% Fe) to one that would be almost entirely water (100% H₂O). It also shows Earth and Venus (between 35% and 40% iron) for reference. There are now a number of known exoplanets with compositions similar to that of Earth and Venus. However, the colors indicate the planet's likely surface temperature, based on the incident stellar flux (relative to that of the Earth). All of those with Earth-like internal compositions orbit very close to their parent stars and therefore will have surface temperatures much higher than that of the Earth. For example, K-78b (or, Kepler-78b) orbits a star similar to the Sun, has an Earth-like internal composition, but has an orbital period of only 8.5 hours (Pepe et al. 2013). It, therefore, probably has a surface temperature in excess of 2000 K.

Figure 12.1.13 also shows that there are a number of super-Earths that have substantial amounts of water. However, if water makes up more than 1% of the planet's mass, then the pressure at the bottom of a water layer will be high enough to form high-pressure ice polymorphs (Levi et al. 2014), which means that there will be no direct contact between the liquid ocean and the planetary interior. This will probably have a

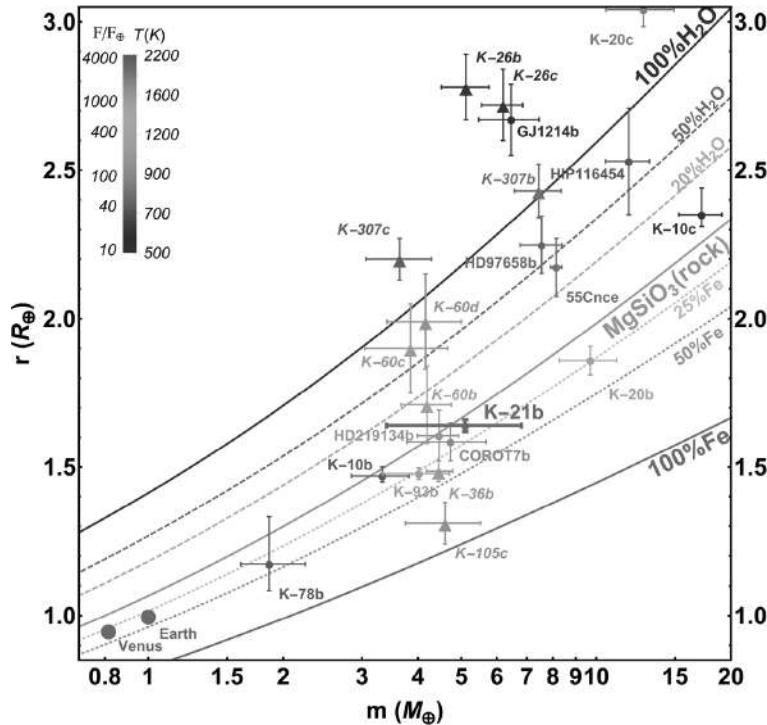

FIGURE 12.1.13 Mass-radius diagram for all exoplanets with masses less than 20 Earth masses and with a mass precision of better than 20%. The curves show different possible internal compositions. Earth and Venus are shown for reference. (From Lopez-Morales, M., et al., *Astron. J.*, 152, 204, 2016.)

substantial impact on the chemical composition of the liquid ocean, which will almost certainly impact the potential habitability of such planets (Kite and Ford 2018).

There also appears to be an approximate gap in the exoplanet radius distribution. Planets tend to have radii below about 1.5 Earth radii, or above 2 Earth radii; there are currently very few with radii between 1.5 and 2 Earth radii (Fulton et al. 2017). Those below 1.5 Earth radii tend to be rocky, while those above 2 Earth radii are either water-rich or have substantial volatile envelopes (Rogers 2015). If we think that habitability requires a predominantly rocky planet, then that would suggest that such planets will preferentially have radii less than 1.5 Earth radii.

12.1.5 EXOPLANET OCCURRENCE RATES

Now that we have a large sample of known exoplanets, we can start to estimate actual occurrence rates, the mean number of planets, within some parameter range, per star. For example, we expect about 10% of solar-like stars to host gas giant planets orbiting within 3 AU (Cumming et al. 2008). The occurrence rate for close-in giant planets (“hot” Jupiters) is considerably smaller, with only about 1% of solar-like stars hosting such planets (Wright et al. 2012). The occurrence rate of very wide orbit giant planets is also low (Biller et al. 2013), potentially also as low as 1% for those with masses between 5 and 13 Jupiter masses (Bowler and Nielsen 2018).

For smaller planets, the occurrence rate tends to be higher, with about 15% of solar-like stars hosting planets with masses

between 3 and 10 Earth masses and with orbital periods less than 50 days (Howard et al. 2010). Overall, we might expect about 50% of solar-like stars to host a planet with an orbital period of less than 85 days (Fressin et al. 2013).

It’s also possible to estimate the occurrence rate of Earth-size planets in a zone where they have the potential to be habitable (i.e., where liquid water could exist on their surface). The result does depend on assumptions about where they might be habitable, but Petigura et al. (2013) suggest that at least 6% of Sun-like stars host a planet with a size comparable to that of the Earth, and that orbits in a zone where liquid water could exist on its surface.

However, we do have to be slightly careful. This is partly based on extrapolating from the known population of small exoplanets. Many of these are very close to their parent stars, are heavily irradiated, and, hence, may initially have had substantial volatile envelopes that they have now lost (Fulton et al. 2017). Therefore, these may not be part of a population of rocky planets that extends to regions where they may be habitable (Lopez and Rice 2018). Consequently, estimates that do not take this into account may suggest a higher occurrence rate than is actually the case.

12.1.6 THE HABITABLE ZONE

As already indicated previously, the habitable zone is typically taken to be the region, around a star, in which a planet could have liquid water on its surface and, hence, could potentially support life. We do have to be slightly careful when

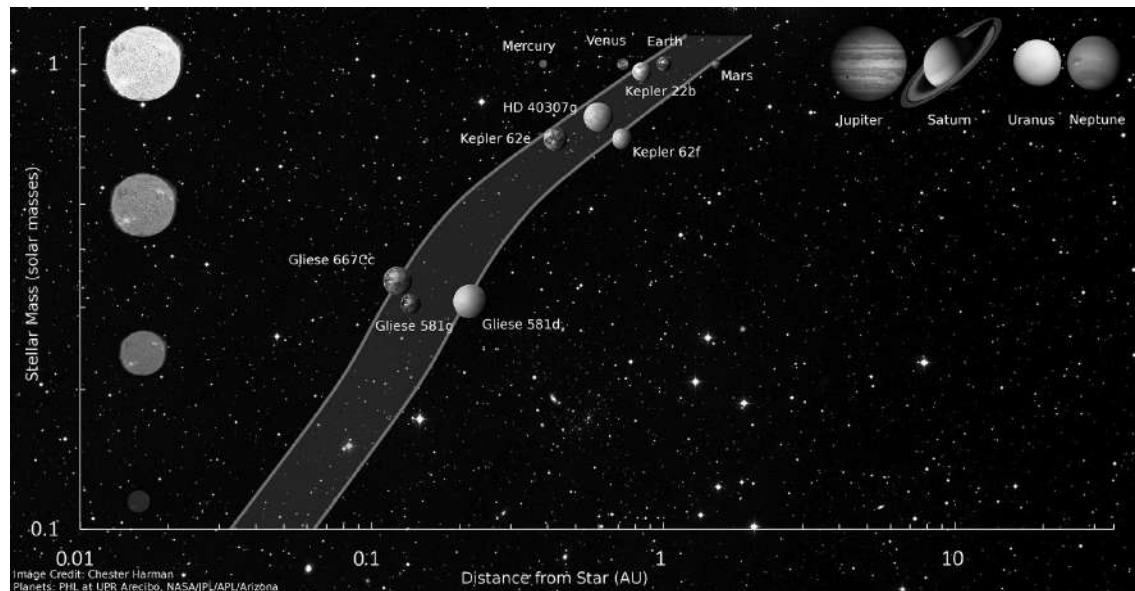

FIGURE 12.1.14 Figure showing the habitable zone (based on the analysis by Kopparapu et al. 2013) around different types of stars. It also shows the solar system planets and a sample of known exoplanets that happen to lie in their stars' habitable zones. (From Kasting, J.F. et al., *Proc. Natl. Acad. Sci. USA*, 111, 12641–12646, 2014.)

using this, because being in the habitable zone doesn't mean that a planet will support life, and being outside it does not necessarily mean that it cannot support life.

The exact region in which a planet could have liquid water on its surface depends on a number of factors, including the type of star, the atmospheric composition of the planet, and how much of the incoming stellar flux it reflects back into space.

A simple estimate might suggest that it extends—around a Sun-like star—from about 0.5 AU to about 2 AU (i.e., from half the distance between the Sun and the Earth to twice the distance between the Sun and the Earth). However, this would imply that both Venus and Mars (in our solar system) lie within the habitable zone, yet neither is regarded as currently habitable. A more accurate estimate might suggest that it is somewhat narrower (Kasting et al. 1993; Kopparapu et al. 2013). However, if a planet is highly reflective, or has a weak greenhouse effect, it could sustain liquid water on its surface even when quite close to its parent star (Zsom et al. 2013). Similarly, a planet with a low reflectivity and/or a strong greenhouse effect could sustain liquid water on its surface even if quite far from its parent star, in extreme cases potentially out to ~10 AU around a Sun-like star (Pierrehumbert and Gaidos 2011). This would, however, require a hydrogen-rich atmosphere. For a planet on which carbon dioxide drives the greenhouse effect, the outer edge is probably well within 2 AU (Kopparapu et al. 2013).

Figure 12.1.14, from Kasting et al. (2014), and based on the work of Kopparapu et al. (2013), illustrates the habitable zone for different types of stars. It also shows the solar system planets and a selection of known extrasolar planets that happen to lie within their star's habitable zone.

What the Figure shows is that around a Sun-like star, the zone probably extends from just inside where Earth is in the solar system to just inside the orbit of Mars. Stars more

massive than the Sun are brighter, and hence, the habitable zone is at larger orbital radii. Conversely, stars less massive than the Sun are fainter, and so, the habitable zone moves to smaller orbital radii. This has implications that we will discuss in more detail later.

12.1.6.1 KNOWN POTENTIALLY HABITABLE EXOPLANETS

As mentioned previously, it is not possible to precisely define the habitable zone, and, hence, it is not possible to determine exactly how many known exoplanets lie within such a zone. However, we could be optimistic and assume that the habitable zone is quite broad (~0.75 AU to ~1.84 AU) and that the range of planets that could sustain liquid water on their surface is also broad (planet mass below about 5 Earth masses and/or planet radius less than 2.5 Earth radii). Given this, there are already about 40 known exoplanets that could have liquid water on their surface.

There are, however, indications that most planets with radii larger than 1.5 Earth radii are not rocky (Rogers 2015; Fulton et al. 2017). Similarly, a more conservative estimate of the habitable zone is probably also preferred (Kopparapu et al. 2013). Consequently, a more reasonable estimate would suggest about 13 known exoplanets in the habitable zones of their parent stars, most of which are around stars less massive than the Sun, known as M- or K-dwarfs.

12.1.6.2 POTENTIALLY HABITABLE PLANETS AROUND LOW-MASS STARS

As mentioned in Section 12.1.6.1, a conservative estimate of the number of known exoplanets in a potentially habitable zone indicates that most orbit stars less massive than the Sun. This, however, is probably mostly a selection effect. As shown in Figure 12.1.14, the habitable zone around a star less massive

than the Sun is closer to the star than it is around a Sun-like star. This means that it is easier to find planets in the habitable zone around lower-mass stars than it is around higher-mass stars. They are more likely to transit, and they induce a larger radial velocity on their parent star.

The next major exoplanet mission is NASA's Transiting Exoplanet Survey Satellite (TESS), due to launch later in 2018. It will survey 200,000 stars and is expected to find around 1700 transiting exoplanets, of which just over 500 will have radii less than twice that of the Earth (Sullivan et al. 2015). Potentially 50 of these planets will lie in their star's habitable zone, and most of these planets' parent stars will be M- or K-dwarfs, stars with masses less than that of the Sun. So, TESS will probably enhance the number of known exoplanets in the habitable zone of these lower-mass stars (Ballard 2018).

However, since the habitable zone around stars less massive than the Sun is closer to the star than around a Sun-like star, planets in the habitable zone around M- and K-dwarfs are likely to be tidally locked (Barnes 2017). This means that they will have a side that always faces their parent star, just like the same side of the Moon always faces the Earth.

How such a configuration will influence the atmospheric properties of a rocky planet in the habitable zone around an M-dwarf is unclear. It was originally thought (Dole 1964) that tidal locking would lead to the night side being so cold that it would freeze out and potentially collapse the atmosphere. However, recent work has suggested that atmospheric transport (Joshi et al. 1997), cloud feedbacks (Yang et al. 2013), and/or ocean heat transport (Hu and Yang 2014) could keep the night side warm enough to prevent such a collapse of the atmosphere.

Hence, such planets may indeed be habitable and may well be good direct imaging targets that would allow us to look for signatures of life in their atmospheric features (Rugheimer et al. 2015).

12.1.6.2.1 Proxima Centauri B

In 2016, it was announced that Proxima Centauri, the Sun's closest stellar neighbor, hosts a potentially rocky planet orbiting in the region where liquid water could exist on its surface (Anglada-Escudé et al. 2016). The planet has a mass of around 1.3 Earth masses, but orbits a star that has a mass just over one-tenth that of the Sun. The planet also orbits this star at a distance of only 0.05 AU—20 times closer to its parent star than the Earth is to the Sun.

There are some indications that atmospheric conditions of Proxima Centauri b might be reasonably insensitive to changes in stellar flux (Boutle et al. 2017), which would indicate quite a large range of parameters over which it might have conditions suitable for the presence of liquid water on its surface. On the other hand, relative to the Earth, Proxima Centauri b is heavily irradiated by extreme ultraviolet (XUV) and x-rays. High-energy photons can cause photo-dissociation of water, the hydrogen from which can then escape if it becomes sufficiently energetic. In fact, XUV heating of the upper atmosphere can also lead to the loss of other volatile elements. Hence, a heavily irradiated planet could lose the atmospheric elements necessary for life. The outcome will,

however, depend on its actual evolutionary history (Meadows et al. 2018), and there are indications that Proxima Centauri b could still have conditions suitable for liquid water to exist on its surface, despite being exposed to far more XUV and x-ray irradiation than the Earth (Ribas et al. 2016).

That Proxima Centauri b is both orbiting the Sun's closest stellar neighbor and in its parent star's habitable zone makes it a fascinating target for observations. Directly observing Proxima Centauri b will, however, probably have to wait for the next generation of ground-based telescope, such as the 39-m European Extremely Large Telescope (Turbet et al. 2016). However, very-high-contrast imaging, together with high-resolution spectroscopy, could be used to observe variations in reflected starlight as the planet orbits its parent star (Snellen et al. 2015), which may provide information about the orbital inclination and the planet's albedo (reflectivity).

Also, given that a tidally locked planet will probably have a dayside to night side temperature gradient, infrared observations with the James Webb Space Telescope (JWST—due for launch in 2020) could be used to detect thermal phase variations (Kreidberg and Loeb 2016). In fact, these thermal phase variations will depend on whether or not the planet has an atmosphere that can redistribute heat from the dayside to the night side. Hence, these observations could give an indication of whether or not Proxima Centauri b actually has an atmosphere.

12.1.6.3 POTENTIALLY HABITABLE PLANETS AROUND SUN-LIKE STARS

As mentioned previously, most of the known potentially habitable exoplanets are around stars less massive than the Sun. Also, we expect that most of the potentially habitable exoplanets that we will detect in the next few years will also mostly be around stars less massive than the Sun.

However, as mentioned in [Section 12.1.6.2](#), this is mostly a selection effect; it is easier to find rocky planets in the habitable zones of M- and K-dwarfs than it is to find rocky planets in the habitable zone of a Sun-like star (also known as a G-dwarf). It seems likely that at least a few percent of Sun-like stars host rocky planets in a region where liquid water could exist on their surface (Petigura et al. 2013).

Detecting such planets will, however, probably have to wait for the ESA's PLATO mission, which is due to launch in 2026. PLATO will survey a large number of bright nearby stars, with the goal of detecting planetary transits. In particular, it will survey enough stars that it is likely to recover a sample of Earth analogues, planets with masses and radii similar to that of the Earth and orbiting a Sun-like star at about 1 AU (Rauer et al. 2014). The targets will also be bright enough that we may be able to use other observational methods to more accurately determine masses and, consequently, their internal composition.

12.1.6.4 DETERMINING HABITABILITY

As already mentioned, simply finding rocky planets in the habitable zones of other stars does not mean that they are indeed habitable. This will require other observations to try

and identify biosignatures. I won't discuss possible biosignatures, as that is covered elsewhere in this volume. However, it is clear that detecting biosignatures will require characterizing the atmospheres of these potentially habitable exoplanets.

We can, however, already say something about exoplanet atmospheres. For close-in exoplanets, we can use transit spectroscopy (Seager 2008) and secondary eclipse spectroscopy (Wilkins et al. 2014). Both these look for changes in the stellar spectrum as a planet move in front of, or behind, its parent star. Such observations have indicated the presence of sodium (Snellen et al. 2008), water vapor (Birkby et al. 2013), and clouds (Evans et al. 2013) in the atmospheres of "hot" Jupiters.

We can even sometimes extend this to lower-mass planets. There are observations suggesting the presence of clouds in the atmosphere of a super-Earth (Kreidberg et al. 2014), and observations indicating that some of the planets in the TRAPPIST-1 system do not have cloud-free, hydrogen-dominated atmospheres. This suggests that these planets are most likely rocky (de Wit et al. 2018). TRAPPIST-1 is a seven-planet system orbiting a very-low-mass star and in which a number of the planets lie within the star's habitable zone (Gillon et al. 2017). With JWST, it may even be possible to use transit spectroscopy to detect ozone in the atmospheres of some of the TRAPPIST-1 planets (Barstow and Irwin 2016).

As already mentioned in relation to Proxima Centauri b, we can also use phase-curve variations to infer something about an exoplanet's atmosphere. As a close-in planet orbits its host star, the side facing toward us will go from being the hot, irradiated dayside to the much colder night side. This can produce a detectable thermal phase variation. The form of this phase curve depends on the presence of an atmosphere and on its properties and so can be used to infer—or rule out—if a close-in exoplanet has an atmosphere (Seager and Deming 2009).

The recently selected ESA's Ariel mission, due to launch in the late 2020s, will use transit, eclipse, and phase-curve spectroscopy to characterize the atmospheres of hundreds of exoplanets. This will include gas giants (Jupiter-like), Neptune-like, super-Earths, and Earth-sized planets around a range of host-star types (Tinetti et al. 2017). It will primarily focus on hot, or warm, exoplanets, with a particular goal of understanding how atmospheres form and how the chemical composition of these exoplanet atmospheres relates to the properties of the host star.

Since planets move much faster than their parent stars, their spectral lines will also be shifted with respect to those from the star. We can therefore use high-resolution spectroscopy to try to identify the planet's spectral lines and hence learn something about its atmospheric composition (Snellen et al. 2013, 2015). Doing so for rocky planets may, however, require us to wait for the European Extremely Large Telescope (E-ELT), due to start operations in the mid-2020s.

Ultimately, however, we would probably like to directly image planets, so as to determine their spectra, and to infer something about their potential habitability. This, however, remains extremely challenging, and the ability to do so depends on both the contrast ratio between the planet and its

parent star and their angular separation. Currently, we can directly observe young, giant planets on wide orbits, both because they are quite bright (planet-to-star contrast ratios of about 10^{-4}) and because the angular separation between the planet and its host star can be quite large. There are already indications, for example, that clouds are present in the atmospheres of some of the directly imaged giant planets (Bonnefoy et al. 2016).

Imagers on 30-m class telescopes (due to beginning of the operating in the next decade) will probably be able to directly image young Jupiter analogues (i.e., Jupiter-mass planets on orbits a few astronomical units from their parent star) and, potentially, rocky planets in the habitable zones of very-low-mass stars (Turbet et al. 2016). However, to directly observe a true Earth analogue (Earth mass/size planet at about 1 AU around a Sun-like star) may require large space telescopes that are currently only being planned, such as NASA's Luvoir mission, which has yet to be formally selected and would only launch in the mid-2030s, at the earliest.

12.1.7 CONCLUSIONS

We now have a very large sample of known exoplanets in orbit around stars other than the Sun. These range from planets larger than Jupiter to ones smaller than the Earth. The various detection methods allow us to probe a wide range of parameter space, in both planet mass and orbital radius, but the one region that we are not yet able to probe is Earth-sized planets orbiting at about 1 AU around a Sun-like star. This region will become accessible through future space-based exoplanet missions.

However, we do now have a small sample of planets orbiting within their stars' habitable zone, defined as being the region in which liquid water could exist on the planet's surface. Most of these planets are, however, orbiting stars less massive than the Sun. The habitability of such planets is still unclear, but we will start uncovering atmospheric characteristics of such planets with the next generation of both ground-based and space-based instruments.

Determining if an exoplanet is habitable, or not, may well turn out to be even beyond the next generation of astrophysical instruments. However, we will almost certainly, in the near future, have a much better understanding of exoplanet atmospheres, what will be required in order to further improve this understanding, and what would be required to actually detect potential biosignatures.

12.2.1 INTRODUCTION

Primitive small bodies, such as asteroids, meteorites, and comets, are the remnants of planetesimals, which did not grow large enough to become planets, and thus, they are thought to preserve the precursor materials in the early solar system 4.5 Gyr ago. These small bodies are originally derived from accretion of interstellar dusts that are composed of an amorphous silicate, refractory organic material, and ice (Greenberg and Li 1997). Afterwards, interaction of organics, water, and minerals in protoplanetary disk and within planetesimals due to a variety of locations and chemical and physical processes (e.g., thermal, photochemical, and aqueous processes) produced compositional and geological diversity of small bodies. Thus, the investigation of these small bodies enables us to understand the history of the solar system formation. As the traditional theory of solar system formation is in the process of revising by the recent hypotheses, such as Nice model (Gomes et al. 2005) and Grand Tack model (Walsh et al. 2012), it is becoming increasingly important to substantiate the distributions and chemical evolution of organic molecules and water in the solar system for determining origins of life and planetary habitability.

To date, our understanding of chemical and physical processes in small bodies has been significantly improved by the extensive chemical analyses of organic materials and minerals in carbonaceous chondritic meteorites, interplanetary dust particles (IDPs), and Antarctic micrometeorites (AMMs) (see review in Alexander et al. 2017; Glavin et al. 2018; Yabuta et al. 2018). However, there have remained uncertainties in

the source and geological information for the chemical evolution, which are not clearly recorded in the fallen extraterrestrial materials. In order to link the cosmochemical features of meteorites, IDPs, and AMMs with geology of their original parent bodies, small bodies' sample return/landing explorations that integrate the outcomes from observation and sample analyses are essential. Another advantage of small bodies exploration is that one can obtain contamination-free extraterrestrial samples.

This chapter reviews (1) the achievements from the past small bodies' sample return/landing exploration missions (*Stardust*, *Hayabusa*, and *Rosetta*), (2) the scientific goals of the ongoing asteroid sample return missions (e.g., *Hayabusa2* and the Origins, Spectral Interpretation, Resource Identification, Security-Regolith Explorer [*OSIRIS-REx*]), and (3) the scientific strategies of future missions (e.g., *DESTINY4*). Integrated understanding of the missions that explore the small bodies in different evolution stages will be able to establish solar system science covering from interstellar medium to planetesimals.

12.2.2 STARDUST COMET DUST SAMPLE RETURN MISSION

Stardust is the first sample return mission of a comet, developed by the National Aeronautics and Space Administration (NASA). The *Stardust* spacecraft was launched in February 1999, collected the dust particles from comet 81P/Wild 2 in January 2004, and returned the samples to the Earth in January 2006. Comet 81P/Wild 2 is a Jupiter-family comet

that was brought into the inner solar system due to perturbations by Jupiter in September 1974. The comet is a 5-km-size oblate body from which jets of gas and dusts were observed, and it contained craters, mesas, and cliffs that were probably formed before its injection into the inner solar system (Figure 12.2.1a) (Brownlee et al. 2004).

Dust particles released from comet 81P/Wild 2 were collected by the spacecraft during its flyby at 6.1 km/s. In order to reduce possible alteration of cometary dust components upon high-velocity impact of dusts on the spacecraft, ultra-low-density silica aerogels (0.03 g/cm^3) were used as a capture material. The silica aerogel capture cells ($2 \times 4 \times 3 \text{ cm}$) were mounted into the tennis-racket-shaped dust collector with aluminum grids in the sample return capsule.

The impacted comet dusts on the dust collector produced impact craters on the aluminum grids and impact tracks (Figure 12.2.1b) with various sizes and shapes in the silica aerogels; this is reflected by diversity in size and density of the comet dust particles (Horz et al. 2006; Tsuchiyama et al. 2008). In comparison with hypervelocity impact experiments, it was suggested that carrot-type impact track is derived from a refractory (e.g., metal-rich) grain, and a bulbous impact track is derived from a volatile-rich particle. The dusts themselves were split into a number of smaller particles from the impact tracks. For the laboratory analyses, a thin section of silica aerogel containing the impact tracks, called *keystone*, was cut by needles mounted on a micro-manipulator, and the comet dust particles were carefully extracted at NASA curation facility.

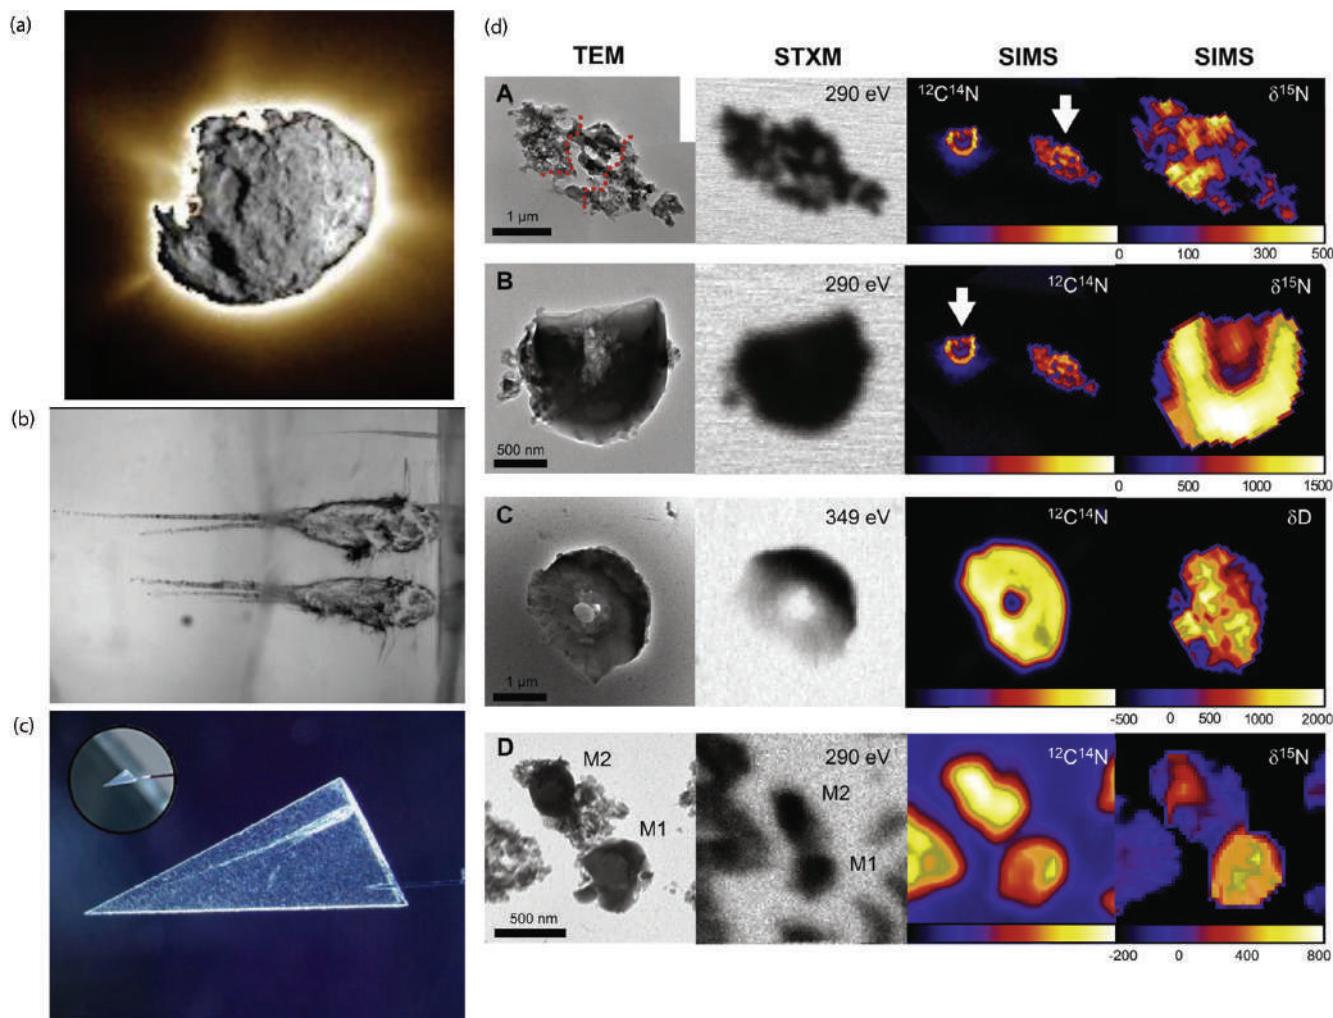

FIGURE 12.2.1 (a) Image of comet 81P/Wild 2 taken by the navigation camera during the close approach phase of Stardust's flyby of the comet. Credit: NASA. (b) Image of the impact tracks formed by two comet particles penetrating the silica aerogel mounted in Stardust spacecraft's comet dust collector. Credit: NASA. (c) Image of a wedge-shaped aerogel slice containing comet dust particles, called a keystone. A specialized silicon pickle fork is then used to remove the keystone from the remaining aerogel for further analysis. Credit: NASA. (d) Transmission electron microscopy (TEM) (left-most column) and scanning transmission x-ray microscope (STXM) (middle-left column) images of and secondary ion mass spectrometry (SIMS) maps of CN^- (middle-right column) and $\delta^{15}\text{N}$ or δD (right-most column) of extraterrestrial organic materials. (A) Organic section in comet Wild 2 dust particles. (B) Organic nanoglobule section in comet Wild 2 dust particles. (C) Organic nanoglobule in comet Wild 2 dust particles. (D) Two organic globules (M1 and M2) found in the insoluble organic residue from Murchison meteorite (De Gregorio et al. 2011).

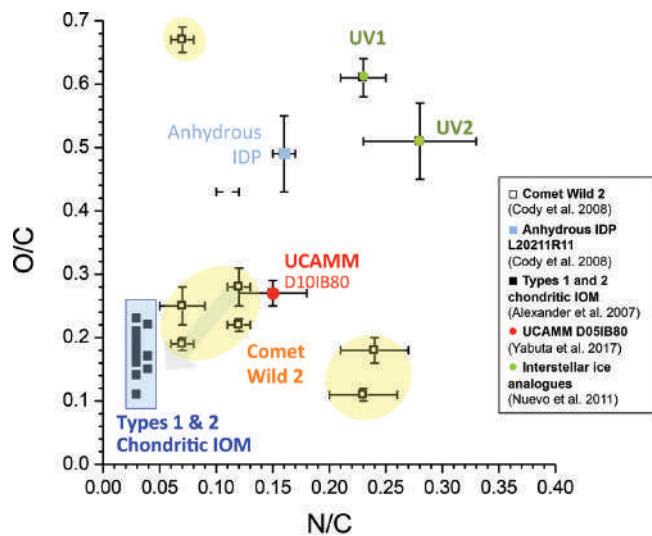

FIGURE 12.2.2 N/C versus O/C ratios of organics in the comet Wild 2 dust particles (□, Cody et al., 2008), the anhydrous IDP L2021R11 (■, Cody et al., 2008), types types 1 and 2 chondritic IOM (■, Alexander et al., 2007), the UCAMM D05IB80 (●, this study), and the UV irradiation products from interstellar analogues (●, Nuevo et al., 2011) ($\text{UV1 } \text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{CO}:\text{NH}_3 = 100:50:1:1$, $\text{UV2 } \text{H}_2\text{O}:\text{CH}_3\text{OH}:\text{CO}:\text{NH}_3:\text{C}_3\text{H}_8 = 100:50:1:1:10$). The ratios were estimated from the fitting of C-, N-, and O-XANES spectra.

Organic materials in some of the comet 81P/Wild 2 dust particles are poor in aromatic carbon, while they are enriched in aliphatic carbon and nitrogen- and/or oxygen-bearing functional groups, such as nitriles, amides, carboxyls, and alcohols (Sandford et al. 2006; Cody et al., 2008). These elemental and molecular compositions are distinct from insoluble organic matter (IOM) from primitive carbonaceous chondrites (Figure 12.2.2). Other comet 81P/Wild 2 dust particles show similar organic functional group chemistry to those of chondritic IOM, and some of the organic nanoglobules (Figure 12.2.1d) found in *Stardust* samples are highly aromatic (De Gregorio et al. 2011). These diversities in organic molecular compositions suggest that Wild 2 was not equilibrated and contains organic materials not found in meteorites or their asteroid parent bodies. On the other hand, hydrogen isotopic compositions of the organics in the 81P/Wild 2 dust particles are in a similar range of those in IDPs and carbonaceous chondrites (McKeegan et al. 2006); however, the highest value of hydrogen isotopic composition ($\delta\text{D} = 2200\text{\textperthousand}$) seen to date is an order of magnitude lower than that of other extraterrestrial materials. Nitrogen isotopic compositions of the organic material in the 81P/Wild 2 dust particles are terrestrial or slightly enriched ($\delta_{15}\text{N} = -55\text{\textperthousand} \sim +70\text{\textperthousand}$), except for a highly ^{15}N -enriched organic nanoglobule ($+136\text{\textperthousand} \pm 15\text{\textperthousand}$) (De Gregorio et al. 2011). Thus, it is suggested that a major fraction of the refractory organics in the comet is of nebular origin.

Polycyclic aromatic hydrocarbons (PAHs) ranging from one ring to six rings are seen in both comet 81P/Wild 2 dust particles and carbonaceous chondrites (Sandford et al. 2006). Methylamine, ethylamine, and glycine detected from the comet-exposed aerogel capture media are thought to be the products from energetically processed icy grains containing

NH_3 , CH_4 , and C_2H_6 (Glavin et al. 2008). Detection of only this one amino acid from comet 81P/Wild 2 is a great contrast to the detection of >70 kinds of amino acids from carbonaceous chondrites; however, this is probably largely due to the fact that *Stardust* samples are so small that the amino acids' abundances are below current detection limits. Another possible reason is that formation of amino acids did not occur efficiently in a cometary icy body, since the many reactions that form amino acids require liquid water (e.g., Strecker synthesis), although some amino acids can be made directly by ice irradiation.

Mineralogy of comet 81P/Wild 2 dust particles (e.g., silicates, glass with embedded metals and sulfides [GEMS]-like objects, Fe-Ni sulfides, and Fe-Ni metals) was mostly similar to that of anhydrous IDPs, while their compositions were diverse, indicating a wide range of formation condition in the solar system (Zolensky et al. 2006). Finding of crystalline silicates, high-temperature minerals, together with amorphous grains in the cometary dusts (Zolensky et al. 2006; Keller et al. 2006), indicated that large-scale mixing occurred in the early solar system (e.g., Brownlee et al. 2006). Discovery of chondrule-like objects from the Wild 2 dust particles further demonstrated the transportation of material from the inner to the outer solar system (Nakamura et al. 2008). According to the densities ($0.80\text{--}5.96 \text{ g cm}^{-3}$) of the cometary dust particles estimated by synchrotron X-ray-based three-dimensional structure analyses of the impact tracks, crystalline particles account for approximately 5 vol% (20 wt%) of the Wild 2 dust particles, which is consistent with the values of chondrules and calcium-aluminum inclusions (CAIs) (Iida et al. 2010).

Although little evidence of parent body aqueous alteration was reported from Wild 2 comet dust particles, several records of weak aqueous alteration, such as the presence of carbonate (Mikouchi et al. 2007), sulfides (e.g., cubanite grain [CuFe_2S_3], a pyrrhotite [$(\text{Fe}, \text{Ni})_{1-x}\text{S}$]/pentlandite [$(\text{Fe}, \text{Ni})_9\text{S}_8$] assemblage, and a pyrrhotite/sphalerite [$(\text{Fe}, \text{Zn})\text{S}$] assemblage) (Berger et al. 2011), cosmic symplectite (Nguyen et al. 2017), and magnetite (Hicks et al. 2017), have been reported.

12.2.3 HAYABUSA S-TYPE ASTEROID SAMPLE RETURN MISSION

Hayabusa is the Japan Aerospace Exploration Agency (JAXA)'s first mission to collect asteroid samples and return them to Earth for the laboratory analyses. The mission explored the near-Earth S-type (stony) asteroid 25143 Itokawa. The spacecraft was launched in May 2003 and arrived at Itokawa in September 2005 (Fujiwara et al. 2006). Itokawa is a 500-m-size asteroid. Its density was low (1.9 g/cm^3), and its porosity was estimated 40%. This asteroid is composed of two parts, the head and the body, and it has boulder-rich regions and smooth regions (Figure 12.2.3a–c). Based on the shape, boulders, low density, and high porosity, Itokawa was regarded as a rubble-pile asteroid, which was formed by re-cumulation of the fragments resulted from a collisional disruption of its parent body (Fujiwara et al. 2006). Near-infrared (IR) spectra of Itokawa were similar to those of an ordinary LL5 chondrite (Abe et al. 2006). However, the slight spectral difference between Itokawa

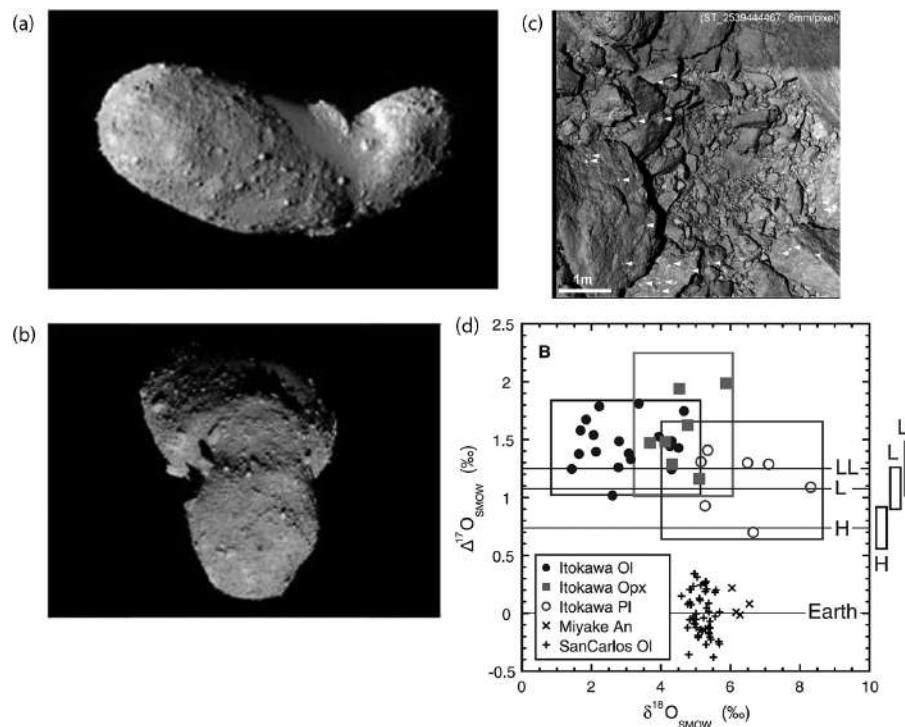

FIGURE 12.2.3 (a) Image of Itokawa taken from about 8 km away from the asteroid. Credit: JAXA. (b) Image of Itokawa taken from 4.4 km away from the asteroid. Credit: JAXA. (c) Close-up image of Itokawa on the east side at ranges below 2 km and down to 63 m. Large gravels generally overlie smaller particles. (Miyamoto et al. 2007). (d) Oxygen isotopic compositions of Itokawa minerals compared with those of a forsterite crystal from San Carlos, Arizona, USA, and an anorthite crystal from Miyake-Jima, Japan. Isotope variation defined by 2σ for each mineral is shown by a rectangle with a color of the corresponding symbol. Ol, olivine; Opx, orthopyroxene; Pl, plagioclase; An, anorthite; Miyake, Miyake-Jima. A mass fractionation line of the average O isotopic composition of LL chondrite group is shown as a reference. Variations (2σ) of whole-rock $\Delta^{17}\text{O}_{\text{SMOW}}$ values for H, L, and LL chondrite groups are shown to the right of the graph (Yurimoto et al. 2011).

and an LL5 chondrite is due to space-weathering processes on the surface of asteroid Itokawa (Hiroi et al. 2006).

The spacecraft faced several engineering troubles during its navigation and touchdown on the asteroid, which postponed the return date. Despite those difficulties, the spacecraft managed to return the sample canister to Earth in June 2010. At the Institute of Space and Astronautical Science (ISAS) curation facility at JAXA, 1534 particles of the asteroid Itokawa were identified (Nakamura et al. 2011), and the 1-year preliminary examination of the collected Itokawa particles was implemented.

For the first time, the direct link between an asteroid (an S-type asteroid) and meteorites (ordinary LL5-6 chondrites) was proved by comparison of the oxygen-isotopic compositions (Figure 12.2.3d) (Yurimoto et al. 2011), mineralogy (Nakamura et al. 2011; Noguchi et al. 2011), petrology (Tsuchiyama et al. 2011), and chemistry (Ebihara et al. 2011) between the Itokawa particles and meteorites. Mineralogical investigations indicated that the highly equilibrated Itokawa particles, which are mainly composed of olivine, low-Ca pyroxene, and plagioclase, experienced intense thermal metamorphism approximately at 800°C and cooled slowly to 600°C on its parent body larger than 20 km (Nakamura et al. 2011; Tsuchiyama et al. 2011). Those sample analyses also revealed the detailed processes of the asteroid surface, which were not seen in meteorites.

The size and three-dimensional shape distributions of the Itokawa particles were similar to those of fragments generated in laboratory impact experiments but they were not similar to lunar regolith particles. This result suggested that the asteroid surface experienced repetitive impact processes and abrasion of grains (Tsuchiyama et al. 2011). Fe-rich nanoparticles were observed in the rims of the surfaces of Itokawa particles, and they were regarded as space-weathering products based on the similarities with those of lunar soils (Noguchi et al. 2011). Additional observation of the surface morphology indicated that the space-weathered rim with blisters was formed mainly by solar wind irradiation (Figure 12.2.4) (Matsumoto et al. 2015). The helium, neon, and argon isotopic compositions of the Itokawa particles were close to the solar wind compositions (Nagao et al. 2011). Various profiles of noble gas release are reflected by repeated solar wind implantation, in addition to a preferential loss of helium due to friction among the particles or sputtering by other solar wind particles (Nagao et al. 2011). According to the cosmic exposure ages estimated by neon isotopic compositions (Nagao et al. 2011) and the crater retention age estimated by a new crater-size scaling law (Tatsumi and Sugita 2018) (Figure 12.2.5), global resurfacing of Itokawa in the main belt occurred 3–33 million years after the complete breakup of its parent body with collisions.

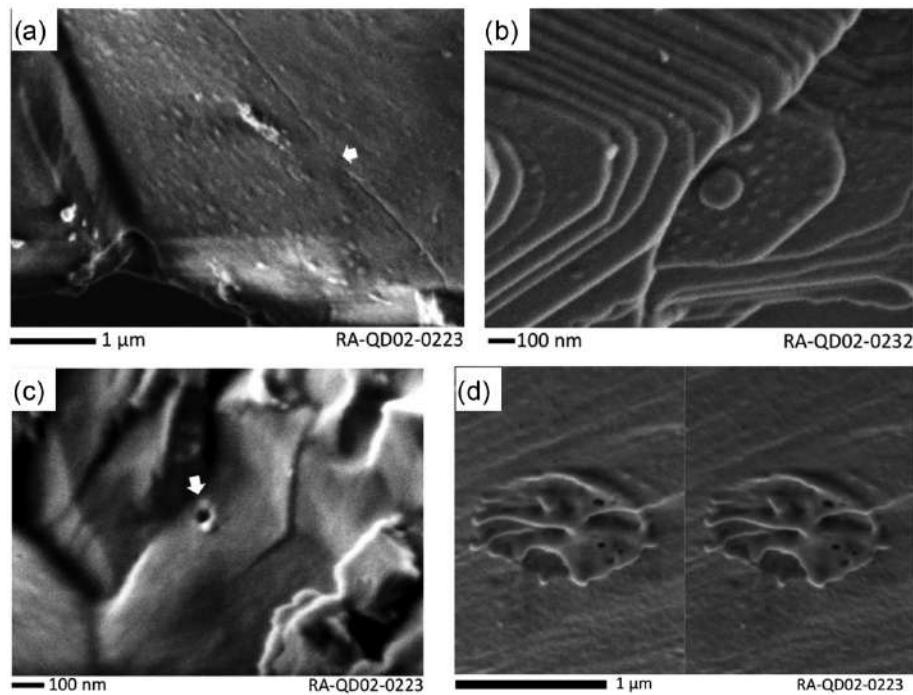

FIGURE 12.2.4 (a) Secondary electron (SE) Field Emission Scanning Electron Microscopy (FE-SEM) image of fine spotted structures (blisters) on a space-weathered rim on the wavy and stepped surface of an Itokawa particle (RA-QD02-0223), (b) SE FE-SEM image showing blisters on a concentric stepped surface of low-Ca pyroxene on an Itokawa particle (RA-QD02-0232), (c) SE FE-SEM image showing a pit or a crater-like structure of about 50 nm in diameter (indicated with an arrow) on a low-Ca pyroxene surface of an Itokawa particle (RA-QD02-0223), and (d) SE FE-SEM stereo image of another crater-like structure some 1 μm in diameter on an opposite surface of the same particle, indicating particle motion due to the regolith activity (Matsumoto et al. 2015).

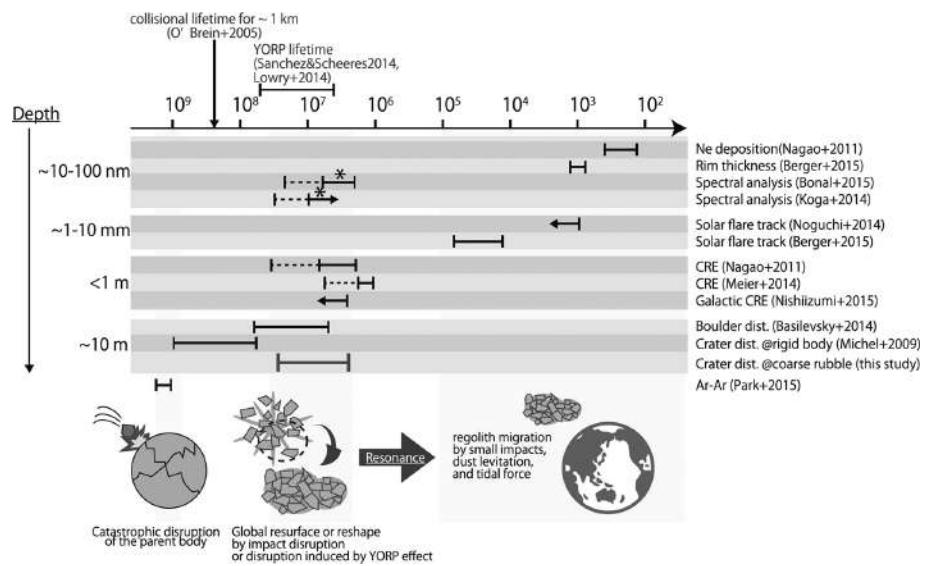

FIGURE 12.2.5 Comparison among Itokawa surface ages estimated from analyses of returned samples and the remote-sensing data. The solid lines indicate original literature values based on near-earth orbits. Dashed lines indicate ages recalculated with a reduced solar wind flux in the main belt. The age estimates with asterisks may be macroscopic surface ages (Tatsumi and Sugita, 2018).

The preliminary examinations of carbonaceous materials/organic compounds for the Itokawa particles were also conducted; however, the carbon contents in the particles were so low that they were below the detection limits of the analytical instruments (Naraoka et al. 2012). Aside from the Itokawa particles,

58 unknown carbonaceous particles were collected from a sample catcher (Yada et al. 2014). In order to determine their origins, the coordinated analytical investigations for the several carbonaceous particles have been carried out (Ito et al. 2014; Yabuta et al. 2014; Uesugi et al. 2014; Kitajima et al. 2015; Naraoka et al. 2015). As a

result, it was revealed that those carbonaceous particles were lack of any robust isotopic or mineralogical evidence of extraterrestrial origin and that they were very likely terrestrial contamination derived from the degradation products of polymer materials used in the spacecraft and/or biological origin. The result that indigenous organic compounds from Itokawa have not been identified is reasonable, considering that the parent body of Itokawa experienced 600°C–800°C, which could have thermally decomposed or dehydrated if there were organics and/or water.

12.2.4 ROSETTA COMET RENDEZVOUS MISSION

The European Space Agency (ESA's) *Rosetta* mission is the first mission to rendezvous with Jupiter-family comet 67P/Churyumov–Gerasimenko (Figure 12.2.6a and b) and land on its surface by using a small lander (Philae). The spacecraft was launched in March 2004, arrived at and released Philae

to comet 67P/Churyumov–Gerasimenko in 2014, and carried out observation for 14 months till December 2015. Remote-sensing observation and in situ analyses of organic molecules and volatiles were made using the Visible, Infrared, and Thermal Imaging Spectrometer (VIRTIS), the Cometary Secondary Ion Mass Analyser (COSIMA), and the Rosetta Orbiter Spectrometer for Ion and Neutral Analysis (ROSINA) instruments on the *Rosetta* mothership and the Cometary Sampling and Composition (COSAC) experiment and Ptolemy gas analyzer equipped on the Philae lander. Altogether, the Rosetta mass spectrometer detected about 60 volatile species in the coma of the comet. This includes the approximately two dozen parent species that had been seen from the ground observation at ultraviolet (UV), IR, and radio wavelengths.

The VIRTIS showed that water is largely absent from the surface of 67P/Churyumov–Gerasimenko, except for small spots of water ice (Figure 12.2.6c) (Auger et al. 2015), indicating that the surface is dehydrated by solar heating (Capaccioni

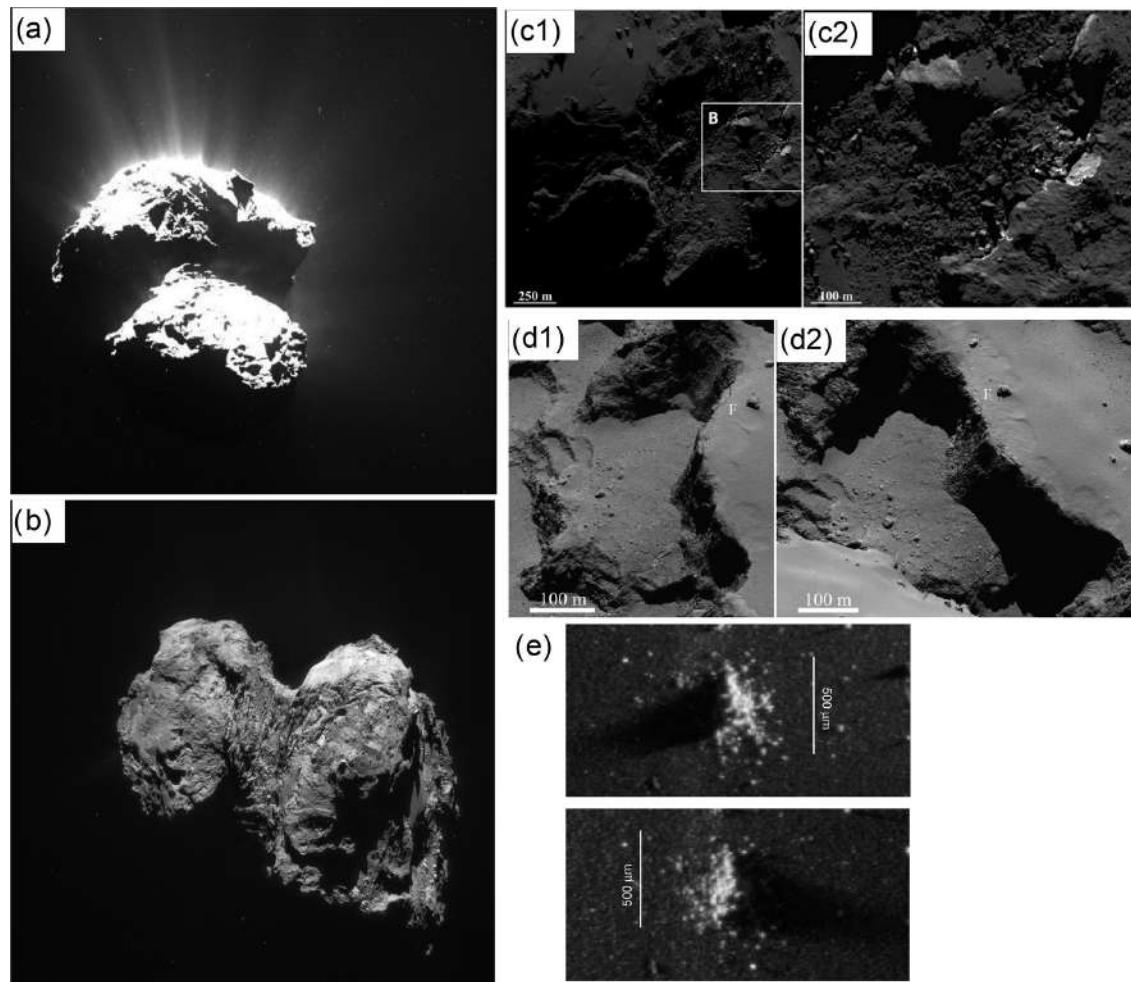

FIGURE 12.2.6 (a) Image of Comet 67P/Churyumov–Gerasimenko taken from a distance of about 170 km. Credit: ESA/Rosetta/MPS for OSIRIS Team MPS/UPD/LAM/IAA/SSO/INTA/UPM/DASP/IDA. (b) Image of Comet 67P/Churyumov–Gerasimenko taken from a distance of 67.6 km. Credit: ESA/Rosetta/NavCam. (c) Color-composite images of possible water-ice patches associated with a scarp east of the region that has been illuminated daily for several months on the surface of comet 67P/ Churyumov–Gerasimenko (Auger et al. 2015). (d) The two views of the cliff edge of comet 67P/ Churyumov–Gerasimenko taken on different dates. The feature likely leads to the slumping of material. Image was taken from a distance of 30 km (Vincent et al. 2015). (e) One of the dust particles (500- μm size) that was collected by the collecting target of COSIMA (Schulz et al. 2015).

et al. 2015; Quirico et al. 2016). For the first time, dark refractory organic materials, which may be associated with opaque minerals (e.g., Fe–Ni metals and FeS), were discovered on the cometary surface. Its reflectance spectra with low albedo features are distinct from those of IOM in carbonaceous chondrites but are close to the aliphatic- and carboxyl-rich organic materials produced by UV irradiation of cometary ice analogs (Quirico et al. 2016).

The COSIMA detected 27,000 dust particles of comet 67P/Churyumov–Gerasimenko and acquired mass spectra of 200 particles of them (Figure 12.2.6e) (Fray et al. 2016). They revealed that the Na/Mg ratio was as high as those of Leonids and Perseid meteor showers, but they were much higher than those of carbonaceous chondrites (Figure 12.2.7a) (Fray et al. 2016). Thus, it was concluded that comet 67P/Churyumov–Gerasimenko dusts were similar to IDPs and AMMs but they were not similar to meteorites. Carbon-bearing ions were detected by both positive and negative ion modes, but unlike other known organic molecule series, the detected ions were only less than m/z (mass) 50, indicating that the organic material in the 67P/Churyumov–Gerasimenko is refractory, hydrogen-poor aromatic structure (Fray et al. 2016). The result appears to be in line with those obtained by VIRTIS. According to the comparison of the mass spectra between 67P/Churyumov–Gerasimenko and carbonaceous chondrites, the H/C ratios

of 67P/Churyumov–Gerasimenko are higher than those of carbonaceous chondrites (Figure 12.2.7b). In addition, C/Si ratios of comet 67P/Churyumov–Gerasimenko dust particles estimated from the Time-of-Flight Secondary Ion Mass Spectrometry (ToF-SIMS) data were similar to that of comet 1P/Halley, while the values were much higher than those of chondritic-porous IDPs and carbonaceous CI chondrites (Figure 12.2.7e) (Bardyn et al. 2017). This difference suggests that the comet records the initial compositions of precursor molecules in the outer region of protoplanetary disk, before the nebula processing and/or parent body alteration.

The COSAC mass spectrometer analyzed volatile and organic compounds in sniffing mode after Philae's touch-down on the comet 67P/Churyumov–Gerasimenko surface. Of the 16 kinds of molecules tentatively identified (Goesmann et al. 2015), 12 are the expected molecules that have been observed by ground observations: H_2O , CH_4 , HCN , CO , methylamine (CH_3NH_2), acetonitrile (CH_3CN), isocyanic acid (HNCO), etc. Newly observed molecules include methyl isocyanate (CH_3NCO), acetone ($\text{CH}_3(\text{CO})\text{CH}_3$), propionaldehyde ($\text{C}_2\text{H}_5\text{CHO}$), and acetamide ($\text{CH}_3(\text{CO})\text{NH}_2$). Sulfur-bearing molecules were not detected. Unexpectedly, typical cometary volatiles, NH_3 , CO_2 , and formaldehyde (HCHO), were not detected, possibly because the measured area (nucleus surface) was depleted in volatile components. In contrast, CO_2 was

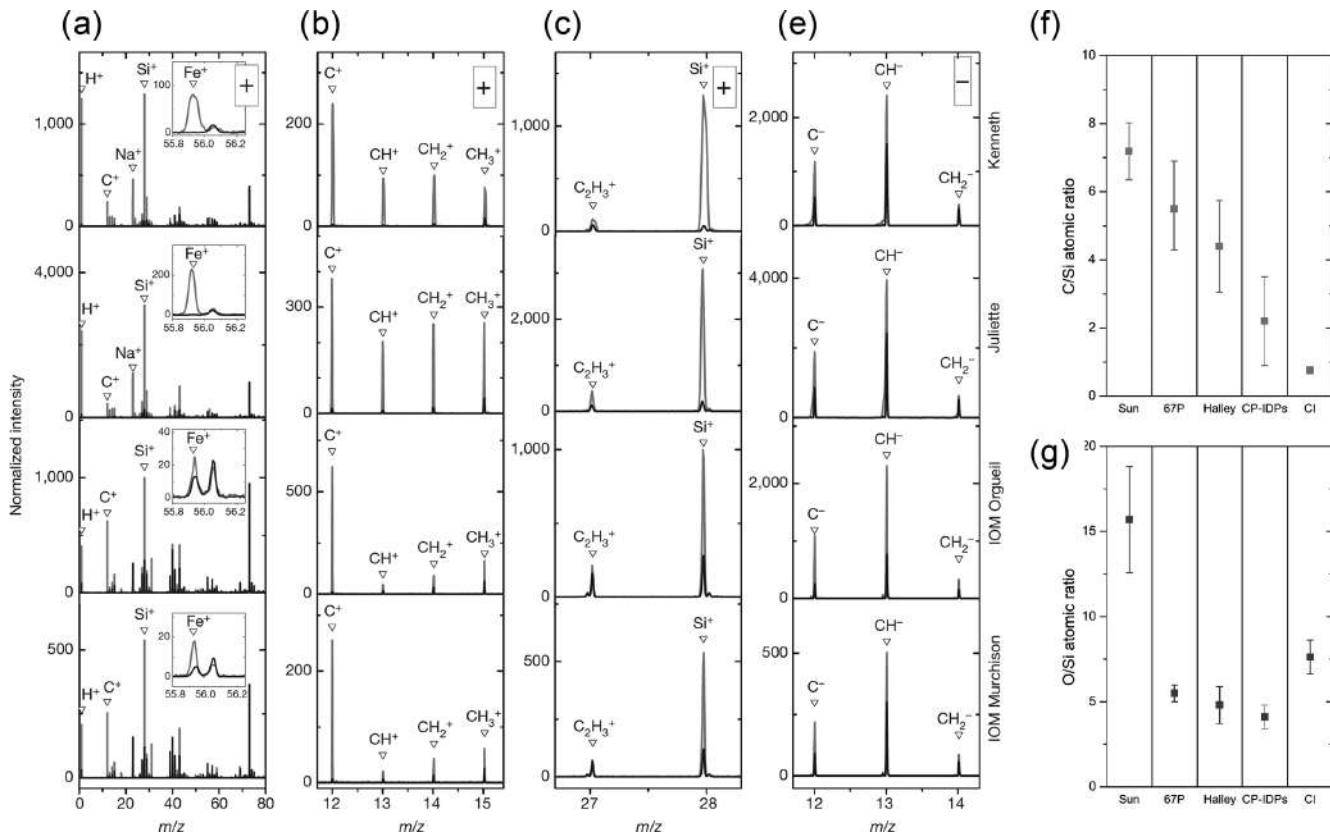

FIGURE 12.2.7 (a–d) Comparison of ToF-SIMS data of comet 67P/ Churyumov–Gerasimenko dust particles (Kenneth and Juliette) and IOM from Orgueil and Murchison carbonaceous chondritic meteorites (Fray et al. 2016). (f, g) Comparison of (f) carbon and (g) oxygen elemental ratios relative to silicon in the protosolar disc (Sun), comet 67P/ Churyumov–Gerasimenko dust particles (based on the data from COSIMA), comet Halley dust particles, chondritic-porous IDPs, and carbonaceous CI chondrites (Bardyn et al. 2017).

detected in abundance by Ptolemy gas analyzer, which measured coma gases. Formation of the identified nitrogen- and oxygen-bearing molecules can be explained by UV irradiation and/or radiolysis of cometary ice.

In addition, the ROSINA detected abundant CO₂ and ethane relative to water from the coma of 67P/Churyumov-Gerasimenko (Le Roy et al. 2015). Also of note is the detection of abundant molecular oxygen at the 4% level. Because protoplanetary disk models suggest that O₂ can only form in the gas phase at mid layers and because of the strong correlation of O₂ with H₂O, it has been suggested that the O₂ is preserved from the interstellar medium (Bieler et al. 2015).

It has been expected that the sources of volatile inventory to the terrestrial planets were recorded in the hydrogen isotopic compositions of small bodies. The ROSINA revealed that the D/H ratio of water from 67P/Churyumov–Gerasimenko [(5.3 ± 0.7)×10⁻⁴] was approximately three times the terrestrial value (Altwegg et al. 2015). If comet 67P/Churyumov–Gerasimenko is representative of all comets, then it is unlikely that comets are the major source of Earth’s water. However, given the large variation in D/H seen in comets so far, no firm conclusion can yet be drawn. An asteroidal origin for terrestrial water is more likely, based on the similarity in D/H between carbonaceous chondrites and terrestrial ocean water (Alexander et al. 2012).

12.2.5 HAYABUSA2 C-TYPE ASTEROID SAMPLE RETURN MISSION

Hayabusa2 is a C-type (carbonaceous) asteroid sample return mission of JAXA to explore the near-Earth C-type asteroid 162173 Ryugu (1999 JU3). The scientific goal of *Hayabusa2* is to investigate organic molecules and water are considered as origin of Earth life and ocean, as well as the major building blocks of the solar system.

The *Hayabusa2* spacecraft was launched on December 3, 2014, and arrived at the asteroid Ryugu on June 27, 2018. During its 18-month stay, remote-sensing observations will be carried out with the on-board instruments. *Hayabusa2* is planned to collect asteroid samples from up to three sites. It is planned that one of the three locations to collect samples will be around the artificial crater created by the small carry-on impactor (SCI) (Saiki et al. 2016), a new component of the *Hayabusa2*, which enables collection of internal materials (i.e., impact ejecta) of Ryugu. The collected samples will be returned to Earth in December 2020.

The sample catcher and container of *Hayabusa2* basically follow those used in *Hayabusa*; a 5-g Ta projectile will be shot at 300 m/s upon touchdown, and the ejecta will be transferred into a sample catcher through an extendable sampler horn under microgravity (Tachibana et al. 2014). Several improvements have been added for collecting volatiles and organics, such as aluminum metal-seal system and gas-sampling interface (Okazaki et al. 2016). The sampling recovery is estimated at a level of hundreds of milligrams.

Ryugu has been thought to be similar to the CM chemical group of carbonaceous chondrite, according to the grand-based

observation that a 0.7-μm absorption feature in a reflectance spectrum, which is derived from iron-bearing phyllosilicates (e.g., serpentine), was detected (Villas 2008). On the other hand, the other ground-based observations did not detect a clear feature of 0.7 μm (Lazzaro et al. 2013; Moskovitz et al. 2013). Thus, hydrous minerals may be distributed locally and/or during a limited time period (Kameda et al. 2015). Their reflectance spectra can also be explained by a combination of the heated Murchison meteorite at different temperatures (Hiroi et al. 1993), and thus the surface of the asteroid Ryugu may have experienced heterogeneous heating, for example, impact, space weathering, and solar radiation heating.

Hayabusa2 mission will perform three types of multi-scale observations: remote-sensing instruments, rover, and laboratory sample analyses. Remote sensing will be carried out by the four onboard instruments: an optical navigation camera (ONC), a near-infrared spectrometer (NIRS3), a thermal infrared imager (TIR), and a light detection and ranging (LIDAR) (Table 12.2.1). These instruments will perform kilometer to meter scale of geological and topographical survey almost all over the Ryugu and provide the global map data of the physical properties and chemical compositions of the asteroid surface, which will be used for the landing site selection. A hopping rover developed by Deutsches Zentrum für Luft- und Raumfahrt (DLR) and Centre national d'études spatiales (CNES), Mobile Asteroid Surface Scout (MASCOT), is composed of four instruments, a camera (Cam), a near-infrared microscope (MicrOmega), a MASCOT Radiometer (MARA), and a magnetometer (MaG), and plays roles of both observation and sample analyses, with centimeter to micrometer scale, helping to bridge between the two different scales. Laboratory sample analyses will conduct the high-precision and high-sensitivity quantitative measurements of elemental, isotopic, mineralogical, and molecular compositions of the returned asteroid samples with micrometer to nanometer scale, for determination of origin, evolution, and chronology of the solar system.

12.2.6 OSIRIS-REx B-TYPE ASTEROID SAMPLE RETURN MISSION

Origins, Spectral Interpretation, Resource Identification, Security, Regolith Explorer (OSIRIS-REx) is NASA’s sample return mission to target a B-type carbonaceous asteroid (101955) Bennu (500-m size) (Lauretta 2016). OSIRIS-REx and *Hayabusa2* share the same scientific goal. Bennu has a relatively featureless spectrum that was similar to that of a carbonaceous CM1 chondrite (Clark et al. 2011). The OSIRIS-REx spacecraft was launched in September 2016 and will arrive at Bennu in 2018. Observation of Bennu will be carried out by the OSIRIS-REx camera suite (OCAMS), OSIRIS-REx laser altimeter (OLA), the visible and infrared spectrometer (OVIRS), and thermal emission spectrometer (OTES). More than 60 g of regolith will be sampled by blowing a N₂ gas jet from a sampler head of the articulated positioning arm (touch-and-go sample acquisition mechanism [TAGSAM]) to the regolith and by collecting them into the collection chamber. The asteroid sample will be returned to Earth in 2023.

TABLE 12.2.1
Remote-Sensing Instruments and Data Products

	ONC-T	TIR	NIRS3	LIDAR
Wavelengths	390, 480, 550, 700, 860, 950 nm	8–12 μm	1.8–3.2 μm	
View angle	$5.7^\circ \times 5.7^\circ$	H16 \times V12	$0.11^\circ \times 0.11^\circ$	1 mrad = 0.057
Pixels	1024×1024	320×240	1	1
Spatial resolution	1 m/pix (@10 km) 1 cm/pix (@100m)	20 m	38 m	20 m
Physical properties of asteroid surface	Shape model Hapke roughness-parameters	Maps of (1) Thermal inertia (2) Grain size (3) Maximum temperature		Distance Roughness
Hydrous minerals	Reflectance spectra and 1- and 7-band image data of: (1) 0.7- μm absorption depth		NIR reflectance spectra and spectral feature maps of: (1) 3- μm band depth (2) 3- μm band center (3) Near infrared albedo	
Organic carboncontents	(2) Albedo at 390 and 550 nm			
Secondary processes	(3) Spectral slope (480–860 nm) (4) Spectral slope in UV		(4) Spectral slope (1.8 μm to 2.6 μm)	
Safety and sampling recovery	(5) Boulder sizefrequency	Same as above (1)-(3)		Same as above

12.2.7 FUTURE SMALL-BODY MISSION: DESTINY+

DESTINY+ (Demonstration and Experiment of Space Technology for INterplanetary voYage Phaethon fLyby dUST science) is JAXA's mission to flyby of Geminids parent (3200 Phaethon and in situ dust analyses; this mission is in a pre-project phase selected as JAXA's Epsilon class small program and it is planned to launch in 2022. *DESTINY+* aims to understand (i) the physical and chemical properties and origins of interstellar dusts and IDPs and (ii) the dust ejection mechanism of the asteroid Phaethon for elucidating the nature and origin of cosmic dusts brought to the early Earth in the context of exogenous delivery of life's building blocks (Arai et al. 2018).

Phaethon has been known as an active asteroid from which recurrent dust ejection is observed at its perihelion (0.14 au) (e.g., Jewitt and Li, 2010; Arai et al. 2018). The unique feature of the small body will be an important clue to unveil the genetic link between primitive asteroids and comets. The reflectance spectra of Phaethon are similar to those of B-type asteroids (e.g., Licandro et al. 2007). The spectra are partially similar to the spectral features of heated carbonaceous CI/CM chondrites (Licandro et al. 2007), carbonaceous CK chondrites (Clark et al. 2010), and carbonaceous chondrites with larger grain sizes (e.g., Cloutis et al. 2012). The surface geology of Phaethon will be observed by panchromatic telescopic camera (TCAP) and visual (VIS) - near infrared (NIR) multiband camera (MCAP) (Arai et al. 2018).

The *in situ* dust analyzer (*DESTINY+* Dust Analyzer, DDA) is a time-of-flight mass spectrometer developed by Stuttgart University, Germany, with heritage of Cassini Cosmic

Dust Analyzer (CDA) onboard Cassini (e.g. Srama, 2014). The great advantage of DDA is to obtain the flux, masses, velocities, orbits, and compositions for the individual dust particles at one time, which will enable the identification of interstellar dusts, cometary IDPs and asteroidal IDPs during the cruise phase. That is to say, *DESTINY+* dust science will have an opportunity to comprehensively decipher the chemical evolution from interstellar medium to solar nebula and planetesimals in the early Solar System.

12.2.8 CONCLUSION

Small bodies sample return/on-site analysis missions will surely continue to be regarded as one of the significant astrobiological approaches after Rosetta, Hayabusa2, and OSIRIS-REx. In future, it is expected to plan to collect not only primitive asteroids but also the small bodies in various stages of evolution, ranging from more primitive icy small bodies (comets) to differentiated asteroids, for better understanding of how diverse the chemical and physical processes in the early solar system occurred. In other words, explorations of both volatile suppliers (e.g., primitive asteroids and comets) and building blocks of the Earth system will be required for answering the question where we came from. It is therefore important to expand chemical analyses strategies, so that we are able to handle any type of returned samples. It is worth improving next-generation analytical techniques targeting a large sample that retains geological information. Destructive techniques (e.g., combustion and pyrolysis) and wet chemistry (e.g., for soluble organic molecules and trace elements) were not positively applied in the past missions, but they are powerful

techniques to obtain the bulk compositions of returned samples, which provide insights on the formation of target bodies.

Therefore, future technological development in close connection with extraterrestrial material research, as well as synergy among the development of sample collection/preservation techniques, curation facility, and laboratory analysis of returned samples, will be extremely important. Collecting larger amount of samples, underground samples of the target bodies, and/or various states of materials (e.g., ice, liquid, and gas) will be of scientific value. In particular, it is necessary that researchers from observation, sample analyses, and engineering work together to share the common picture of multi-scale small-body science.

12.3.1 INTRODUCTION

Earth's ocean is unique in the solar system. No other world orbiting our Sun has a surface covered in liquid water. By contrast, subsurface oceans appear to be relatively common in the outer solar system. Three giant oceans have been confirmed in moons of Jupiter: Europa, Ganymede, and Callisto. Saturn hosts two, and possibly four, worlds with subsurface oceans: Enceladus and Titan. For discussion of Saturn's moons Mimas and Dione, we direct the reader to work by Beuthe (2016). Beyond Saturn, Neptune's moon Triton likely contains an ocean, as does the Kuiper-Belt object Pluto. These worlds contain the first prerequisite for life as it exists on Earth. From the handful of additional available constraints obtained by spacecraft missions, some of these worlds also appear to provide the chemical conditions needed to sustain life. Planned spacecraft missions will begin to look for signs of habitability and extant life in some of these icy ocean worlds, and missions to follow in the ensuing decades may have the chance to sample living organisms directly. This chapter focuses on the astrobiological context of icy ocean worlds. For an excellent review of their physical workings and details on different means for detecting subsurface oceans, the reader is directed to the paper by Nimmo and Pappalardo (2016) ([Figures 12.3.1](#) and [12.3.2](#)).

12.3.2 EVIDENCE FOR OCEANS AND PROSPECTS FOR HABITABILITY

12.3.2.1 EUROPA

A present-day ocean has been inferred from the magnetic field induced within the near subsurface by Jupiter's changing field, as observed during multiple flybys of the *Galileo* spacecraft (Kivelson et al., 2000). This measurement reveals only that a global electrically conductive layer exists near the surface, consistent with salty water. The overall conductance (the product of conductivity and thickness) is not well constrained. Thus, based on the induced magnetic field alone, Europa's ocean may be highly saline and only a few kilometers thick or more dilute than Earth's ocean and hundreds of kilometers thick. The latter seems more likely, based on geochemical measurements of Europa's bulk structure.

Galileo and *Voyager* spacecraft measurements determined that Europa has a large bulk density and small gravitational moment of inertia ([Table 12.3.1](#)).

From these, it can be inferred that Europa is strongly differentiated, likely hosting a metallic core underneath a rocky mantle. The H₂O covering Europa is 80- to 170-km thick (Anderson et al., 1998). The corresponding pressure at the seafloor is as high as ~200 MPa, not much higher than in the

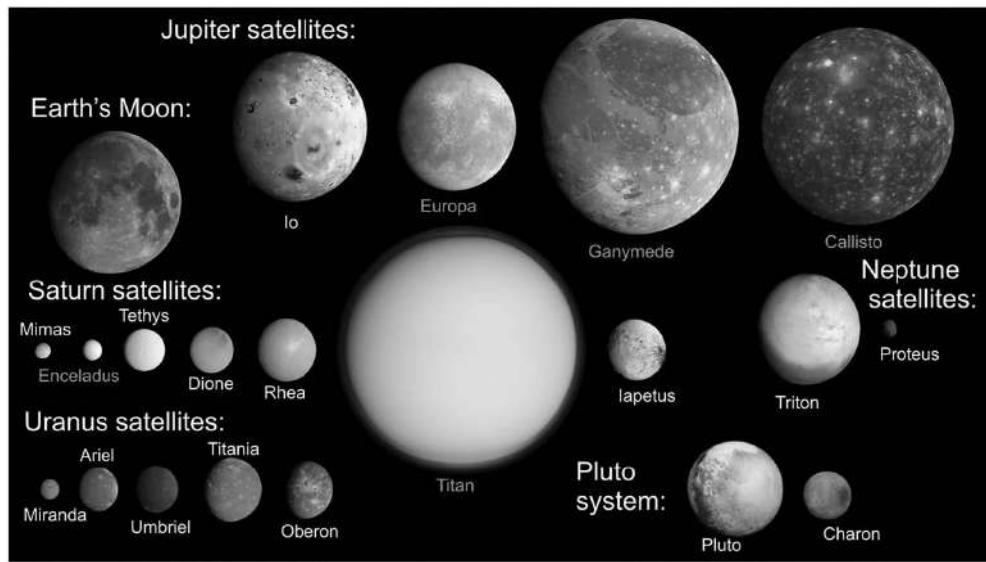

FIGURE 12.3.1 Some prominent worlds of the outer solar system, with Earth’s Moon for comparison. Nine of them show evidence for extant subsurface oceans. (Courtesy of NASA/JPL/SSI/JHUAPL/SwRI data, processed by Emily Lakdwalla, Ted Stryk, Gordan Ugarkovic, and Jason Perry.)

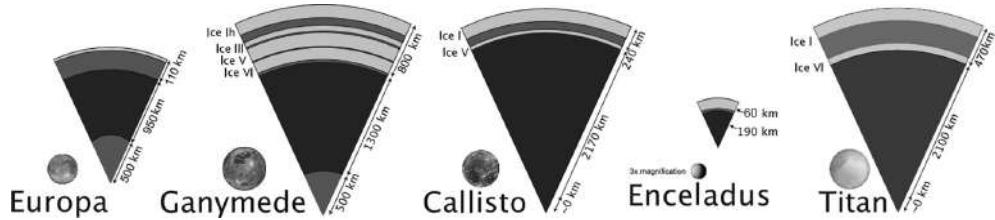

FIGURE 12.3.2 Basic interior structures of known icy ocean worlds based on observed bulk densities and gravitational moments of inertia. Layer thicknesses are not provided with precisions commensurate with known radii (Table 12.3.1), because the interpreted thicknesses depend on the assumed material properties. (Modified from Vance, S. D. et al., *J. Geophys. Res. Planets*, 123, 180–205, 2018; see that reference for more detailed exploration of interior structure and composition, as they relate to the habitability of icy ocean worlds.)

TABLE 12.3.1
Internal Structure Properties of Confirmed Ocean Worlds, Obtained from Robotic Missions of Exploration

	Radius (km)	Density (kg m ⁻³)	Moment of Inertia
Europa ^a	1565.0 ± 8.0	2989 ± 46	0.346 ± 0.005
Ganymede ^a	2631 ± 1.7	1942.0 ± 4.8	0.3115 ± 0.0028
Callisto ^a	2410.3 ± 1.5	1834.4 ± 3.4	0.3549 ± 0.0042
Enceladus ^{b,c}	252.1 ± 0.2	1609 ± 5	0.335
Titan ^c	2574.73 ± 0.09	1879.8 ± 0.004	0.3438 ± 0.0005

(Eds.), *Jupiter: The Planet, Satellites and Magnetosphere*, pp. 281–306, Cambridge University Press, Cambridge, UK, 2004; ^bThomas, P., *Icarus*, 208, 395–401, 2010; Iess, L. et al., *Science*, 344, 78–80, 2014; ^cJacobson, R. et al. *Astronom. J.*, 132, 2520–2526, 2006; Iess, L. et al., *Science*, 337, 457–459, 2012.

deepest parts of Earth’s ocean. Given the expected long history of tidal heating of Europa, it seems likely that the interior has fully differentiated to create a metallic core (Hussmann and Spohn, 2004).

Europa’s geology suggests a high heat flux and thus a thick ocean. The icy surface appears to be geologically active; *Galileo* imaging may have even captured evidence of active resurfacing (Schmidt et al., 2011). The ice is perhaps <10-km thick. Tectonic activity has remade the entire icy surface, layering it with linear fractures and broader banded features. Based on the incomplete imaging coverage, the driver for tectonic resurfacing of Europa’s ice may be plate tectonics and subduction analogous to the dynamics of Earth’s mantle (Greenberg et al., 1998; Kattenhorn and Prockter, 2014).

Extrusion of brines in chaotic terrains (Collins and Nimmo, 2009; Schmidt et al., 2011; Kattenhorn and Prockter, 2014) may create conditions analogous to geyser formation and eruption on Earth. This is exciting from a standpoint of mission design, because it may be possible to sample materials

from the ocean, without landing on the surface. To date, three separate *Hubble* Space Telescope observations have shown evidence for eruptive emissions, water jetting hundreds of kilometers above Europa's surface (Roth et al., 2014; Sparks et al., 2016, 2017). These intermittent detections suggest, by contrast with Saturn's moon Enceladus, that eruptions from Europa are infrequent. Alternatively, the emissions may not escape Europa's higher gravity and so may not be as easily detected with available instrumentation. Modeling suggests that dense particles and gas emissions from Europa rarely exceed the 100 km in altitude (Southworth et al., 2015).

12.3.2.2 GANYMEDE

Ganymede is the largest icy ocean world and is altogether different from Europa and from Earth. Ganymede's low density means that it contains hundreds of kilometers of water, like the other large satellites Callisto and Titan. However, Ganymede is more differentiated than the other large satellites, with a low moment of inertia (Table 12.3.1), corresponding to an H₂O thickness of up to 900 km.

Based on models of the interior structure that account for the diverse properties of water and ice, and that account for the freezing point suppression of various salts that may be dissolved in the ocean, Ganymede's seafloor is covered with hundreds of kilometers of high-pressure ice (III, V, VI; Vance et al., 2014, 2018), unless the ocean is very warm and saline. The ice Ih covering Ganymede is at least 30-km thick and possibly thicker than 150 km if Ganymede cooled efficiently during its long history (Hussmann and Spohn, 2004; Bland et al., 2009; Kimura et al., 2009). Its young surface (Collins et al., 2013) and evidence for active resurfacing (Hammond and Barr, 2014) also support the notion of a warm interior.

Ganymede has an endogenous dipolar magnetic field (Schubert and Soderlund, 2011). This unique feature among icy ocean worlds is consistent with a hot interior with a molten iron core that creates a dynamo similar to Earth's (e.g., Bland et al., 2008; Kimura et al., 2009). The implied high heat flux is perhaps more consistent with the thinner-ice scenario. *Hubble* tracking of the oscillating auroral ovals (Saur et al., 2015) provides further evidence for Ganymede's ocean, placing minimum bounds on the salinity of roughly 1 g kg⁻¹ (as estimated from Hand and Chyba, 2007, Figure 12.3.1).

12.3.2.3 CALLISTO

Callisto may be nearly frozen. Its icy surface appears to have been geologically inactive for the past 4 Gyr; it is heavily cratered and darkened by dusty materials that were not completely characterized by Voyager or Galileo (Moore et al., 2004). Despite its apparent inactivity, *Galileo* flybys revealed an induced magnetic response to Jupiter's field (Khurana et al., 1998; Zimmer et al., 2000) and thus evidence for a present-day ocean. The ice covering probably undergoes solid-state convection under the upper 100 km or more of warm ice below, making Callisto the only known example of solid-state convection under a fully stagnant lid (McKinnon,

2006). If Callisto's ocean is nearly frozen, its remaining fluids should approach a eutectic composition, the composition with the lowest freezing point. Suppression of the freezing point may mean that high-pressure ices are mostly absent in Callisto. Densification of the fluids means that where such ices occur, they may be buoyantly unstable.

12.3.2.4 ENCELADUS

Though tiny by comparison with the other known ocean worlds, Enceladus is cryovolcanically active (e.g., Spencer and Nimmo, 2013). Its south polar plumes dissipate >10 GW of heat, which can only be explained by tidal flexing of the interior (Choblet et al., 2017). Possible mechanisms driving the plumes include flowing liquids within the ice (Roberts and Nimmo, 2008; Kite and Rubin, 2016), boiling liquids reminiscent of geysers or volcanoes on Earth (Postberg et al., 2009), or some combination thereof (Ingersoll and Nakajima, 2016; Nakajima and Ingersoll, 2016). The eruptive output is modulated with Enceladus's orbit (33-hour period; Hedman et al., 2013); fluxes are highest when the conduits at the south pole are under tension from tidal forces.

The ocean's pH is constrained from direct sampling of gas and dust from the plumes, based on the abundance of CO₂ (Glein et al., 2015). Silica nanograins found in ice particles from the plumes (Hsu et al., 2015) are best explained as forming in the rocky interior from hydrothermal rock-water interactions in alkaline solution above 90°C. A fully water-permeable interior would facilitate such water-rock interactions and has been predicted on the basis of thermal fracturing (Vance et al., 2007, 2016a) and gravity models (Vance et al., 2018; Waite et al., 2017). Taken at face value, thermal fracturing should enable water-rock alteration to produce the high hydrogen and methane concentrations, observed in the Enceladus plumes (Waite et al., 2009). The high inferred ocean pH (>11), consistent with active serpentinization (Glein et al., 2015), could imply that the ocean is relatively young—perhaps owing to recent migration into tidal resonance with Dione (Cuk et al., 2016)—or that serpentinization has proceeded very slowly.

12.3.2.5 TITAN

Saturn's largest moon (comparable in size to planet Mercury) has a hydrocarbon-rich atmosphere (1.4 atm N₂ at its surface; Teanby et al., 2012; Hörst, 2017). The surface covering of solid and liquid hydrocarbons at 92 K generates hydrological features familiar on Earth: channels carved by rains (Turtle et al., 2011; Burr et al., 2012) and rivers flowing into hydrocarbon seas that grow and shrink with Saturn's decade-long seasons (Aharonson et al., 2009; Hayes et al., 2011). Titan's Earthlike atmosphere and hydrological cycle invite questions of “weird life,” whether alternative biological frameworks might have evolved to support life in non-aqueous liquid solutions (Schulze-Makuch and Grinspoon, 2005; Schulze-Makuch et al., 2011; Stevenson et al., 2015).

Titan's internal heat has typically been assumed radiogenic, but it appears that some amount of tidal flexing occurs.

A time-variable component to Titan's gravity field was revealed by *Cassini* radio science measurements (Iess et al., 2012). The changing tides are consistent with deformation on timescales of days. Any resulting tidal heating requires an explanation for why Titan's high orbital eccentricity has not been damped out. Conveniently, the same scenario for explaining present-day serpentinization on Enceladus—recent orbital disruption of Saturn's satellites—might explain the high eccentricity of tidally forced Enceladus (Cuk et al., 2016). A recent onset of tidal heating might also explain the outgassing of the atmosphere, which should have escaped if it formed 4 Gya (Yung et al., 1984).

In addition to the organic hydrosphere on its surface, Titan appears to have a global liquid-water ocean under its icy lithosphere. The high tidal potential Love number k_2 requires the icy lithosphere to be thinner than about 100 km and requires the underlying ~400-km layer to be 1,200–1,400 kg m⁻³. The dense lower layer is best explained by a very salty ocean (Mitri et al., 2014). The density structure of the watery upper part of Titan is difficult to reconcile with the high gravitational moment of inertia (Table 12.3.1), because it implies a low-density interior (<2,500 kg m⁻³), inconsistent with a purely rocky core resulting from differentiation; a high-density ocean also implies that ice VI may be the only high-pressure phase in Titan's ocean (Vance et al., 2018). Additional clues to the nature of Titan's subsurface water ocean come from the putative Schumann resonance observed by the *Huygens* lander deployed by *Cassini*. This low-frequency electromagnetic oscillation between Saturn's magnetic field, Titan's atmosphere, and an electrically conducting subsurface liquid layer provides further evidence for an ocean beneath an ice shell 55- to 85-km thick (Bégin et al., 2012).

How much exchange occurs between Titan's organic surface and aqueous interior is unknown (e.g., Fortes, 2000; Fortes et al., 2007; Grindrod et al., 2008). Surface geology, to date, has provided few clues. The majority of landforms can be interpreted as exogenic features modified only by fluvial and aeolian processes (Moore and Pappalardo, 2011). Surface hydrocarbons interact with the near subsurface (Hayes et al., 2008) and may reduce the shear strength of surface materials to enable contractional tectonism (Liu et al., 2016b). Recent analyses of the fuller set of *Cassini* radar-imaging data have revealed potential tectonic features (Liu et al., 2016a), but these also do not require complete overturning of the lithosphere. Outgassing from the interior may have occurred episodically as Titan cooled and its ices thickened and methane-enriched clathrates migrated upward through the ice by solid-state convection (Tobie et al., 2006). However, solid-state convection may or may not occur in Titan's frozen lithosphere (Mitri and Showman, 2008, also see the discussion of convection in ice Ih later in this chapter). Even in the absence of ongoing convection, resurfacing of the lithosphere has been proposed to occur through periodic eruptions of ammonia-water blebs formed from 10-km cracks at the base of the lithosphere (Mitri et al., 2008). If such eruptions occur, mass balance requires displacement of materials toward the ocean, but these need not include lighter hydrocarbons and organics from the surface.

Because of the many open questions pertaining to Titan's surface and the nature of its lithosphere, it is difficult to evaluate the composition and habitability of its ocean. Methane, ethane, and ammonia clathrates may have a role in regulating ocean chemistry and atmospheric composition (Choukroun et al., 2010; Choukroun and Grasset, 2010). To a lesser extent, organic materials figure into the composition and dynamics of other icy ocean worlds in the solar system.

12.3.2.6 TRITON

Neptune's moon Triton is undergoing extreme orbital degradation. Its orbit is retrograde opposite the direction of Neptune's orbit around the sun, highly inclined, and has near-zero eccentricity. These imply an energetic orbital-tidal evolution (Chyba et al., 1989), potentially beginning with the moon's capture from a binary pair (Agnor and Hamilton, 2006). Triton's surface has arcuate fractures reminiscent of cycloids on Europa (e.g., Kattenhorn and Hurford, 2009). Plumes of nitrogen gas and frozen particles may be linked with fractures (Collins and Nimmo, 2009) and thus to an active ice shell. Although Triton's geology has been attributed to exogenic processes (e.g., changes in solar insulation), arguments have been made that favor a warm interior, perhaps including a liquid water ocean, caused by obliquity tides (Nimmo and Spencer, 2015). Stresses from the gradual shrinking of Triton's orbit toward Neptune may drive ongoing activity (Prockter et al., 2005; Correia, 2009), such as hypothesized for Phobos, the tiny moon of Mars (Hurford et al., 2016).

12.3.2.7 PLUTO

The *New Horizons* mission revealed Pluto to be an extremely cold ocean world. Its surface, like Triton's, is covered in nitrogen. Solid nitrogen in the Sputnik Planitia region appears to be undergoing mobile-lid convection (McKinnon et al., 2016). The low thermal conductivity of nitrogen and the presence of anti-freeze materials such as ammonia and methanol may explain the persistence of a liquid water ocean under Sputnik Planitia (Keane et al., 2016; Nimmo et al., 2016).

12.3.3 HABITABILITY OF ICY OCEAN WORLDS, BY ANALOGY WITH EARTH

The composition (salinity, pH, and redox state) of an icy ocean world determines the types of metabolism that will be energetically favored and the environmental stresses that organisms must endure (Marion et al., 2003). The ocean's pH and associated salinity result from the geochemical evolution of the world in question; a low-pH ocean would be dominated by sulfate anions, whereas a neutral or basic ocean would be dominated by chlorides (Zolotov, 2008; Zolotov and Kargel, 2009; Figure 12.3.3).

The first chemical models of icy moons predicted that they would have eutectic ocean compositions dominated by sulfates (Lewis, 1971; Kargel, 1991; Kargel et al., 2000).

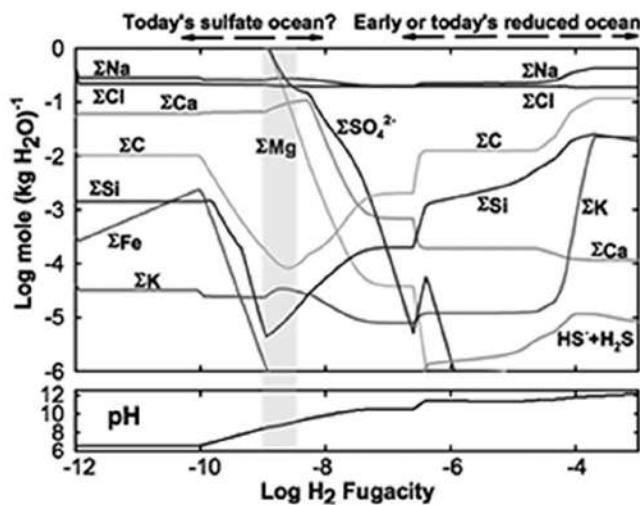

FIGURE 12.3.3 Europa's modeled ocean salinity and pH versus redox state. The vertical bar notes the transition from a chloride-dominated to a sulfate-dominated ocean. (Modified from Zolotov, M., Oceanic composition on Europa: Constraints from mineral solubilities, in *Lunar and Planetary Institute Science Conference Abstracts*, vol. 39, p. 2349, 2008.)

However, a reducing and chloride-dominated ocean might be expected instead, if oxidants were not delivered to the ocean (Hand et al., 2007; Zolotov and Kargel, 2009). The high water content of ocean worlds would seem to imply more dilute compositions (Zolotov and Shock, 2001; McKinnon and Zolensky, 2003; Figure 12.3.3). On the other hand, greater depths of water-rock interaction may cancel this effect, leading to effective water-rock ratios more similar to Earth's.

Ocean composition measurements cannot be based on surface imaging or atmospheric sampling alone, due to unknown fractionation within the ice. On Europa, chlorides inferred from surface infrared reflectance spectra of Europa's surface (Brown and Hand, 2013; Fischer et al., 2015; Ligier et al., 2016; Trumbo et al., 2017) are not a conclusive proxy for its ocean salinity, because chlorides fractionate relative to sulfates in ice shelves (Cragin et al., 1986) and sea ice (Gjessing et al., 1993; Maus et al., 2011). Thus, additional constraints from geophysical measurements are needed (Vance et al., 2018).

Cassini provided the first semi-direct measurement of the salinity and redox state of an icy ocean world. Sodium detected in ice particles from Enceladus captured in Saturn's E-ring is consistent with an NaCl-rich ocean of unknown salinity.

Particle (dust) and gas measurements from the Enceladus plumes indicate a reduced ocean with a pH in the range of 9–11 (Glein et al. 2015; Waite et al. 2017). This provides a first indication that Enceladus is currently habitable: methanogenesis ($\text{CO}_2(\text{aq}) + 4\text{H}_2(\text{aq}) \rightarrow \text{CH}_4(\text{aq}) + 2\text{H}_2\text{O}$) has a chemical affinity of $50\text{--}120 \pm 10 \text{ kJ per mol CH}_4$ at 1 bar pressure and 273 K temperature at pH 9–11 for the hydrogen/water mixing ratio of 0.004–0.02 measured in the plume. That is, methanogenesis generates excess Gibbs energy under these conditions and could thus be a reaction used by life.

12.3.3.1 REDOX BALANCE

Earth's biogeochemical cycles rely on the mantle to provide reduced materials (e.g., Hayes and Waldbauer, 2006). This is balanced by oxidants produced mainly by photosynthesis (e.g., Catling and Claire, 2005). On icy ocean worlds, tides and irradiation may facilitate similar reservoirs of redox energy. Prior published work on Europa illustrates this (Hand et al., 2007; Vance et al., 2007, 2016a). Except in the case of Titan, where the atmosphere is an additional chemical interface, the ice covering ocean worlds in the solar system is the direct interface to space. Photochemistry and impacts may be key sources of oxidants for the ocean, with fluxes depending on both the rate of production at the surface and the efficiency of delivery to liquid regions in the interior. The production and movement of liquids within the ices may thus be essential to the possible presence of life.

12.3.3.1.1 Oxidants Produced by Surface Irradiation

Ultraviolet light and energetic particles oxidize the icy surface or atmosphere by dissociating water, causing the loss of lighter hydrogen to space. Among icy ocean worlds, oxidant production is predicted to be largest at Europa because of its active geology and intense surface irradiation (Cooper et al., 2001; Johnson, 2004; Hand et al., 2007). The radiation belts of the gas giants capture charged particles from the solar wind. {Europa, Ganymede, Callisto} receive averages of {125, 6, 0.6} mW m⁻² (Cooper et al., 2001; Johnson, 2004). Enceladus and Triton receive less flux than Ganymede (Cooper et al., 2009).

An oxidant's delivery to the ocean depends on its generation at the surface and the efficiency of transport through the ice. The delivery of ionizable materials is expected to occur by impact gardening of micrometeorites and by geodynamic churning (e.g., Kattenhorn and Prockter, 2014).

12.3.3.1.2 Oxidant Fluxes to Europa's Ocean

Irradiation generates oxygen-rich materials (O_2 , H_2O_2 , SO_4 , SO_2 , CO_2 , ...) on Europa to depths greater than 10 cm (Hand et al., 2007). If the delivery time is less than the surface age of Europa (<100 Myr), this yields a delivery rate for O_2 in the range of 10^9 mol yr^{-1} . However, Greenberg (2010) and Pasek and Greenberg (2012) suggest that geological overturn will oxidize the entire ice after 2 Gyr if the rate of irradiation is constant through time. This will lead to a higher oxidant delivery rate in the current era, up to $2 \times 10^{11} \text{ mol yr}^{-1}$. Vance et al. (2016a) assume that the relevant geophysical overturn time is 30 Myr, based on findings suggesting near-surface liquids (Schmidt et al., 2011) and liquids deeper within the ice (Kalousová et al., 2014) and possible plate tectonic-like behavior (Kattenhorn and Prockter, 2014). The upper limit of $3 \times 10^{11} \text{ mole O}_2 \text{ yr}^{-1}$ (Greenberg, 2010) is within two orders of magnitude of Earth's net photosynthetic oxygen flux of $2 \times 10^{13} \text{ mole O}_2 \text{ yr}^{-1}$ (Catling and Claire, 2005).

The oxidant flux into a 100-km ocean, integrated over 1 Gyr, is comparable to that in Earth's ocean (0.1–0.2 mmoles O₂/L Schmidt et al., 2017) and well above the minimum oxygen concentrations found in some regions of Earth's ocean

(Childress and Seibel, 1998; Hand et al., 2007). If the ice delivers oxidants on timescales of less than a few Myr and there are no buffers to neutralize them in the ocean, the concentration of oxidants may exceed that of Earth's ocean by factors of 10. However, the complementary fluxes of reductants generated by water-rock alteration in Europa's interior may match or exceed the fluxes of oxidants or may have done so earlier in Europa's history.

The delivery of oxidants from the surface to the ocean depends most likely on the mechanics of solid state convection in ice Ih. A high Rayleigh number is expected for ice shells exceeding 10-km thickness. Thus, solid-state convection should occur (e.g., Mitri et al., 2008; Kalousová et al., 2014, 2016). The rheology of ices is somewhat well-known (Durham et al. 2001), but grain size dependence and intragranular effects complicate predictions of onset and vigor of convection. Non-linear rheology has been a focus for studies of convection in icy ocean worlds (e.g., Barr and Pappalardo, 2005). The characteristic ice grain size determines the viscosity of the ice and thus the activation, vigor, and longevity of convection (e.g., Barr and McKinnon, 2007). In addition, the viscosity may increase as tidal and other stresses in the ice increase the mean grain size, so-called dynamic recrystallization. The influences of large-scale and intragranular impurities on ice dynamics (Mitri and Showman, 2008; Mitri et al., 2008; Choukroun and Sotin, 2012; Choukroun et al., 2013; McCarthy and Cooper, 2016) may limit the growth of grains and thus facilitate transport of materials through the ice.

12.3.3.1.3 Reductant Fluxes to Europa's Ocean

The fluxes of reducing material from the silicate interiors of ocean worlds, in the solar system and beyond, may be maintained by low- ($\sim 100^{\circ}\text{C}$) or high-temperature ($>350^{\circ}\text{C}$) water-rock alteration. High-temperature hydrothermal fluids on Earth have a global mass flux $Q_{ht} \approx 3 \times 10^{13} \text{ kg yr}^{-1}$ and produce $F_{H_2} \approx 0.06 \text{ Tmol H}_2 \text{ yr}^{-1}$ (Sleep and Bird, 2007). Earth's total flux of hydrothermal fluids is $Q_{hydr} = 10^{15}$ to $>10^{17} \text{ kg yr}^{-1}$ (Johnson and Pruis, 2003; Nielsen et al., 2006).

The production of high-temperature hydrothermal H_2 can be estimated based on global fluid fluxes, as a function of H_{mantle} : $F_{H_2,ht} = n_{H_2} Q_{ht}$, with $H_{ht} = 0.1 H_{hydr} = 0.05 H_{mantle}$. High-temperature mass flux is:

$$Q_{ht} = \frac{H_{ht}}{c_w \Delta T} \quad (12.3.1)$$

where $\Delta T = 350^{\circ}\text{C}$ and $c_w = 4 \text{ kJ kg}^{-1}$ is the heat capacity of water at 350°C and pressures around 100 MPa (Wagner and Pruss, 2002). A representative value for the hydrogen content of high-temperature hydrothermal fluids on Earth is $n_{H_2} = 2\text{--}6 \text{ mmol H}_2 \text{ kg}^{-1}$ (Holland, 2002).

The heat produced in Europa's mantle (Lowell and DuBose 2005; H_{mantle}) sets an upper bound for high-temperature hydrothermal reductant flux of $\sim 0.03 \text{ Tmol H}_2 \text{ yr}^{-1}$, comparable to Earth's flux. Figure 12.3.4 shows $F_{H_2,ht}$ as a function of mantle tidal heating, up to $H_{mantle} = 3.5 \text{ TeraWatts (TW)}$. Europa's maximum global hydrothermal fluid mass flux has been

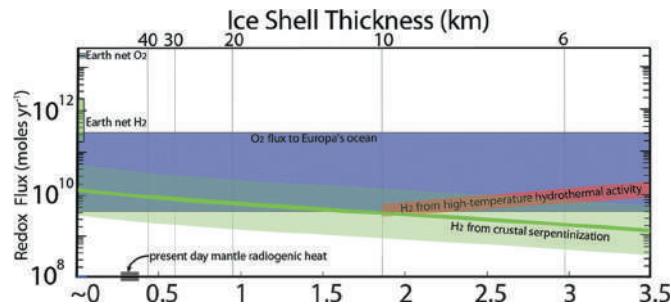

FIGURE 12.3.4 Present-day fluxes of H_2 and O_2 to Europa's ocean versus tidal heating in the rocky interior. Top axis: equilibrium thickness of a thermally conductive ice shell heated from below. (From Vance, S. D. et al., *Geophys. Res. Lett.*, 43, 4871–4879, 2016. With permission.)

computed as (Lowell and DuBose, 2005) $Q_{hydr} = 10^7 \text{ kg s}^{-1}$, or $\sim 3 \times 10^{14} \text{ kg yr}^{-1}$. They assume $H_{hydr} = 0.5$ and $H_{mantle} = 5 \text{ TW}$, with H_{mantle} accounting for the majority of Europa's tidal heating. This extreme is unlikely today (Tobie et al., 2003; Sotin et al., 2009) but probably occurred early in Europa's history (Pasek and Greenberg, 2012).

The flux of hydrogen from low-temperature serpentinization has been computed from thermal fracturing, assuming an Earth-like oxidation state of the rocky interior. Europa's predicted present-day hydrogen production (Figure 12.3.4; Vance et al., 2016a) is nearly an order of magnitude larger than Earth's on a tidal heating in Europa's mantle (TW) (Table 12.3.2).

A big-picture result of studies to date, coupling to studies of life's origin on Earth, is the possibility that alkaline serpentinizing systems fostered an independent origin of life on Europa and other icy ocean worlds and that vigorous ecosystems might arise at the ice-ocean interface, where redox gradients are strongest due to the delivery of oxidant-rich fluids from the overlying ice (Russell et al., 2014, 2017).

12.3.3.2 REDOX FLUXES IN LARGER ICY OCEAN WORLDS

In ocean worlds with very thick ice shells, high fluxes of chemical energy may be difficult to sustain, thus limiting the production and transport of oxidants from the surface to the underlying ocean. This is illustrated most profoundly for Callisto (Section 3.2.3) but also pertains to the thick ice covering of Ganymede and Titan. Despite the expected slow overturning rates relative to Europa, the extent of oxidant production and delivery to the oceans of these worlds deserves further investigation.

Reductant fluxes may also be limited in the larger ocean worlds due to the high overburden pressures at the hundreds of kilometers of depth, where rocks occurring in those worlds may limit the extent of water-rock interaction (Vance et al., 2007; Byrne et al., 2018). However, the low density of Titan's interior (Vance et al., 2018) would seem to require extensive mineral hydration. Clearly, this is a paradox that needs to be addressed. Recent work (Journaux et al., 2013, 2017; Kalousová et al., 2018) suggests that high pressure ices are less of a barrier to the transmission of materials into the

TABLE 12.3.2

Heat and Hydrogen fluxes in Europa, Enceladus, and Earth, based on Vance et al. (2007), including present-day fracture depth (z), and rate (\dot{z}). R_p and M_p are the radius and mass of the planetary body, respectively. d is the ocean depth. T_o and T_z are the average temperatures at the surfaces of the bodies, and at the depth of the fracture front (z). H_{rad} is the computed heat production from radioactive decay of U, Th, and K. H_{serp} is the heat from serpentinization of material exposed by new fracturing (at rate \dot{z}). Hydrogen fluxes from serpentinization (FH_2) are listed as a ratio to Earth's in terms of relative aerial fluxes and as global flux in $Tmol$ per year. The predicted fracture depth for a present-day 100-km-deep-ocean on Europa is 24 km. Europa produces up to 50 Gmoles of H_2 per year from water-rock reactions with newly exposed material. This is 4x the calculated flux for Earth

	R_p (km)	M_p ($\times 10^{20}$ kg)	d (km)	T_o (°C)	T_z (°C)	P_z (MPa)	z (km)	\dot{z} $\frac{\mu m}{yr}$	H_{rad} $\frac{mw}{m^2}$	$\frac{H_{serp}}{H_{rad}}$ (%)	FH_2 $\frac{Tmol}{F_{Earth}}$	$\frac{Tmol}{yr}$
Earth	6371	59742.00	4	0	114	237	6	0.3	60.0	0.00	1	0.2
Europa	1565	487.00	100	0	71	248	24	1.0	9.0	0.07	4	0.05
Enceladus	252	0.73	80	-20	0	45	172	—	0.6	7.0	12	0.003

overlying ocean, providing room to speculate that chemical gradients across thick ice layers and oceans may create conditions suitable for life.

12.3.4 DYNAMICS OF OCEANS, ICES, ROCK, AND NEEDED FUTURE WORK, INCLUDING LABORATORY STUDIES

It seems likely that ice-covered oceans will be strongly convecting. Because they are heated from below and cooled from above, and because of their great depths and the low viscosity of water, they have a high predicted Rayleigh number ($Ra \gg 1000$) (e.g., Vance and Brown, 2005; Vance and Goodman, 2009; Travis et al., 2012; Travis and Schubert, 2015). In fact, recent progress in fluid dynamics suggests that turbulent convection may be the rule, organizing the heat transport to be primarily equatorial (Soderlund et al., 2014). A caveat to this prior work is that it did not account for dissipation due to flow along seafloor and sub-ice topography. Such dissipation could be a significant source of tidal heat but is currently not well understood, in large part due to the uncertainty in the topography of the ice (Tyler, 2008, 2014; Chen et al., 2014). Though the vigor of turbulent convection awaits further studies and confirmation by future missions, it is important to consider, because strong turbulence could erase Taylor columns at moderate latitudes that might otherwise permit a more or less direct connection between seafloor hydrothermal systems and the underside of the ice (Goodman et al., 2004). Pole-to-equator variations in the thickness of the ice, known to occur on Titan and Enceladus (McKinnon, 2015; Corlies et al., 2017), and possible for Europa (Nimmo et al., 2007), could give rise to melting where the ice is thick and refreezing where it is thin. This redistribution of ice also implies the dilution of the ocean's salinity where ice melts and concentration

where it forms. The result of this lateral flux of ice and salt could be an additional driver for overturning circulation, analogous to thermohaline circulation in Earth's oceans (Zhu et al., 2017).

An organizing theme of the study of icy ocean worlds is the occurrence of conditions familiar on Earth at atypical pressures and temperatures (Figure 12.3.5). As discussed previously, the very high pressures and temperatures of the larger worlds may impede the occurrence of water-rock interactions. Thermodynamic conditions of pressure, temperature, and composition are primary drivers for exotic properties of icy ocean worlds. Experiments and theory continue to reveal new phenomena that await confirmation or refutation by future missions. This work has an excellent synergy with studies of Earth's carbon cycle and water-rock interactions in subduction zones and at even greater depths.

Geochemical modeling has benefited in recent years from extrapolation of water's dielectric properties beyond 0.5 GPa (Sverjensky et al., 2014a, 2014b). Studies of high-pressure aqueous systems are revealing a change in the organization of water around dissolved ions at $P > 0.4$ GPa, with a pseudo-phase transition to the so-called "high-pressure water," facilitating the increased association of ions. This implies a fundamental shift in the shape of the Gibbs energy surface. On this basis, chemical reactions predicted by extrapolation from lower pressures should be viewed critically. Also, the resulting decrease in electrical conductivity with pressure is directly relevant to planned efforts to measure the induced magnetic field response of Ganymede's deep ocean (Vance et al., 2018).

New laboratory measurements have been obtained in recent years, mitigating the need for extrapolation of chemical properties from standard pressures and temperatures (e.g., Bollengier et al., 2013; Mantegazzi et al., 2013; Vance and Brown, 2013; Bezacier et al., 2014). This work has produced large data sets,

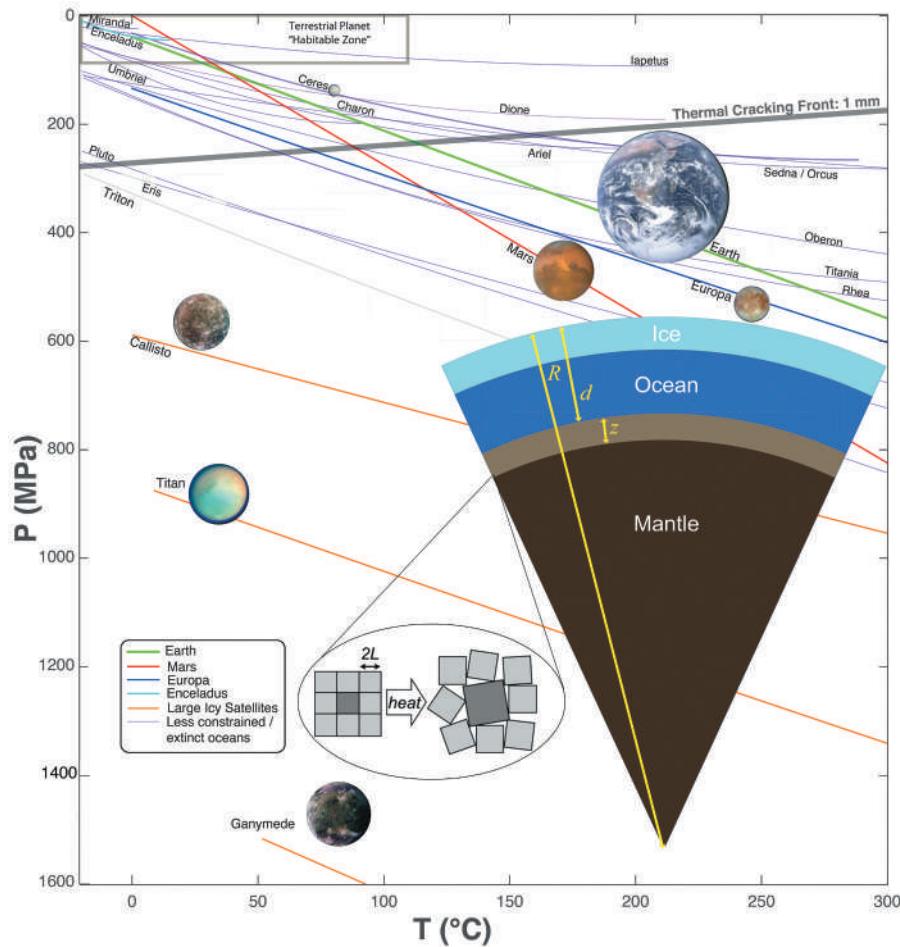

FIGURE 12.3.5 Pressures and temperature profiles for known and putative ocean worlds used in the fracture model. The inset schematic, (Modified from Neveu, M. et al. *J. Geophys. Res. Planet.*, 120, 123–154, 2015), illustrates the mechanism for cracking due to thermal expansion anisotropy. (From Vance, S. D. et al., *Geophys. Res. Lett.*, 43, 4871–4879, 2016. With permission.)

mainly comprising surfaces of sound speed in pressure (P) and temperature (T) at various compositions. Equations of state in Gibbs energy and chemical potential are derived from these surfaces by integration in pressure and temperature. The application of modern geophysical inverse theory, aided by modern computational capabilities, has proven to be a key tool in such efforts (Brown, 2018). The use of standard spline fits, which serve as local basis functions, has enabled a shift away from the global damped polynomial approach (e.g., Lemmon and Jacobsen, 2005) that requires refitting when new data sets are added to the fits.

Laboratory studies are also yielding surprising findings regarding the possible retention of volatile materials in the rocky interiors of icy ocean worlds. For example, diamond anvil cell studies of the $\text{CO}_2\text{-H}_2\text{O}$ system have revealed the stability of crystalline carbonic acid at higher pressures than previously predicted (Abramson et al., 2017a, 2017b). A possible implication of this work is the more efficient retention of carbon in Earth's crust and in the rocky interiors of other ocean worlds.

Clearly, there is much work yet to do in laboratories and offices on Earth.

12.3.5 FUTURE PROSPECTS AND MISSIONS

As a new decade of planetary exploration approaches, missions are being planned and formulated to investigate the habitability of ocean worlds and possibly to look directly for signs of life.

Europa will be visited in the mid to late 2020s by NASA's planned Europa Clipper mission (Pappalardo et al., 2016), which will be able to search for and characterize plumes. It will also map nearly the entire surface at better than 500 m/pixel spatial resolution, at wavelengths spanning the ultraviolet to thermal infrared, and peer through the ice with an ice-penetrating radar at radio frequencies of 9 MHz high frequency (HF) and 60 MHz very high frequency (VHF). These investigations will thus address the mystery of how Europa's ice works, the composition of its ocean, and its potential habitability.

Whereas the Europa Clipper concept focuses on the context of Europa's habitability, a studied Europa Lander (Hand et al., 2017) would directly sample a young region on Europa's surface, with the goal of searching for signs of life. It would achieve this by making use of modern mass spectrometric techniques, Raman spectroscopy, and high-resolution imaging to map the

context of organics on the surface and seismology to improve our understanding of the regional ice and deeper interior.

The JUpiter Icy satellite Explorer (JUICE) is planned to orbit Ganymede in the late 2020s, with a complement of instruments similar to those on the Europa Clipper (Grasset et al., 2013). At present, the JUICE mission plan calls for also for executing 2 science flybys of neighboring Europa and 12 flybys of Callisto, during the approach to Ganymede orbit.

A NASA mission dedicated to exploring Titan is under concept and technology development (“Phase A”¹) as a New Frontiers class mission (Turtle et al., 2017). The Dragonfly lander would leverage Titan’s dense atmosphere and low gravity, using an eight-rotor copter system to fly to multiple landing sites, studying and sampling different landforms in Titan’s equatorial region. Such a mission could reveal Titan’s compositional evolution and habitability by studying its hydrocarbon dunes (Hand et al., 2018). It could also probe Titan’s radial interior structure by using seismology.

Missions to Uranus and Neptune were prioritized for the current decade. Completing the detailed reconnaissance of the large planets after the fashion of *Galileo* and *Cassini* remains a high priority (Hofstadter et al., 2017). Flagship-class missions to Uranus and Neptune could map the remaining potential ocean worlds, constrain their sizes and densities, and use the tilted magnetic fields of their respective parent ice giants to search for induced magnetic responses indicative of subsurface oceans.

12.4.1 INTRODUCTION

Beyond humankind's relentless quest for learning about various life forms that populate our planet, including our fellow human beings, we also seem to have a fundamental desire to know where else there may be life in the universe. Are we alone?

An extension of this desire, from the viewpoint of scientists, is to learn how another form of life might be constituted. Will it be tantalizingly similar to our own biochemistry? Or, will it be so radically different that we could not have imagined its existence? These two outcomes span the range of possibilities. In either case, however, the results will have far-reaching implications.

The search for life elsewhere is still in its infancy. Indeed, when it was finally discovered that the surface of Venus is so hot as to be inhospitable to life, attention turned to Mars. Flyby missions and the Mariner 9 orbiter at Mars (see <https://www.nasa.gov/missions/journeymars/index.html>) dispelled the ideas of canals and the waxing and waning of crop patterns, unceremoniously demolishing

earlier claims by astronomers of evidence of intelligent life based on their telescopic observations from Earth. Five years later, the Viking landers touched down on opposite sides of the red planet, obtaining nearly identical results in analyzing Martian soils (Klein 1978; Horowitz 1986; <https://mars.nasa.gov/programmissions/missions/past/viking/>)

Now, four decades later, the life detection results are still in dispute because of the challenges of making *in situ* measurements of an unknown surface within the practical constraints on instrumentation designed for space flight.

Because liquid water is considered essential to life as we know it, subsequent missions to Mars (see <https://www.nasa.gov/topics/journeymars/index.html>) have focused on exploring the geologic and atmospheric history of the planet, with an emphasis from the viewpoint of when and where was the planet habitable. More recently, the evidence has been mounting that some of the larger satellites of the giant planets, as well as large asteroids such as Ceres, currently or in the past, had oceans beneath icy surfaces. Enceladus, and now possibly

Europa, harbor plumes of ejected water that are accessible to space exploration missions.

It now seems time to again begin the earnest search for extant life within our solar system and to face the challenges that must be overcome to reach for the ultimate discovery that resonates so strongly with the science community and the public at large.

12.4.2 CRITERIA FOR LIFE

Living things are intrinsically different from the inanimate objects that populate our universe. Life is a phenomenon that is, in many ways, unlike all other phenomena. Yet, the ancients had difficulty understanding the differences. For example, “gods” were attributed to phenomena such as fire, volcanism, and even the ocean itself. Only through painstaking scientific research were these phenomena demystified and explained by the natural laws deduced from the study of physics, chemistry, biology, and mathematics. The criteria for determining whether each given observation or test is definitive for life, or simply circumstantial, must be carefully examined and justified.

12.4.2.1 WHAT ARE WE TRYING TO FIND?

Even though various forms of life are often clearly identifiable by their appearance or their actions, the reality is that these characteristics alone are generally insufficient. Camouflage hides some—for example, fish and lizards that look like rocks; see [Figure 12.4.1](#).

Yet, other non-living entities can have most of the attributes of higher forms of life (e.g., animals and other beings with intelligence). The painting forming the basis of [Figure 12.4.2](#) was created during advocacy of a 1979 or 1981 follow-on mission after Viking-1 and -2, employing the third flight vehicle but replacing footpads with tracks originally developed as

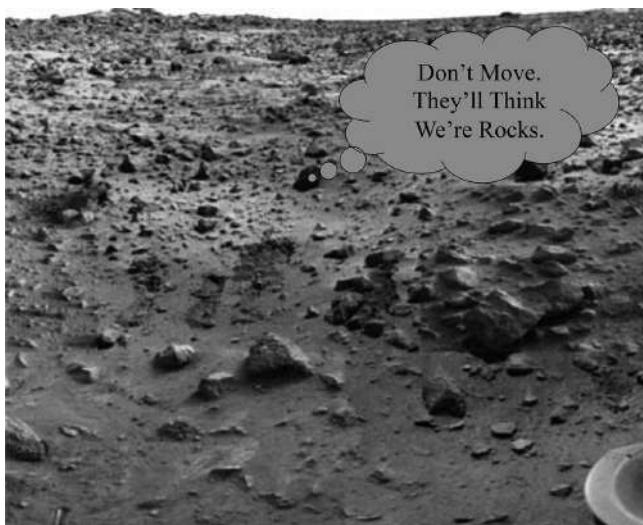

FIGURE 12.4.1 Viking Lander-1 touched down on a surprising abundance of rocks of all shapes and sizes, up to boulder-sized. (Courtesy of NASA, Washington, DC.)

candidates for the Apollo lunar buggy. This would have created a roving vehicle that may have discovered salts or evidence of thermal activity. In the context of discovering life, would an alien civilization mistake a robot for a living being?

Far more consequential is that there is an enormous and essential portion of the biosphere that consists of microbes, invisible to our eyesight because of the limited resolution of the human eyeball as well as the fact that the size of most bacteria is comparable to or less than the wavelengths of visible light. Viruses are generally smaller and can typically be “seen” only with the aid of the electron microscope.

Furthermore, the natural geologic world creates objects that can be confused with organisms. Spherical concretions form in aqueous sediments. Tektites, geodes, and other ellipsoidal objects form without the aid of biological activity. Manganese oxides crystallize in dendritic patterns reminiscent of biological forms such as plant root systems or colonies of filamentous microorganisms.

Yet, the biological science community seems to agree to disagree on what should be the precise definition of what constitutes a living organism. Numerous attempts at a “definition of life” have been put forth (Kolb, V. M. 2018, [Chapter 2.1](#) this handbook), yet there is no universal agreement on a single formulation.

The so-called NASA definition is “Life is a self-sustained chemical system capable of undergoing Darwinian evolution” (Joyce 1994). Although this is an admirable synopsis of the characteristics of life as we know it, it has some quite limited aspects and is also very difficult to put into practice in a first exploration for life on an alien world. For example, the term “self-sustained” can be interpreted as independence from everything else, including other organisms. Yet, parasites and predators are forms of life that are everywhere and, in many cases, would be easier to detect than their victims (e.g., mice vs. earthworms and seeds). We also now know that more than 99% of all microbial species cannot be successfully cultivated in the laboratory, presumably because of mutual interdependence on other microbes. Finally, we also know that organisms in our biosphere depend on the primary productivity of photosynthesizers, powered by sunlight, and that all organisms have requirements for nutrients in various forms (dissolved key elements, atmospheric gases, etc.). The term “self-sustained” might possibly be interpreted as the ability to utilize energy from the environment to accomplish evolution.

The NASA definition goes on to specify a “chemical system” as being necessary. This is also perhaps too restrictive. We already know that biological systems are not strictly chemical but also often involve electrical properties (e.g., photosynthesis electron transport, membrane interactions with ions, and mitochondrial proton pump) as well as sensor systems and mechanical processes. It could even be envisioned that some forms of life may involve more electrical processes than chemical ones.

The term “Darwinian evolution” in the NASA definition is meant to point out the central feature of life compared with non-life, that is, it can evolve to future versions that are different, and sometimes more capable, than the existing version of

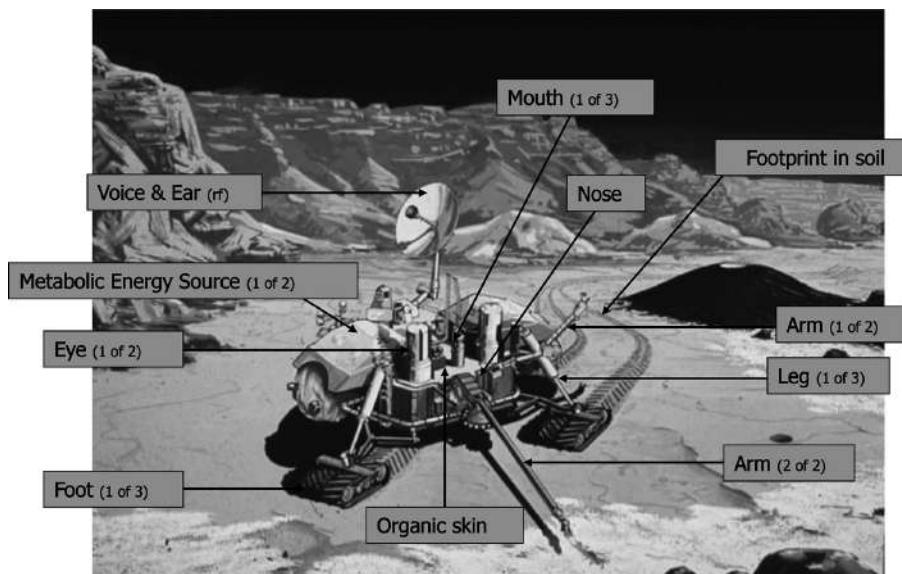

FIGURE 12.4.2 Earthling roaming Mars?

Artist's painting of proposed Viking-3 rover mission, showing anthropomorphic similarities to animal characteristics, including purposeful movement, internal energy source, and ingestion of soil. The "skin" is a resilient paint applied to bounce off abrasive wind-blown sand; the "nose" is the inlet to the GCMS; the "mouth" is the inlet to the VLBI; and the energy sources, producing heat, are the Radioisotope Thermoelectric Generators (RTGs), which power the "alien." (Courtesy of Martin Marietta.)

the organism. Clearly, evolution is the hallmark of life-forms, as compared with objects such as rocks or phenomena such as lightning. These latter examples can in fact change over time (rocks can weather and a lightning bolt changes course during the development of the strike), but they do so along known pathways that follow the laws of physics and chemistry. On the other hand, the specification of "Darwinian" evolution pays homage to the conclusion by Darwin and Wallace that evolution in our biosphere is driven by random chance and natural selection of successful progeny. There is, however, no fundamental impediment to Lamarckian evolution, whereby changes that occur during the lifetime of a single organism in adapting to its environment can be immediately passed on to future generations. Indeed, proving whether a given instance of evolution is either Darwinian or Lamarckian can be extremely difficult. Clearly, the evolution of human civilization is intended to be more Lamarckian than Darwinian (although sometimes difficult to discern).

In Chapter 2.2 of this handbook (Clark 2018), I offer a more generalized and universal definition of life. It also includes evolution as the central essence of a living system but explicitly calls for energy transduction, which is something that can be tested for in a realistic experiment. It also points out that not all living organisms are reproductive (e.g., worker bees, mules, and sterile human beings).

Perhaps, the most important qualification is that organisms can become dormant until environmental conditions change for the better. Bacterial spores, as well as seeds, are ubiquitous. They are so passive, however, as to be non-detectable, except perhaps by their intriguing morphology. Yet, they can be alive, although the only way to find out, in general, is to provide them with a "suitable environment," which coaxes them

out of dormancy into activities of growth and reproduction. This feature of so many organisms, especially microbes, can be of extreme importance in designing investigations to test for life. What constitutes a suitable environment can be somewhat pre-judged but only verified by actual experimentation.

The conclusion from defining life is that it is not at all trivial to prove that something is truly alive. First, it must be observed to be reproductive. This may require experimentation with different environments, including not only the physical conditions (temperature, pressure, etc.) but also the provision of nutrients. Next, it must be shown to be capable of evolving. This is yet more challenging because of the slow course of evolution, generation to generation, and the need to identify phenotypical traits that can be tracked. Testing a putative organism to prove that it satisfies a definition of life can be difficult, especially in the context of a space mission with limited resources and sometimes limited duration. Clearly, we need to consider other approaches that can be used to "screen" for the possible presence of living entities to choose which samples to study more exhaustively.

12.4.2.2 PRAGMATIC APPROACHES

Obvious signs of life include evidences of intelligence, such as the canals and croplands imagined by early astronomers using the limited observational techniques available at that time. If, when Viking touched down on the surface of Mars for the first time, the images had shown shrub brush, cacti, or a freeway overpass bridge in the distance, both the public and the science community would have quickly concluded that there was convincing evidence of life. Instead, the images were of rocks and soils, just like some deserts on Earth.

This was, in fact, not surprising to most scientists, who expected Martian life to be limited to microbial organisms in the soil. The life-detection payload selected for the Viking lander missions was designed to test Martian soils in a multiplicity of ways. Originally, there were four separate biology experiments with incubated samples and a gas chromatograph-mass spectrometer (GCMS) to test for organics in the soils.

Years before the Viking landings, Nobel Prize winner Joshua Lederberg opined “A negative assay for organic materials would preclude biology” (Space Studies Board [SSB] 1965, p. 129). This opinion was shared by many of the members of the biology team, such that when the GCMS team reported detecting no organics in Martian soils above about one part per million at either landing site (Biemann et al. 1977), there was pessimism that living (or dead) organisms could be in the samples. The Viking pronouncement of no organics in soils was later challenged (Navarro-Gonzalez and McKay 2011), and subsequent analysis of Martian sedimentary rocks and soils by the Sample Analysis at Mars (SAM) instrument on the Curiosity rover have detected chlorinated (Freissinet et al. 2015) and sulfonated (Eigenbrode et al. 2018) organics in Martian soil, albeit at extremely low levels.

The Viking Lander Biology Instrument (VLBI) originally included the “Wolf Trap” experiment (Space Studies Board [SSB] 1965, p. 497), which would have incubated Martian soil in water to measure pH and use optical scattering to seek evidence for growth and reproduction of microbes, a common experiment in beginning microbiology courses. Because of the increased costs and complexity encountered during development of the VLBI instrument, this one experiment was “descoped” (i.e., eliminated) from the mission. The three remaining experiments focused on attempts to detect metabolic activity of various types but could not readily detect reproduction and certainly not evolution of the putative Martian microbes. These three experiments are shown schematically in Figure 12.4.3.

Up to four incubation chambers were provided for each experiment. Because water would boil at these temperatures under the low ambient Martian atmospheric pressure, an inert cover gas was added after delivery of soil to raise the pressures in the incubations chambers.

One of the experiments measured the composition of gases in the headspace of its incubation chamber, with the aid of a gas chromatograph. This “Gas Exchange” (GEx) experiment provided the soil with a generous supply of nutrients: an aqueous solution containing virtually all the amino acids used by biology on Earth (in both D and L forms), as well as nucleosides, vitamins, several simple metabolites, and numerous key ions and trace elements as salts. When the soil was allowed to be humidified, before introduction of the liquid “chicken soup,” it was found to release oxygen (Klein 1978), which indicated that there was a strongly active chemical oxidant in the soil. Once wetted, there was no release of any metabolic gases (or uptake of Martian gases or the added CO₂). These results were taken as a lack of metabolic activity in the soil samples.

VIKING MISSION TO MARS

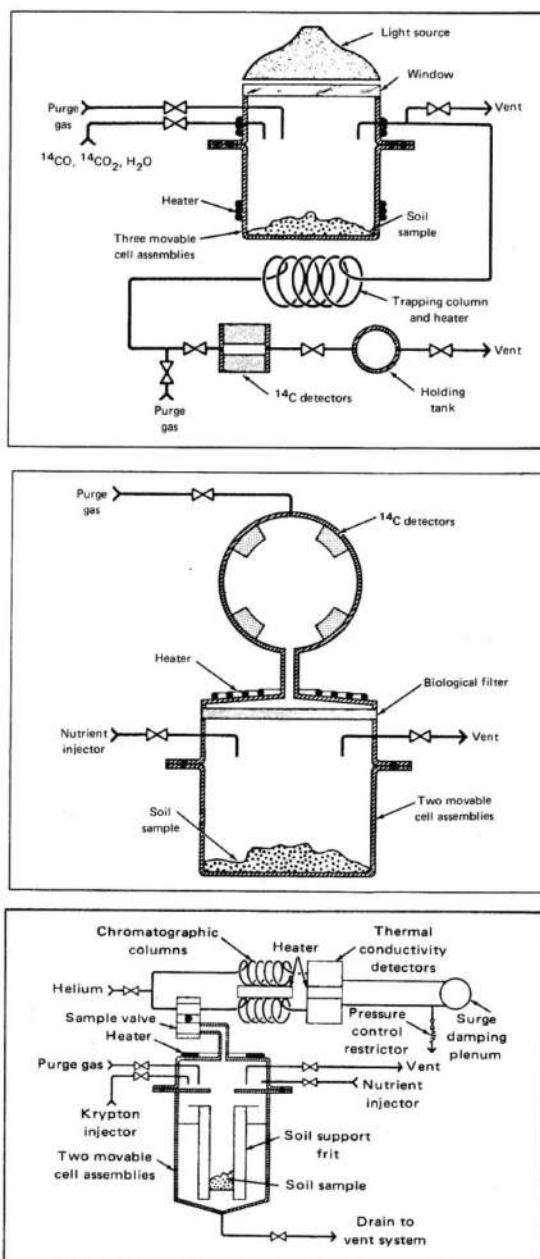

FIGURE 12.4.3 The Viking experiments were elegantly simple and seemingly straightforward. Top, Pyrolytic Release (PR) experiment; middle, Labeled Release (LR) experiment; and bottom, Gas Exchange (GEx) experiment. (Courtesy of NASA SP-334, p. 58.)

Two of the experiments utilized radiolabeled ¹⁴C compounds and looked for transformation from one molecular form to another. In the case of the “Pyrolytic Release” (PR) experiment, soil was incubated with labeled CO₂ and CO, and then, after removal of these gases, the soil was pyrolyzed to release any carbon that might have been metabolically fixed (incorporated into organic molecules). Oxidation of the thermally volatilized organics was achieved with the aid of heated CuO. This procedure could be performed in the dark or with a solar simulator to stimulate any photosynthetic capability of

the sample. Except for one particular experiment considered anomalous, the incorporated gas was very small or negligible.

The “Labeled Release” (LR) experiment (Levin and Straat 1976, 2016) added to its aliquot of soil a small amount of aqueous nutrient containing five different organic compounds and measured the evolution of gas containing the ^{14}C . A positive result was obtained. As hoped, there was a sharp release of gas, as the putative organisms metabolized one or more of the nutrients, and perhaps multiplied, with an eventual decrease in the rate of gas production because nutrient was consumed, as portrayed in [Figure 12.4.4](#).

When a fresh soil sample was heated to high temperature (160°C) to sterilize it, this response did not occur, indicating the putative organisms had been killed or otherwise inactivated. This seemed to be convincing evidence of life. However, additional experiments on Mars showed that when fresh nutrient was added after a first response, there was a complete lack of evolution of new gas. The expectations were additional metabolic activity and creation of gas (upper points of [Figure 12.4.4](#)). If there was, in addition to growth, actual multiplication of organisms (reproduction), the rate of activity would have increased even more. In fact, there was no positive response, which is a negative indicator for life and has been pointed out a few times before (Horowitz 1986; Schuerger and Clark 2007). Instead, the total gas actually decreased somewhat, and there were smaller but quite noticeable fluctuations in the head gas concentration on a diurnal basis, which are indications that the solution created was dissolving a portion of the gas. These results led to two camps—those who favored an interpretation as metabolic activity of organisms and those who sought geochemical explanations. As summarized in [Table 12.4.1](#), it seemed possible to explain the various results either way.

Overall, the results of the Viking biology experiments were viewed as being negative for life (Klein 1978 1999; Horowitz 1986), and there began an extended series of experiments by others to emulate the LR results by adding various oxidizing agents to soils.

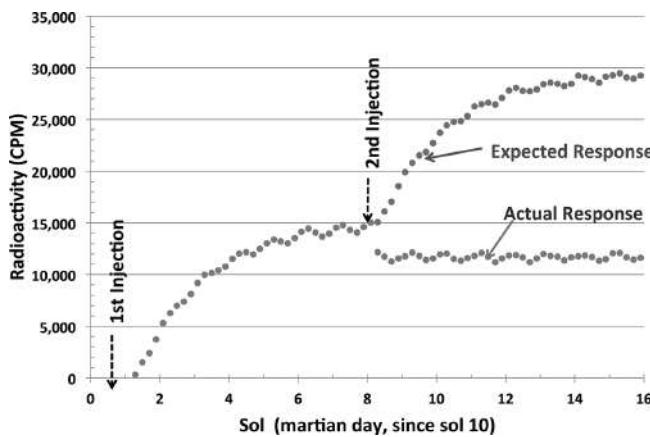

FIGURE 12.4.4 Diagram of actual and expected results from the Labeled Release biology experiment. See text and [Table 12.4.1](#) for additional explanation. (Basis: Figure 6 of Levin, G.V. and Straat, P.A., *Science*, 194, 1322–1329, 1976.)

TABLE 12.4.1 Explanations Offered for LR Results

- First injection produces strong signal
Life: just as expected
Non-life: one or more oxidants in soil
- Second injection
Life: liquid re-absorbs released gas, and organisms have died
Non-life: soil oxidant was consumed (destroyed by first injection)
- Diurnal oscillation of amount of gas in headspace
Life: circadian rhythm
Non-life: temperature-dependent uptake in soil (e.g., carbonate)
- Heat sterilization treatments
Life: aha! Proof positive of signs of life!
Non-life: oxidant is heat labile, or release of H_2O from soil destroys it

12.4.2.3 FUTURE APPROACHES

The NASA “Ladder of Life Detection” is provided on its astrobiology website: <https://astrobiology.nasa.gov/research/life-detection/ladder/>

The purposes of this very useful chart have been to capture and summarize current scientific thinking on approaches to life detection and to stimulate new thought on potential techniques and their advantages, disadvantages, and potential ambiguities in their results. As a result, the chart is subject to continuous update. Most assessments within the chart are adjectival, rather than any attempt at numerical evaluations. Although absolute metrics might be desirable, they would undoubtedly have large error bars, such that synthesizing overall numerical scores would almost assuredly have very large error bars (propagation of errors), undermining confidence in assessing the relative merit of each of the approaches. A variety of criteria, including practicality, reliability, cost, precision, accuracy, sensitivity, and uniqueness in interpretation, render judgments questionable, at best. However, attempting objective judgments on *relative strengths* can be fruitful in setting a basis for the selection of one approach over another. Different missions may take different approaches to searching for life. It must be remembered that “life as we *don’t* know it” mandates a broadly based line of attack to the problem. If Martian life is chemically Earth-like, whether because our biochemistry is the predominant option that nature has available or because of transport between the two planets (panspermia), then the tests can be much more focused. Since we have no overt evidence for discarding either of these cases, there are grounds for both strategies, even on the same mission.

The “ladder rungs” are keyed to the various properties entered in the first column of each row (or “rung”). At the highest level is the goal of demonstrating evolution, which, as we discussed earlier, would be extraordinarily challenging if the life-form had not yet even been detected, isolated, or cultivated in the laboratory. An indirect method of detecting evolution would be, however, a discovery of two different types of organisms that differ from one another in significant ways, such as their response to stimuli, robustness to environmental stressors, and/or morphological differences in appearance in

structure or colonization. If these observations imply the presence of two or more different species, then evolution may be inferred.

The second rung is “Growth and Reproduction.” These are two separate properties, with reproduction being most significant. However, a spherical organism needs to increase only by 26% in diameter (sometimes difficult to measure this accurately) to double its volume and hence be ready for division. Even more challenging is when the progeny cell is born much smaller in size and then grows to maturity. For micron-sized organisms, and below, morphology can be evaluated well only with short-wavelength microscopy, such as ultraviolet (UV), x-ray, and electron microscopes. Without cultivation in the laboratory, the number of organisms that occur naturally in soils is relatively small, with mean free distance of 100 cell diameters between them if dispersed uniformly. This means there must be extensive searches to locate individual cells, which is either a major data load of images sent back to Earth or else invokes the use of smart algorithms or artificial intelligence on site to choose the images of most interest to send back to Earth.

The third rung of the ladder is “Metabolism.” As discussed previously, this was the primary approach of the Viking experiments, which have the advantage that neither morphology nor even quantity of organisms is critically important. Furthermore, it can target extant, active, living organisms—the Holy Grail of astrobiology. A potential pitfall is the possibility of non-biologically mediated reactions that can mimic likely biochemical ones. This is, of course, the root cause of the lingering controversy over whether the Viking LR measurement results were indicative of organisms or rather of unexpected chemical ingredients in the global soils.

This rung can benefit from the use of isotopes as tracers. Viking employed radioactively labeled (^{14}C beta emitter) organic substrates to trace chemical reactions. Modern approaches may be able to utilize rare but non-radioactive isotopes such as deuterium, ^{13}C , ^{15}N , ^{17}O , ^{36}S , and/or ^{58}Fe to trace chemical changes. This may require purification of sought-after products and will also benefit very much from high-resolution mass spectrometry, possibly combined with very advanced tuned-laser techniques (e.g., polycyclic aromatic hydrocarbon [PAH] detection). A dilemma is which soluble substrates to provide (e.g., saccharides, amino acids, amphiphiles, and energy-rich molecules such as ATP or thioesters) and which bioactive gases to test (e.g., H_2 , H_2S , CO , CO_2 , CH_4 , NH_3 , and NO_x).

A sub-rung of the ladder’s “Metabolism” category would be discovery of the juxtaposition of redox pairs of reactants, the logic being that if life did not exist, the reactants could remain chemically stable due to kinetic inhibition, whereas life takes advantage of such occurrences and catalyzes their reaction to obtain free energy in a controlled and useful way. However, there are numerous examples of ecologies in which such seeming anomalies exist, such as the abundance of organic matter over vast surfaces of planet Earth while surrounded by atmospheric oxygen gas, without reacting unless a “combustion temperature” is provided (e.g., lightning). Although there is a major portion of the biosphere, the respiring organisms,

which does, in fact, attempt to eliminate this disequilibrium, the action of the oxygenic photosynthesizing organisms predominates. Paradoxically, the existence of such unexploited redox couples is often invoked by astrobiologists as evidence of “habitability” and hence the likelihood of finding life. Finally, the interactions of the natural non-living world should also have eliminated many non-equilibrium situations, such as the joint presence of water, CO_2 , and Ca- and Mg-containing minerals, which should be thermodynamically converted to various states of hydrated carbonates. Yet, carbonates on Mars are relatively rare, and it is the widespread and powerful biological activity on Earth that is invoked as a key enabler for these and many other kinetically inhibited mineral conversions. Consequentially, the existence of unexpected redox couples or ingredients can be interpreted in multiple ways and requires a full understanding of the current as well as past environments at the location of interest.

Below these three major attributes of life (evolution, reproduction, and metabolism), the ladder labels the subsequent rungs as “Suspicious Biomaterials.” Following the NASA definition of life, this means the presence of biochemicals that are of paramount importance for life as we know it (DNA, RNA, amino acids, proteins, and lipids). Specific tests for individual molecules or classes of molecules can be readily devised, although not all are straightforward to implement for spaceflight.

Some of these tests are not uniquely positive for either extant or extinct life. For example, a whole range of amino acids and other organic molecules of biochemical importance has been found to occur naturally in carbonaceous chondrite meteorites and some in comets and interstellar space (Kwok 2016). Polycyclic aromatic hydrocarbons are abundant in biological systems, yet also widespread in the universe.

Hopanes are often invoked as important biological tracers, because they are so resistant to degradation. However, hopanoids are not universal among life-forms, being at very low abundance in some plants and low or absent in one entire branch of the three main branches of life, the archaea microorganisms (Brassell et al. 1981; Belin et al. 2018).

Lipids are present in carbonaceous chondrites, but the pattern (even vs. odd molecular weight) is different in biological systems compared with natural non-biological processes such as Fischer-Tropsch synthesis of organic molecules from CO and H_2 (Georgiou and Deamer 2014). Life on Earth utilizes only a restricted set of amino acids compared with the three-fold or more larger collection of amino acids found in carbonaceous meteorites.

In a planet’s atmosphere, gases that are unstable with respect to chemical reaction with the environment, or the action of UV light, must have a source to replenish them. Methane can be biogenic, or it can be a by-product of the serpentinization reaction of water with ultramafic minerals.

Another pattern diagnostic of terrestrial life is chirality, with unequal enantiomeric pairs of molecules. It is expected that other biological systems will exhibit chirality in certain molecular forms. This was a test that could not have been accomplished by the Viking GCMS, because the necessary pre-processing of

samples was not incorporated. However, the SAM instrument on the Curiosity rover has this capability, as does the MOMA instrument on the ExoMars rover (Goetz et al. 2016).

Aside from organic compounds, there are certain elements, especially transition metals, that are incorporated into protein-based enzymes and were probably involved early in the origin and evolution of life because of their strong catalytic properties for certain reactions. These elements include Fe, Mn, Ni, V, Cu, Zn, and several others, especially when complexed with S. Phosphorus also plays key roles in several aspects of the known biology (nucleic acids, phospholipids, ATP, and others). It is only rarely, however, that an enrichment of such elements remains as a tracer of biological activity, because their relatively low concentration in biological systems tends to mirror their natural geochemical occurrences.

Aside from advanced instruments for gas and liquid chromatography, as well as very-high-resolution mass spectrometry, various so-called “agnostic approaches” are also under consideration. In this more generalist approach, Johnson et al. (2018) advocate techniques that rely on assessing chemical hierarchy by conducting binding experiments on candidate organic assemblages and sequencing of the resulting complex polymers. This is one step beyond looking for patterns in one molecular class, such as amino acids and lipids, and, in principle, might provide a pathway to determining if information storage is occurring, the basis of genetics and evolution.

12.4.3 HABITATS

In evaluations of habitability, various locales in the solar system have different degrees of likelihood as incubators of life. These evaluations have tended to be highly terrestrial-centric. For example, our biosphere includes various forms of life capable of existing over extremely broad temperature ranges but primarily restricted to the range at which H_2O is in the liquid state. Perhaps, a non-terrestrial life-form may have achieved the capability to live off deeply frozen ice, by sufficient harvesting of solar or some other form of energy. Nonetheless, because mission priorities must optimize the chances of successful outcomes, it has become prudent to adopt guidelines based on terrestrial experience.

12.4.3.1 BACKGROUND AND HISTORY

When the Viking mission was first formulated and approved, there was very little knowledge of where would be the most promising landing sites for finding life on Mars. On the one hand, it was believed that peak temperatures more compatible with life were restricted to the lower latitudes. At the same time, the fact that water ice was apparent in the polar regions was a factor favoring higher latitudes. As a result, the two nuclear-powered Vikings landed at 22° N and 47° N. However, the primary driving factor in each case was the perceived safety of the chosen landing site (low surface slopes, minimum rock hazards, etc.). The original landing site for Viking-1 was revealed, via Viking Orbiter imagery, to have geomorphological features indicating past flooding. This imagery was not of

sufficiently high resolution to detect the presence or absence of boulders, but the presumption was that the terrain might be too rugged for a safe touchdown. Although the pre-selected site was apparently where water had flowed heavily in the past, the plans were aborted and the landing target moved to where there was no such apparent activity in the past. Decades later, the Mars Pathfinder mission landed successfully with its airbags at the original prime landing site.

The Viking mantra was “If life is anywhere, life is everywhere,” which was based on the fact that microbial activity is found in soils virtually everywhere on Earth, including hot and cold deserts (Antarctica). Now that we know the soil of Mars is global in nature (Clark et al. 1982; Gellert and Clark 2015), and therefore that the two Vikings sampled the same type of material, we can speculate that there must be different environments that might be more favorable to life. The Viking robot arm did manage to successfully push away a rock and sample the soil that had been protected underneath that rock, which was a valiant attempt at a second environment (Moore et al. 1987). The concern with the global soil unit, of course, is that the periodic global dust storms levitate soil and cause it to be fully exposed to sterilization by the EUV, which reaches down to the surface of Mars because of the lack of the equivalent of Earth’s stratospheric ozone layer that absorbs the more energetic photons. A total of four different samples were taken for the VLBI instruments on each lander, some of which included testing of soils taken from shallow and deeper depths below the surface (Moore et al. 1987).

Viking also attempted, unsuccessfully, to break open rocks for sampling, although little was known at the time about endolithic communities in Antarctica and other deserts. The salt-enriched duricrust fragments were also not tested.

Ocean worlds are quite different. Originally, there was one putative ocean world, Europa, and that was unproven. However, the surface lineaments and clear evidence of an icy crust were intriguing clues. To sample the ocean itself, it was thought to be necessary to find cracks that opened periodically. Now, it appears that some, if not most, ocean worlds have breaches through their outer ice shells, which allow liquid to spew forth, creating plumes of material that reach high altitudes. This is certainly the case for Enceladus, and apparently for Europa as well. Such plumes are somewhat difficult to discover without thorough searches, so it remains unanswered at this time how many such worlds may be ejecting oceanic material into space. Because these bodies have liquid water, which is almost surely in contact with a core containing minerals and carbonaceous matter, they are considered habitable.

12.4.3.2 WHERE TO SEARCH: MARS

The attitudes for where to land on Mars have changed dramatically since Viking. The “life everywhere” mantra has, itself, died. Orbital and rover missions at Mars since Viking, as well as the Viking Orbiter imagery, have discovered a vast diversity of hydrologic landforms on Mars. Remote sensing of mineralogy by infrared spectroscopy has likewise discovered

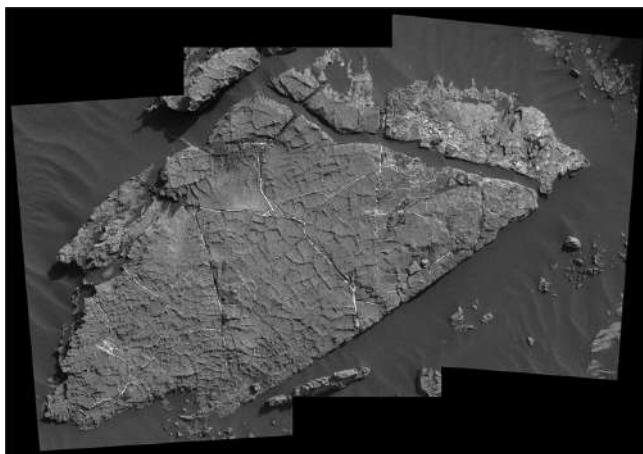

FIGURE 12.4.5 Mud-cracked material crisscrossed by veins of calcium sulfate salt, termed “Old Soaker,” discovered in Gale Crater, Mars. (Courtesy of NASA Curiosity Rover.)

variegated deposits of minerals such as clays and salts, which can only be produced by long-term aqueous alteration of igneous rocks. An abundance of areas that have had substantial quantities of water, as rivers or lakes or perhaps even oceans, is now apparent. Layered sediments containing clays, salts, ferric oxides or interbedded with several constituents, have been discovered. In Gale crater, the Curiosity rover has discovered strong evidence not only of a great lake, but also of inflow fans and evidence for waxing and waning of water levels, complete with areas populated with mud cracks, [Figure 12.4.5](#).

Higher latitudes are now looked upon with greater interest because of the proven presence of near-surface ice, discovered by the Phoenix lander at 68° N. Not until more than a decade after the Viking landings was it realized that Mars undergoes major cycles, whereby its obliquity (axis tilt) systematically changes and, at some point, induces much warmer climates at higher latitudes (Ward 1992). For this reason, Mars, which is now cold was once, and will be again, warm enough to melt the ice that pervades the soil.

The relentless bombardment by cosmic rays, unimpeded by a geomagnetic field and raining down through the thin atmosphere of Mars, has resulted in destruction or conversion of environmental organic compounds originally present from meteoritic in-fall, abiotic synthesis, and possibly life. For this reason, there is strong interest in drilling into the regolith to some depth where this ionizing radiation has been attenuated. The European Space Agency (ESA’s) ExoMars rover slated for launch in 2020 will have a drill capable of penetrating to a depth of up to 2 meters.

One version of locations of special interest is the feature termed recurrent slope lineae (RSL). The RSLs are gullies, located on steep slopes, which have shown one or more change during observation by orbital imagery. Changes seem to occur mainly in local springtime, implicating the possibility that ice or salt-rich brines are involved. They actually may be less interesting than this, simply reflecting downslope movement of relatively dry soil, triggered by temperature changes. However, because of the possible involvement of

liquid water, they have been tentatively identified as special regions (SP) where terrestrial (and Martian) organisms might flourish. Exploring such locations in the search for life is of great interest but very challenging for a variety of reasons.

Ultimately, it will be desirable to sample material at such a depth that the natural geothermal gradient inside Mars reaches the temperature of, or above, 273 K, such that H₂O ice will melt (or shallower, if freezing-point depressing brines are involved). Although it would be quite challenging for a robotic space mission to drill so deep, ~2 or 3 km, there might be areas that provide access to material from such depths, such as crater ejecta. Assuming Mars has a cryosphere with warm ice or liquid water at these depths, this would be an ideal place for organisms to have survived, as surface conditions worsened due to today’s less hospitable surface environment, with its cold, oxidizing atmosphere, lack of liquid water, and UV radiation. Water-rock serpentinization reactions involving ultramafic minerals can result in the production of hydrogen or methane, which would be important metabolites for a subsurface biota.

Other potential habitats that have been suggested include organisms adapted for caves, as well as biota that might live in cracks (chasmoliths), inside rocks (endoliths), inside moist salt deposits (halophiles), or on pro-solar slopes at high latitudes, where surface ice is nearby.

12.4.3.3 WHERE TO SEARCH: OCEAN WORLDS

It is now clear that there are many ocean worlds, and some, such as Enceladus and apparently Europa, have active plumes, where the water can expel and expand into the vacuum of space. The Cassini mission has already successfully flown through the plumes of Enceladus and detected not only the water (ice grains) but also silicates, salt (NaCl), and organics (Postberg et al. 2011, 2017). This was one of the most spectacular discoveries of the Cassini mission to Saturn and its moons, and the instruments used to make these discoveries were not at all optimized for this opportunity.

NASA’s “Europa Clipper” mission is currently in its design phase. In addition to accomplishing multiple close flybys, it may have the opportunity to fly through plumes. A Europa Lander has also been under intensive study (Hand et al. 2016). The ESA’s JUpiter ICy moons Explorer (JUICE) mission is already under development and will make detailed remote-sensing observations of three of Jupiter’s large satellites, which are all thought to be ocean worlds: Ganymede, Callisto, and Europa.

Future missions could consider drilling down into the icy crusts of these worlds, although the best opportunity for accessing unfrozen water (brine?) would probably be to find a location where the crust has natural access, via cracks where plumes are emitted or where a recent impact has breached the surface. The most ambitious of far-future missions would be special submarines designed to descend the ocean depths to study stratification and ultimately to reach the presumed rocky cores where the source of organics and other nutrients may exist.

12.4.3.4 WHERE TO SEARCH: ICY WORLDS

Some planetary objects may contain abundant ice in their interiors, although not currently liquid. In addition to abundant subsurface ice, the dwarf planet Ceres has clays and salts, clearly implicating the past presence of liquid water (Prettyman et al. 2017). Comets are rich in organic compounds, as well as ices. Although the general model of comet formation does not allow for temperatures warm enough for liquid water to have existed, there are some models that invoke radioactive heating, which might have caused some liquid phase at depth early in their history. There are even some minerals found in comet particles (e.g., cubanite, magnetite, and pentlandite) that may be indicative of aqueous alteration (Brownlee 2014), the presumption being that they were produced on other bodies and were incorporated later. Nonetheless, comets as well as carbonaceous chondrite meteorites and their asteroidal parent bodies are of considerable interest in the origin of life, because they may have provided the seed organics from which life arose.

12.4.4 METABOLISM AND GROWTH/REPRODUCTION

The Viking PR and LR life detection experiments focused on anabolism and catabolism of simple carbon compounds, while the GEx experiment was seeking evidence of metabolism that involved uptake and/or release of simple gaseous products.

12.4.4.1 BEYOND VIKING

Many more experiments directed toward metabolism were possible and were incorporated in a proposed experiment for subsequent flight, prior to even the landing of the Vikings (Radmer and Kok 1971). This experiment incorporated a mass spectrometer and a large number of incubation chambers with a variety of metabolites to probe for various metabolic activities, including the LR experiment as well as nitrogen fixation and various tests of nitrate, sulfate, sulfide, and phosphate metabolism. Although many current approaches often include mass spectrometry, their focus is typically on biomarkers rather than real-time active processing of organics and other biochemicals to search for active metabolism.

12.4.4.2 PROVIDE A SUITABLE ENVIRONMENT

One major difficulty in testing for biological activity lies in finding the conditions under which it will be active, as opposed to dormant. The diversity in metabolic repertoires that we encounter in various species on Earth may not be prevalent elsewhere, nor the ability to flourish in as many different environments. In consideration of the cold Martian environment, Viking used low incubation temperatures (typically +6°C to +26°C)—above freezing, but well below the traditional 25°C to 37°C temperature optima that encompass a wide variety of terrestrial organisms. Also, because the degree of wetting needed was uncertain, the aqueous solutions were added

incrementally (1:5 water/soil ratio for the LR experiment) or through a porous barrier (GEx humidification, then 2:1 water/soil ratio) to gradually wet the soil and permit moisture gradients to occur (i.e., don't “drown” the putative organisms). The PR experiments were conducted alternatively under both wet and dry conditions (Brown et al. 1978).

Other considerations for incubation media are such factors as pH and salt concentrations. The ionic strength of the solution and the nature of the ions may be important (Na^+ , Mg^{++} , Cl^- , SO_4^{--} , etc.) for eliciting metabolic activity.

As with many organisms on Earth, there could be a lag phase before activity responds. Reproduction could be slow or even absent. Metabolic activity as an indicator has the advantage that it could be detected well before reproduction itself would occur, especially if the organisms had been dormant.

We now know, of course, that a very large fraction of microbes that inhabit natural environments have never been successfully cultivated under laboratory conditions. However, if they are metabolically active, then their products would contribute to the overall response.

12.4.5 MEASUREMENT TECHNIQUES AND INSTRUMENTS

Analyses of Martian materials for evidence of life can be conducted in numerous ways. To the extent that there are obvious patterns that cannot be explained by geological processes, an orbiting spacecraft could discover evidence of life. Notwithstanding the absence of the purported canals, the so-called “face on Mars” was claimed to be evidence akin to the Egyptian pyramids but was eventually revealed to be jumbled terrain, which, with the aid of shadowing and poorer resolution imagery, appeared somewhat face-like. Orbital observations of atmospheric composition, such as the early claimed detections of methane, can be used as evidence and will be a key objective in future studies of exoplanets. However, investigations done at ground level, and sub-surface, are expected to provide the most convincing evidence for the presence or absence of reliable clues to life.

12.4.5.1 REAL-TIME IN SITU ANALYSIS

Molecular analysis remains one of the key approaches for future studies of Mars in the search for life. Virtually, all landed science missions have included mass spectrometers to probe Martian samples for organic compounds, with the exception of the M2020 rover. Over the decades, mass spectrometers built for spaceflight have improved in both resolution and sensitivity. In addition, pre-analysis chemical processing of samples has been incorporated, with the ExoMars rover MOMA experiment incorporating three different types of derivatization agents to render targeted classes of molecules, such as amino acids, more volatile, so that they can be analyzed (Goetz et al. 2016). MOMA also incorporates laser desorption and ionization to replace the more conventional pyrolysis to release organics. This technique avoids the problem of oxidation of organics during analysis by the

perchlorate (and perhaps other oxidants) within Martian global soils. The Europa Clipper mission also includes mass spectrometers of advanced design.

Element analyzers using x-ray fluorescence (XRF) have flown on nearly all landed missions, although the ExoMars rover will rely on Raman spectroscopy to identify minerals. On the M2020 rover, the PIXL instrument will employ micro-beam XRF analysis to search for minor and trace mineralizations and possible evidence of biological activity via, for example, vanadium or manganese hot spots.

High-resolution imagers have been incorporated post-Viking. Although their resolution is typically a few tens of microns per pixel, far too crude to identify typical microbial cell forms, they are very useful to image microbe-formed structures such as two-dimensional (2-D) microbial mats or three-dimensional (3-D) stromatolites. Their main use, of course, has been to substitute for the hand lens that no field geologist would be without.

12.4.5.2 SAMPLE RETURN

In many respects, the ideal approach to searching for life is to simply bring back to Earth selected samples for more detailed analysis. Not unlike the early explorers, notably including Charles Darwin, the collection of specimens in the field for return to well-stocked laboratories with highly experienced scientists and technicians is eminently to be desired. This allows the full panoply of measurement resources, including the crews who operate the state-of-the-art analytical systems in unique, specialized laboratories. Some instruments simply are difficult to miniaturize. The classical example, to cite an extreme absurdity, is the synchrotron (which occupies many acres for the primary accelerator). Perhaps surprisingly, attempts at miniaturizing a scanning electron microscope (SEM) for spaceflight have so far been unsuccessful, perhaps partially because its greatest value is in analyzing thin sections of materials. Even the petrologist's standard sample approach of making thin sections for analysis, using a variety of types of microscopes, element mapping systems, and diffractometers, has not yet been developed for flight. A dilemma with such equipment is that there is a seemingly infinite number of thin sections that could be prepared and analyzed, invoking petabytes of data just to understand one geologic location's complex history.

Finding microfossils is similarly challenging. Some previous studies (SSB (Space Studies Board) 1977) have gone so far as to recommend only sample return missions for continuing the search for life in Martian samples.

12.4.6 CHALLENGES OF FLIGHT MISSIONS

As is broadly well known by participants in space missions, there are many challenges to the engineering development of the spacecraft and rockets that make such activities possible. Even more challenging, often, are the scientific instruments and sample processing devices because of the strong motivation to continue to incorporate state-of-the-art advances in

capabilities while, at the same time, needing to stay within the boundaries that constrain spaceflight.

12.4.6.1 INSTRUMENT CHALLENGES

The most significant challenge for instrumentation has traditionally been and continues to be the miniaturization of laboratory techniques, which sometimes is measured in meters, rather than centimeters in size, and is tens or hundreds of kilograms, as opposed to a few to twenty or so maximum kilograms. Indeed, mass continues to be a salient metric because costing models are generally proportionally anchored to this benchmark parameter. Volume is also generally related to mass because overall density seldom exceeds that of water, in spite of higher-density components, because of intrinsic void spaces in the packaging (e.g., between optical elements, spacing of detectors from sources, and voids between components of sample acquisition and handling systems).

Other major constraints include power consumption, generally just 10 or a few tens of watts available, once the mission is beyond Earth orbit and especially if more remote than Mars from the sun. Typically, however, if the instrument does not need to be operated continuously, then the critical parameter is electrical energy (W-hr) per measurement sequence, rather than power consumption, because the orbiters, landers, or rovers have sizeable batteries, which can provide higher power wattage than the average it must achieve per day. For example, rovers and landers typically go into low-power modes ("nap," "sleep," and "deep sleep") whenever possible to achieve the low average power that must be less than what the solar arrays or nuclear power sources provide, so that the battery can be recharged. An instrument with very high power requirements will therefore not be allowed to operate as often as desired, compared with one that is so low in power that it may be allowed to operate virtually continuously.

Scientific investigations must be robust to the rigors of spaceflight, which include not only the ultrahigh vacuum of space but also wide temperature ranges for instrument operation and even wider ranges for instrument survivability. For optically based systems, there may be requirements to survive unplanned direct impingement by sunlight. Such systems must also contend with "stray light," whereby sunrays undergo reflection or diffuse scattering from multiple locations on the spacecraft to reach the sensor and cause undesired background or faux signals.

Other issues are data quantity, especially when averaged over the course of the mission, and also the permissible data latency. If large amounts of data must be returned immediately, it will drive the telecommunication system more than if that data can be spread out over a period of days or weeks (sometimes, months, if from very deep space). With modern flash memory storage, the quantity of data stored onboard is no longer such a limited resource as it was in the earlier history of space exploration. For enormous data sets, such as image cubes that involve both high spatial resolution mapping and high-resolution spectroscopy for each image element (pixel), an approach that is starting to gain more serious interest is

onboard processing to select and return more refined results to Earth, without all the raw data. Radar imaging is another example where onboard processing is needed. Although imaging missions originally strove to return all data with no compression, so that radiometric accuracy would never be sacrificed, modern data compression algorithms produce images that are scientifically useful with as low as two bits per pixel average. For operations purposes (e.g., planning of driving routes for a rover), ever-greater losses in fidelity are permissible. The engineering cameras on the M2020 Mars rover will be of higher resolution and in color; this invokes data issues, because the telecommunications pipeline from Mars to Earth still relies on short relay periods per sol, limited to when one of the Mars orbiters happens to pass overhead within range of the surface asset.

A much greater limitation, due to the orbiter-relay based architecture, is the latency of data. Thus, new results from a rover on Mars typically occur only once or twice per day, and the data may therefore be more than one sol old before the ground can react to the results of driving. The longer-term solution, which could dramatically speed up exploration, will be when aerostationary satellites (aka geostationary satellites around Earth) can monitor a Mars ground asset with a continuous line of sight. A few multiple synchronous satellites will be needed, however, to cover all longitudes of Mars, or else, new missions would be constrained by the pre-existing positioning of one single satellite.

Cost is a very major concern for instrumentation, although with high-enough importance, the cost of an instrument that is central to the topmost mission science objectives can be much higher than that of the instruments making ancillary measurements. A traditional metric is that science instruments cost approximately one order of magnitude more, per kilogram, than the host spacecraft itself. Some science instruments cost much more.

The more an instrument costs, the greater the concern for its reliability. In general, although the spacecraft may have two redundant copies of every “black box” function, so that if one box fails the other can be switched on, that is almost never the case with science instruments. Both a spacecraft’s subsystems and its scientific payload are operated for many hundreds of hours before launch to ensure that “infant mortality” failure modes or defects are found, if they exist. Likewise, all the software modes of operation are fully checked out. Due to a number of spacecraft failures during the faster-better-cheaper (FBC) era, spacecraft are also operated before flight in off-nominal conditions as part of “stress-testing” to establish robustness and margins against failures.

Achieving an instrument configuration that is functional yet can be accommodated by the location and viewing limitations intrinsic to the design of the spacecraft is termed the “packaging” issue. If the instrument requires low-temperature cooling of its sensors via use of a thermal radiator, that radiator will need a relatively unobstructed or clear view of deep space. These are the issues that can only be solved by close interaction between instrument designers and spacecraft designers.

The VLBI life detection instrument on Viking is a classic example of constraints-driven packaging, which resulted in complexity and high cost. As an anecdote, I was once delivering terrestrial samples potentially simulating Martian soils, based on his measurements of the soil composition, to George Hobby, a member of the PR investigation team. The meeting place was a particular biology laboratory at the California Institute of Technology. Reaching the laboratory, and looking through the window panes in the door, the experiment did not appear to be hosted in that lab. However, upon entering, it was seen that the experimental setup was in one small corner, spread out horizontally over a single lab bench. The PR experiment was actually relatively simple compared to wet chemistry analysis or multi-step chemical synthesis lab set-ups. However, in the VLBI flight instrument, the PR experiment had to be reconfigured into a small, three-dimensional version, with convoluted tubing around the incubation chamber, solar light source, heaters, valves, etc., as evident in [Figure 12.4.6](#).

For space experiments, the valves themselves are a major challenge, since they must be greatly miniaturized yet resistant to leaks and backflow, while being highly reliable and ultra-clean. Ironically, although the Viking landers would be operating in Martian sunlight and on the very cold Martian surface, it was found necessary to incorporate a solar simulator (xenon lamp) into the packaging and also thermoelectric coolers for the incubation chambers. The latter were necessary because the dissipative heat from nearby electronics and the thermally controlled lander compartment would raise temperatures above those desired (the interior of the Viking thermal compartment, where the VLBI and other equipment were located, was maintained near “room temperature” by waste heat from the nuclear power sources—the radioisotope thermoelectric generators).

Requirements for cleanliness and minimization of contamination by organic molecules, by living organisms, and also by dead organisms (the “dead bug bodies” problem) are typically severe compared with the already-existing standards of clean room operations in assembling hardware and spacecraft. Assays of biologically active contaminants are routine for Mars missions, which are intended to reach the surface, requiring monitoring assays for organisms as well as other types of contamination. For life detection sampling and instrumentation, such cleanliness levels are daunting (Viking-equivalent, after heat-soak “sterilization”) but achievable if clearly identified and pursued.

The bioload assessment comes under the cognizance of the Planetary Protection Office (PPO) of each space agency. The organic cleanliness is specified by the science team for the mission and implemented by the spacecraft provider. Fairén et al. (2017) have argued for a relaxation of requirements for bioburden levels, because ever since Viking, the cost of implementation has seemed to preclude missions for searching for active life. The Viking landers went through a dry heat “sterilization” procedure, which required that they be sealed in a bioshield, and operated properly after being subjected to 112°C temperatures for 26 hours in a special oven, [Figure 12.4.7](#).

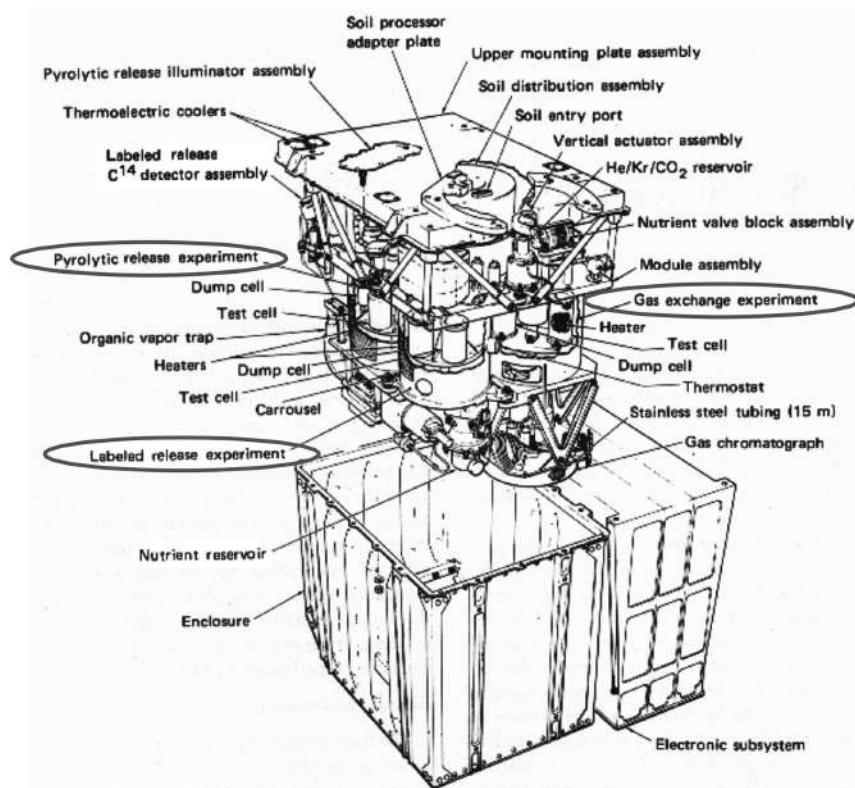

FIGURE 12.4.6 Complexity of the Viking Lander Biology Instrument, and its three main experiments. A major challenge was packaging all the required functions within the limited volume available and its cubical configuration. (From Reproduction of figure 3 from Brown, F.S. et al., *Rev. Sci. Instrum.*, 49, 139, 1978, with the permission of AIP Publishing.)

FIGURE 12.4.7 Viking lander inside bioshield, being moved into oven for dry heat “sterilization” prior to mating with the rocket for launch. (Courtesy of NASA, Washington, DC.)

A major problem is finding organizations with experience in designing, building, and testing high-performance science instruments for flying in space, with little or no previous heritage for that instrument. Often, this unique instrument expertise is to be found in laboratories within a few limited universities, NASA laboratories, and even fewer industrial organizations. As a result of the relatively minimal competition, the principal investigator (P.I.) who invents/conceives the investigation and associated instrumentation is at the mercy of the engineering organization with which she or he is teamed. Thus, it is important that the investigation P.I. retain an appropriate level of decision authority to safeguard scientific performance, within the bounds of the constraints of the sponsoring space agency (typically, mainly instrument cost but also that the instrument be accommodated at reasonable cost, complexity, and reliability by the spacecraft implementer). It is also important that the P.I. plan on less, typically much less, time available for on-going science activities because of the need to devote significant efforts for maintaining the forward progress in instrument development and learning the protocols and exigencies of mission operations. In some cases, the P.I. may lose significant portions of career time for a duration of 10 or more years. This dedication is in the face of the risk of spacecraft or instrument failure, which is real, although reliability has steadily improved in deep space exploration (with the exception of the period during which the FBC cost caps caused loss of several missions). In the end, since most missions are groundbreaking and filled with new discoveries, the dedication required may be compensated by being one of the most rewarding portions of their overall careers.

12.4.6.2 ENVIRONMENT UNCERTAINTIES

One major drawback to the Viking search for life was that although much was already known about the Martian environment at the surface (freezing surface temperatures, low pressure, low humidity, and extreme UV flux) before landing, there were other characteristics neither known, nor envisioned. For example, the extremely fine nature of Martian dust (4- μm characteristic size, a factor of 10 below the mean size of lunar soils) was not fully appreciated, and the life detection techniques were tested against only a very limited number of soil analogs. The relatively high concentrations of sulfates, chlorates, and perchlorates were not expected—the XRF spectrometer (XRFS) instrument had been calibrated for more than a dozen common geochemical elements, but not at all for S or Cl. In particular, it was not *a priori* expected that there would be salts or relatively strong oxidants in the soil. It is now appreciated that oxidants such as perchlorate presumably react with the small quantities of organics in Martian soil at the pyrolysis temperatures used to volatilize organics (and also release some inorganic molecules). Perchlorate, especially when converted into other products by long-term cosmic ray damage, may have provided the oxidant(s) that produced the reactions in the LR experiments on Viking (Quinn et al. 2013; Georgiou et al. 2017).

With the high sulfate content of Martian soil, it would have been logical to add hydrogen (H_2) gas to incubation chambers.

Numerous microorganisms on Earth can metabolize it, especially using sulfate as the electron acceptor, and hydrogen (H_2) may have been an important greenhouse gas, which allowed early Mars to be warmer and wetter (Wordsworth and Pierrehumbert 2013; Wordsworth et al. 2017). Although the GC column in the GEx experiment could analyze for H_2 gas, the only bioactive gas purposely supplied to the incubation chamber was CO_2 . Ironically, just adjacent to the VLBI instrument was the GCMS instrument, which contained a relatively large tank of hydrogen gas at high pressure, utilized as the carrier gas for its gas chromatograph portion of the experiment. There was no possibility of tapping that gas to test for sulfate reduction or methanogenesis, for example, because the two instruments were built by separate organizations and had no cross-coupling of capabilities. Likewise, since Mars is a very sulfur-rich planetary surface, it is regrettable that there was no attempt to introduce H_2S into the incubation chambers, especially since this volcanogenic gas may have provided the earliest electron donor for non-oxygenic photosynthesis on Earth, and similarly on Mars. Many other constituents of the Martian soil, some still unknown (chlorites? peroxy sulfates? other oxidants?), may be only fully understood when samples are brought back to Earth for much more extensive analysis.

Although much remains to be learned, and Viking had only limited tests, we already have tantalizing evidence for the suitability for an origin of life on Mars. First and foremost, Mars was at one time eminently habitable, as several missions have proven. This is true because of the availability of not only liquid H_2O , and the clement temperatures that go with it, but also the entire panoply of carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur (CHNOPS) essential elements (available in the atmosphere, global soil, or both). Most importantly, as pointed out previously, in addition to CO_2 , there may have been abundant H_2 gas (and perhaps CH_4) in Mars' early history, because these are the greenhouse gases now considered as the most likely candidates for facilitating the warm climate in spite of the faint early Sun. These gases are, of course, of enormous interest as participants in early metabolic architectures for microorganisms. With a highly reducing atmosphere, other important gases such as H_2S and NH_3 may have also been available.

Life should have arisen on Mars, according to current knowledge. At least, it should have had a probability of occurrence competitive with the Earth. Several different theories of the chemical and physical conditions that could facilitate abiotic chemical evolution are providing promising avenues for plausible routes to life. One issue is what might be the initial endowment of organic matter. Contributions of exogenous organics are often attributed to carbonaceous asteroids, meteorites, and comets. Both Mars and Earth may have accreted a late veneer relatively rich in these materials. With Mars closer to the asteroid belt and outer solar system, it has had the opportunity to accrete organics as well or even better than Earth.

According to the Sutherland/Powner scenario (Sutherland 2017), a cyanosulfidic set of chemical pathways can account for all of the most fundamental constituents of living systems.

Mars is clearly S-rich compared with Earth and may at one time have been equally endowed with (H, C, and N) ingredients. These reactions are catalytically favored if copper ion is available as a catalyst. On Mars, examples of Cu enrichments have now been reported by both the APXS instrument analyses (Berger et al. 2017) and ChemCam instrument analyses (Goetz et al. 2018) in Gale Crater.

Other studies of chemical pathways invoke the need for borate availability to stabilize RNA (Benner et al. 2012). Boron is rare in igneous minerals, but boron enrichments in the lacustrine environment at Gale Crater have now been also discovered on Mars (Gasda et al. 2017).

Hydrothermal activity has been often invoked as a triggering precursor to the origin of life. Multiple causes of such activity are on Mars, including volcanism, intrusive magma chambers, and/or the thermal energy deposited by the abundant impacts that formed the widespread craters. Hydrothermal occurrences on land are favored by some researchers as abodes for the origin of life (Deamer and Georgiou 2015; Damer 2016). At Home Plate in Gusev Crater, an apparent hydrothermal edifice, the Mars Exploration Rover mission (MER) Spirit rover, has discovered high silica deposits analogous to the microbe-rich hot springs at El Tatio (Ruff and Farmer 2016).

Mars has apparently been eminently suited as a host for the early origin of life. Whether Earth or Mars was the original source of life in our solar system remains an open question.

12.4.6.3 SAMPLE RETURN CHALLENGES

Not unlike typical scientific field work, a sample return mission itself is a major undertaking, especially since it needs to be conducted at a distance of some tens of millions of kilometers. For spaceflight, the cost of a roundtrip mission to the ocean worlds or to the surface of Mars is somewhere between three and ten times more expensive than a one-way mission and also is less likely to succeed because there are more activities that can go wrong and result in a lack of total mission success (samples safely in labs on Earth). Thus, reliability can command exceptional attention, which translates into additional cost for the overall program. Whether on Earth or in space, it is also always the case that there are far more samples of interest in the field location than can be brought back. Thus, there is a significant amount of triage that must be undertaken, yet without the portable and powerful analytical equipment (relatively speaking) and versatile sampling tools that might be taken into the field on Earth.

All sample return missions suffer from this shortfall in potentially finding and returning the “Rosetta stone” sample. Yet, they must try. At the same time, it is incumbent to also collect sufficient samples that are representative of the broad context of the site being studied. This is compounded by the kaleidoscopic variety of sedimentary samples that we now know populate the Martian surface.

For spacecraft missions, it has been learned over and over again that it is the mechanical moving parts (mechanisms) that are the weakest link—the most likely items to fail. Thus, rovers have had problems with wheels and sampling tools

such as drills, and other spacecraft have had problems with gimbal mechanisms that position antennae to communicate back to Earth or reaction wheels, which orient the spacecraft for targeting their cameras. Thus, it is to be expected that one of the greatest challenges to success is simply the collection, storage, and transfer of samples. A simple rock hammer to collect chips of larger rocks is not available on rovers. It is difficult to drill into small rocks. Drilling deeper than 1 meter invokes special challenges in design and reliability.

Landing on a planetary object can be challenging, and Mars is about the most difficult place to land in the solar system because its thin atmosphere invokes the necessity of a heatshield and affects the trajectory during descent but is not sufficiently dense to slow down the lander by parachutes alone to a safe touchdown velocity. Terminal descent propulsion is therefore mandatory, after extraction of the vehicle from its enclosing aeroshell. On Earth and Titan, a parachute is all that is needed for safe landing, for example, of sample return capsules or astronauts. On the moon or other airless bodies such as asteroids, cometary nuclei, and most planetary satellites, the descent and landing can be done straightforwardly and accurately with a propulsion system alone. Landing is simpler but sampling is not, which is why the OSIRIS-REx mission will employ touch-and-go techniques and a rapid sample acquisition mechanism.

Operations to collect samples from a small body are also problematic, because the low gravity and the specter of a weak regolith might not allow successful anchoring, complicating any attempts at sampling to depth by drilling or excavation.

Collecting samples by flying through a plume of material is simpler, but the flyby velocities can severely damage or destroy any included biota or their biomarkers. As a result, additional propulsion or special time-consuming maneuvers may need to be made to reduce flythrough velocities to less than 2 or 3 km/s, in an effort to avoid compromising the integrity of the constituents of the plume if they are organic and/or alive.

Contamination control is another major issue, especially when searching for life, which may be sparse in abundance and perhaps delicate. When taking multiple samples at a complex site, cross-contamination can be a concern. For example, there may be multiple sample containers, but the drill bits may be limited and hence can cause some material from a previous sample to contaminate subsequent samples.

Molecular cleanliness of the spacecraft, with particular attention to the chain of sampling mechanisms, is of paramount importance. Organic-based lubricants must be avoided or fully contained. Many materials that would normally be used, such as plastics and epoxies, must be screened or not used at all. Many elements and their isotopes are also important for scientific analysis, which imposes stringent constraints on the permissible level of metallic particulates.

Of great concern is contamination by terrestrial organisms, including dormant or dead ones. This is also non-trivial and requires special cleaning as well as constant monitoring of cleanliness to ensure that the controls put into place are effective. Clean room operations must include education

of the workers as well as extensive use of outer garments, face masks, taped gloves, tucked booties, etc., to achieve the specified goals.

These requirements for cleanliness are generally set by the project, under the guidance of the science team. For biological contamination, there is an additional layer of responsibility, however, which is the PPO, whose primary aim is to ensure that the total bioburden, which is transported via the space-craft to the target location (Mars, or ocean world), does not inadvertently transfer too many viable terrestrial organisms so as to potentially contaminate the target for all future time. Stringent requirements and protocols are set by the PPO, which are part of the launch readiness approval process.

Once samples are acquired in clean containers, their integrity must be maintained. Seals must not fail. Temperatures should be controlled. For example, in missions that collect samples for organic analysis, a maximum temperature of +50°C is typically set (Stardust and OSIRIS-REx), although sample return from a comet's surface may require even lower temperatures. The Mars 2020 rover mission (M2020) has set a requirement for a maximum temperature of +60°C for the samples stored on the Martian surface. Although this allows preservation of many hydrated sedimentary minerals, it is well above the temperatures that were found to alter the response of the LR experiment on Viking, simulating sterilization (Levin and Straat 2016). Hence, it would behoove that mission to protect some soil samples against temperature excursions to this level, such as by shallow burial, until retrieval for return to Earth. Otherwise, any metabolic-like activity by putative organisms or labile inorganic oxidants could be destroyed and result in an inability to convincingly explain the results of the Viking analyses.

The PPO is also charged with responsibility of imposing the requirement on the Flight Project organization that the returned samples, which may contain biological activity, be carefully controlled so as to not present a threat to the Earth's biosphere. This hazard could be more than just issues of human health, because a Martian microbe might be unusually hardy and able to propagate in cold regions on Earth, out of control, like many species from formerly isolated locations on Earth, which cause damage of various kinds once transported elsewhere ("invasive species" problem). This issue of "back contamination" can be extremely serious, because if insufficient precautions are taken to ensure the reliability of containment of samples in returning to Earth, the approval of the final phases of the mission may be in jeopardy.

Once on Earth, any samples suspected of harboring alien life-forms will be kept in special containment facilities, similar to the Biosafety Level-4 facilities used to study Ebola and other dangerous biological agents. Such facilities will be an even greater technical challenge for extraterrestrial samples, because they must not only prevent release of sample (restriction of outward flow) but also must prevent organics and organisms from the laboratories and researchers themselves from contaminating the samples (restriction of inward flow). Traditional techniques for contamination control, such as maintaining pressure differentials, will need to be augmented. This also greatly restricts the number of scientists

and, to some extent, the number of analytical techniques that can be brought to bear in studying the retrieved samples. It has often been proposed that some sub-portions of the samples be subjected to sterilizing processes (heat or radiation) and then released to the larger science community. This can become an issue if there is no agreement on what a satisfactory sterilizing protocol should be, taking into account the fact that the putative life-forms may not react the same as our DNA/protein-based organisms.

12.4.7 SOCIETAL ISSUES

With the vast public interest, if life is found on another world, will come questions and concerns. Is the discovery valid? What is the full extent of it? Could it be dangerous to humans, to the environment, or to our economic underpinnings?

These are questions that will be raised if life is found and especially if it will be brought to our home planet. Although future public reactions are almost impossible to predict, it will be prudent to consider the possibility and ramifications of major public alarm, possibly fueled by some group of scientists, however small, with professional qualifications but espousing dire concerns.

12.4.7.1 CONFIRMATION OF LIFE

When asked whether there is life on Mars, scientists can only point to the continually increasing evidence for habitability, especially in ancient times, on Mars. It is always difficult, sometimes impossible, to prove a negative—that is, in this case, to prove that life never has existed on Mars or even that it cannot exist today. Likewise, as some investigators have found, it can be very difficult to prove that life exists, in spite of positive results based on preconceived notions about the planet. This has been true for several cases, ranging from the telescopic maps of apparent activities of intelligent life, to the Viking LR results, and to the detailed studies of putative microfossils in meteorite ALH84001 from Mars.

For scientists, it will require a preponderance of evidence of different sorts, most likely including morphological evidence of complexity, with cellular characteristics, as well as chemical evidence such as organic molecule patterns and isotopic anomalies. These criteria only assert evidence for past life. To affirm extant life-forms, it will be necessary to exhibit active metabolic functions of growth and reproduction, and presumably, eventually, evolution.

To the general public, microbial life will not be nearly as exciting for them as it will be for the biosciences community. However, life-forms of any type will nonetheless create global interest, because it will verify the hypothesis that life is to be found elsewhere in the universe, perhaps not even rarely. If it is learned that life-forms on Mars are so similar to terrestrial life that interplanetary panspermia (Clark 1985, 2001; Horneck and Buecker 1985; Melosh 1988) is a candidate explanation, and *not* forward contamination, there will arise the equally intriguing question: on which planet did it first arise? Are we all Martians?

12.4.7.2 FUTURE FALLOUT

As much as it may be difficult to prove the existence of an alien life-form, it is even more challenging to prove the negative—that is, that no life of any kind exists in any retrieved samples. By extrapolation, it is likewise difficult to prove that an alien organism is wholly benign in all respects.

The quantities of returned samples will be very limited, with dozens of scientific analytical techniques waiting in the wings for their chance to investigate all properties of the precious cargo. Furthermore, there will purposely be a variety of sample types, ranging from rocks and soils to consolidated sediments, including, hopefully, some organic-rich samples. All must be considered dangerous, invoking a battery of tests to be performed multiple times because of the multiple sample types. Until such samples can be shown to be benign with respect to potential hazards to our civilization, the sending of astronauts to the red planet may be delayed.

In spite of all the impediments to a search for life on Mars, and elsewhere in the solar system, the value of the search should not be ignored. Space exploration occurs because of the endorsement of the general public and the tax revenues they provide for funding these projects. Technological feats, such as landing rovers and driving them around the planet, are inspirational. Although news media often report that “scientists drove the rover to...”, the reality is that it is engineers who actually plan and “drive” the detailed routes for reaching the locations the scientists request. Likewise, it takes a consortium of engineers with a variety of talents to design the spacecraft, rocket, rover, and even the science instruments. Again, unbeknownst to the general public, it is seldom the engineers who actually construct the designs they develop but rather highly trained and skilled technicians who carefully follow the detailed plans and instructions for building, assembling and testing the hardware and software that will conduct the next mission.

The results of Viking, which were widely regarded as negative, set Mars exploration back for the next two decades. When I asked Carl Sagan if the life issue was dead and we needed to find new rationales for exploring the red planet, he responded that the prospect for life was so important that it would continue to be the underpinnings of Mars exploration. He was correct. In recent decades, the emphasis has focused on discovering if Mars was truly habitable at one time, with the new mantra of “Follow the Water.” This goal has now been proven dramatically, with the discovery of bedded salt-rich sediments by MER rover Opportunity, of pure salt layers by MER rover Spirit, as well as of montmorillonite-clay-like compositions at both MER exploration sites. The Mars Science Laboratory mission (MSL) rover Curiosity has found yet more evidence of aqueous activity, as have numerous orbiter observations by Mars Express and Mars Reconnaissance Orbiter. An emphasis on geological formations and geochemistry has become central, while the question of evidence for extinct or extant life has receded into the background.

However, maintaining the past level of support for further exploration will not be advanced if scientists must attempt to convey to the public the subtleties of “eolian versus lacustrine cross-bedding” or “instances of juxtaposed metabolic redox

couples.” As advanced in the introduction, now is the time for rejuvenation of the search for evidences of life on Mars and, if it cannot be found, to seek to understand why not. Likewise, it is time to begin seriously the study of the ocean worlds to the same end.

ACKNOWLEDGMENTS

It is with special gratitude that I acknowledge the encouragement, advice, and editorial assistance of V. M. Kolb, without which this article would not have been possible.

12.5.1 INTRODUCTION

12.5.1.1 OVERVIEW OF PLANETARY PROTECTION CONSIDERATIONS

Previous sections of this book have reviewed in great detail the historical and ongoing efforts to understand the origin and evolution of life on Earth, as well as the potential for life to exist on other planets. One of the critical questions in searching for life elsewhere is to ensure that contamination from Earth does not

interfere with detection of extraterrestrial signals—this could lead to interpretation of results that are either "false-positive" (e.g., reports of fossil Mars life in the meteorite ALH84001 that was subsequently shown to be abiotic; see Steele et al. 2010) or "false-negative" (e.g., failure to identify indications of Mars organic compounds in data from NASA's Viking missions to Mars; see Glavin et al., 2013; Freissinet et al., 2015). The potential for Earth contamination to interfere with scientific investigations of other planetary objects and the need

for international standards to reduce this risk were recognized internationally around the launch of Sputnik (e.g., Committee on Contamination by Extraterrestrial Exploration [CETEX], 1958, 1959). Very rapidly thereafter, guidelines and practices were put in place to prevent contamination; these are collectively known today as “planetary protection,” as described in detail by Meltzer (2011). Planetary protection policy and guidelines are founded in the best available scientific knowledge and maintained by the International Council for Science to provide consensus standards, for use by all countries and space exploration activities, as part of complying with United Nations (UN) treaty obligations. The policy and guidelines are regularly updated to reflect new scientific discoveries, following a process that continues to this day.

12.5.1.2 RELATIONSHIP TO ASTROBIOLOGY AND PLANETARY EXPLORATION

All missions coming in close proximity to other planets have a potential to introduce Earth contamination, which could reduce confidence in scientific conclusions relating to extraterrestrial life detection. In addition, the introduction of Earth organisms capable of surviving for long periods in a dormant state could put in jeopardy future human goals such as settlement or terraforming, which are entirely outside the scope of near-term scientific missions or other exploration activities. Control of Earth contamination on planetary spacecraft is a technological challenge that has been surmounted on multiple occasions, most notably during NASA’s Viking program in the 1970s (Daspit et al., 1988) and the European Space Agency (ESA’s) ExoMars missions ongoing today. “Forward contamination” is the term used to describe these processes, which have risks that can be determined and quantified—at least to the extent that we understand the capabilities of Earth organisms and non-living contamination to be present on spacecraft, and can persist after introduction to planetary environments.

In contrast, potential risks resulting from the introduction of extraterrestrial organisms into the environment of the Earth, termed “backward contamination,” are entirely unknown and currently unquantifiable, because, to date, we have no evidence regarding the characteristics of possible extraterrestrial life and thus no basis to assess pathogenicity or ecological consequences. From a policy and regulatory standpoint, these uncertainties about the actual risks of backward contamination are compounded by challenges associated with detecting extraterrestrial life, if it is present. The two Viking and the Mars Science Laboratory (MSL) missions to Mars carried sensitive instruments to detect metabolic activity (Viking) or organic compounds (Viking and MSL) on Mars (e.g., Glavin et al., 2013; Freissinet et al., 2015). Each of these missions returned data indicating levels of Earth contamination that exceeded detection limits for Mars organics, and these data were interpreted as non-detections of Mars life—however, in the case of the Viking Life Detection Package, one of the principal investigators still publishes papers disputing this conclusion (e.g., DiGregorio et al., 1997).

In 1964, a decade prior to the Viking missions, the US Space Science Board (SSB) was asked to evaluate backward contamination issues for NASA’s Apollo program and future Mars missions. It noted that “negative findings could provide a sense of security which might well be false” (Space Science Board [SSB], 1964). The possibility that extraterrestrial organisms could be hazardous, either to the environment of the Earth or to humans directly, makes detecting them at very high sensitivity a primary concern for ensuring the safety of the Earth.

12.5.1.3 INTERFACES WITH WIDER SOCIETY

On Earth, humans have a long history of transporting biological organisms from one location to another, which has often caused major disease outbreaks and/or ecosystem disruption, as reviewed in Mann (2011) and many others. It is not knowable, until we have an example of extraterrestrial life, whether that life could become pathogenic or disrupt the ecosystems that humans rely on. In contrast, we do know that Earth organisms inadvertently transported on spacecraft could interfere with future objectives of human settlers, as they have done on Earth in the past. Avoiding the accidental transport of Earth organisms, before decisions are made to introduce them, is a long-term concern for planetary protection, because one single release of a self-replicating entity into a habitable environment can engender a persistent population and thus cause permanent contamination.

For the reasons mentioned above, it is essential to address planetary protection at the highest levels of global societal decision-making, which for 60 years has been done via the UN and the International Council for Science. In addition, to ensure that one bad actor does not cause permanent damage to everyone, individual nations have obligations under the 1967 Outer Space Treaty to take appropriate measures to ensure that all exploration of other planets carried out under their auspices, whether governmental or private/commercial, follows the same guidelines. Space exploration is the first effort in human history for which we, as a global society, have recognized the potential risks of contamination before it happened, and planetary protection is the first time humanity as a species has taken responsible steps to prevent contamination of pristine environments even before our very first efforts to explore them.

12.5.2 PLANETARY PROTECTION: DEFINITION AND SCOPE

Planetary protection covers explicitly the search for extraterrestrial life and also the potential for Earth life to interfere with future human objectives: the focus of planetary protection is exclusively on biological contamination and does not address other kinds of contamination such as radiation or physical detritus. Due to the very high level of concern for protecting the Earth on which we all live, relative to the more limited concern about contaminating other planets, the guidelines and policy for planetary protection are divided, conceptually, on the basis of whether spacecraft are only traveling outward to other planetary bodies and therefore could

cause forward contamination, or whether there is an expectation that hardware will return back to Earth, possibly carrying extraterrestrial material, which could release backward contamination.

12.5.2.1 FORWARD CONTAMINATION CONCERNS

Spacecraft traveling to another planetary body (moon, asteroid, comet, etc.) have the potential to cause forward contamination by depositing organic material and/or organisms from Earth onto the target object. Forward contamination is of concern for planetary protection only to the extent that contaminants could interfere with scientific or other human objectives at the target object. The vast majority of objects in the solar system are known to support conditions inhospitable to all Earth life (e.g., no atmosphere, too irradiated, and too dry), and therefore, spacecrafts going to them are not controlled to prevent introduction of Earth organisms. To the extent that a non-habitable object is of scientific interest for understanding the origin and evolution of life in the solar system, which involves studying whatever organic compounds could be present, a mission may be required to provide a list of materials present on the spacecraft and to report locations where spacecraft hardware is left at end of mission. Missions going to non-habitable targets are required to provide only a straightforward set of documentation about hardware composition, spacecraft operations, and final disposition.

In contrast, when a planetary body has the potential to provide a habitat for Earth organisms, spacecraft traveling to them are required to avoid introducing Earth organisms into habitats: this involves applying very strict decontamination procedures to hardware that could introduce Earth organisms and also (or instead) avoiding contact of contaminated hardware with potentially habitable environments. Currently, three solar system objects are of concern for contamination by Earth life: the planet Mars, and the moons Europa around Jupiter and Enceladus around Saturn. Other planetary bodies may be added to this list as additional potential habitats are identified, and requirements to prevent contamination of them should be put in place. Missions going to habitable targets are required, as part of mission formulation, to submit and receive approval for detailed plans that describe proposed decontamination procedures; during hardware assembly and launch operations, they will undergo regular inspections and extensive reviews to confirm compliance prior to launch, and after launch, they continue to ensure contamination avoidance during spacecraft operations, as well as to provide information about relevant research findings and report final hardware disposition.

12.5.2.2 BACKWARD CONTAMINATION CONCERNS

When spacecraft hardware is being brought back to Earth after contact with another planetary body, it is of primary concern to ensure the safety of the Earth's biosphere and everything that lives in it. Again, the focus is on biological contamination, so the same conceptual distinction is made relating to

habitability and the potential for extraterrestrial life—defined as biochemistries that could function in the surface physical environment (temperature, pressure, etc.) of Earth—with very different levels of concern around preventing release of material from “potentially habitable” versus “non-habitable” target objects. Missions returning from all non-habitable target objects, including the Earth’s Moon and near-Earth asteroids, follow planetary protection guidelines to provide documentation of the target’s non-habitability during mission planning phases and receive no further planetary protection requirements once appropriate review is completed.

As with forward contamination, restrictions are only imposed on spacecraft returning from objects that might host extraterrestrial life, which is *by definition* considered biohazardous until tests demonstrate otherwise—currently, this includes the three “potentially habitable” objects: Mars, Europa, and Enceladus. If other solar system objects are found, in future, to host physical conditions that could support biochemistries also potentially active on Earth, then these other objects would be added to the short list requiring stringent precautions for sample return. Missions sending hardware intended for return from potentially habitable targets are required stringently to limit contamination from Earth that could interfere with detecting extraterrestrial life, as well as all requirements appropriate to the particular outbound mission—these missions are also required to maintain an archive and detailed record of potential Earth contaminants and the provenance of samples collected, in a format that can be provided to a pre-return “Earth Safety” review process that will be carried out at international level (e.g., Haltigin et al. 2018; Kminek et al., 2017).

Appropriate documentation on the return status of all missions also needs to be carried through whatever local/national approval processes apply to a re-entry event into the Earth’s atmosphere.

12.5.2.3 INTERNATIONAL, NATIONAL, AND AGENCY-LEVEL OBLIGATIONS AND RESPONSIBILITIES

The current set of accepted international consensus guidelines on how to implement planetary protection is held by a permanent committee of the International Council for Science, the Committee on Space Research (COSPAR) (Kminek et al., 2017). The 1967 Outer Space Treaty, more accurately the “United Nations Treaty on Principles Governing the Activities of States in the Exploration and Use of Outer Space, including the Moon and Other Celestial Bodies,” is the major international agreement governing how treaty signatories (“States Parties to the Treaty”) go about exploring and using outer space (United Nations [UN], 1966). This treaty has been signed by all countries involved or interested in space exploration, numbering over 100 and including North Korea (United Nations [UN], 2018).

The United Nations Committee on the Peaceful Uses of Outer Space (UN-COPUOS) is the committee of the United Nations in which discussion of matters related to the treaty takes place. The UN-COPUOS, in its 60th meeting report to

the UN General Assembly in 2017, noted the long-standing role of COSPAR in maintaining the planetary protection policy as a reference standard for spacefaring nations and in guiding compliance with article IX of the Outer Space Treaty (United Nations Committee on the Peaceful Uses of Outer Space [UN-COPUOS], 2017). This recognition reiterates the role that COSPAR has played over the 60 years since its creation in 1957 (described in [Section 12.5.3.1](#) and reviewed in Meltzer, 2011).

States parties to the Outer Space Treaty, by signing and ratifying the document, agree to abide by all 17 treaty articles, including Article IX which reads, in part:

States Parties to the Treaty shall pursue studies of outer space, including the moon and other celestial bodies, and conduct exploration of them so as to avoid their harmful contamination and also adverse changes in the environment of the Earth resulting from the introduction of extraterrestrial matter and, where necessary, shall adopt appropriate measures for this purpose.

The COSPAR planetary protection policy addresses *harmful contamination* in the context of forward contamination and *adverse changes in the environment of the earth resulting from the introduction of extraterrestrial matter* in the context of backward contamination. As noted previously, other forms of contamination or environmental damage are not addressed by the COSPAR planetary protection policy or guidelines.

Other articles of the Outer Space Treaty impose additional obligations on States Parties to the treaty that are relevant to planetary protection. Article VI requires that:

States Parties to the Treaty shall bear international responsibility for national activities in outer space, including the moon and other celestial bodies, whether such activities are carried on by governmental agencies or by non-governmental entities.

Further, States Parties must assure that:

The activities of non-governmental entities in outer space, including the moon and other celestial bodies, shall require authorization and continuing supervision by the appropriate State Party to the Treaty.

In general, each State Party to the Outer Space Treaty has assigned the responsibility to ensure compliance with international planetary protection guidelines to their national space agency, which, in some cases, also requires cooperation with other national agencies that regulate activities within the Earth's atmosphere. In the case of the ESA, which is a regional organization with multiple national members, the responsibility of each State Party to ensure compliance with planetary protection policy and guidelines, for ESA missions in which they participate, has been transferred to ESA. Individual States Parties are also responsible for developing internal processes to provide the required *authorization and continuing supervision* of the actions of their non-governmental entities.

12.5.3 A BRIEF HISTORY OF PLANETARY PROTECTION

12.5.3.1 EARLY CONCERNs

Fictional accounts of interplanetary travel causing biological contamination, including ecological damage and pathogenicity (e.g., Wells, 1898), reflect historical experiences from European colonialism and the Columbian Expansion. For related historical reasons, “planetary quarantine” was the term used instead of “planetary protection” prior to the mid-1980s, but the practices and precedents are identical. Planetary protection as a practice began after World War II, with concerns expressed by scientists involved in organizing the 1957–1958 International Geophysical Year. In preparatory discussions, the international scientific community recognized that advances in rocketry would soon permit artificial satellites to be launched from Earth to the Earth’s Moon and other planets. Concerns about potential biological contamination were first raised at the 7th International Astronautical Congress held in Rome, Italy, in September 1956 (Phillips, 1974; Meltzer, 2011). Both the United States (US) and the Soviet Union (USSR) announced plans to launch Earth-orbiting satellites for scientific research purposes, with the USSR launching two Sputnik satellites in 1957 and the US launching the Explorer and Vanguard satellites in 1958, as reviewed in Doyle and Skoog (2012).

Starting in 1958, with the formation of UN-COPUOS and COSPAR, as well as multiple national space agencies, extensive discussion of how to prevent biological contamination by planetary spacecraft took place in the international community, including Europe, the US, and the USSR, facilitated by interactions associated with the International Geophysical Year (e.g., Committee on Contamination by Extraterrestrial Exploration [CETEX], 1958, 1959). Within the US, the National Academy of Sciences (NAS) convened a working group known as the West Coast Committee on Extraterrestrial Exploration (WESTEX), chaired by Melvin Calvin and including Joshua Lederberg and the graduate student Carl Sagan, that supported the NAS’ newly formed Space Science Board as well as COSPAR. Discussions held during WESTEX meetings, as documented in their final report and appendices (Space Science Board [SSB], 1959), addressed all the concerns of planetary protection that inform policy today, emphasizing both their historical basis and global scope.

Statements made in 1959 by this committee, on the topic of transporting extraterrestrial materials to Earth, are surprisingly pertinent in providing clarity to current debates:

We know of many unhappy examples of biological competition from the introduction of new organisms into fresh niches—e.g., many insect pests in the US; rabbits and prickly pear in Australia, smallpox into the New World, and syphilis into Europe. Even the relatively limited damage of these incidents should not be duplicated as a byproduct of space research. (WESTEX Report, pg. 17)

Finally, it may be remarked that the task of evaluating the potential hazard of a planetary biota will be multiplied if this has to be isolated from organisms inadvertently transferred from Earth. (WESTEX Report, pg. 18)

12.5.3.2 EVOLUTION OF PLANETARY PROTECTION POLICY AND GUIDELINES

During the late 1950s and early 1960s, frequent discussions were held in the international arena that informed the development of guidelines on how to respond to policy-level concerns about planetary contamination and potential consequences for scientific research and other human endeavors (reviewed in Phillips, 1974; Meltzer, 2011). The need for a risk-based approach that included the careful sterilization of spacecraft hardware was recognized very early, and methods for accomplishing this were proposed and evaluated (e.g., Space Science Board [SSB], 1959, 1964). Early missions implemented an approach based on a “probability of contamination” model, with information gained from each mission, leading to refinements in policy and guidelines over time.

In the 1980s, COSPAR accepted a conceptual shift in the formulation of planetary protection policy, moving from an explicit risk-based probabilistic approach to the “by exception” approach used today (COSPAR internal decision memo No. 7/84, accepting the proposals in DeVincenzi et al., 1983). This shift responded to accumulated scientific data, showing that most solar system objects were not contaminable by Earth life and, therefore, by inference, were also unlikely to host extraterrestrial life that could be biohazardous to the Earth. Four categories of possible outbound missions were described, as in [Table 12.5.1](#), determined by the level of interest in the target object for understanding the origin and evolution of life and also the mission operations to be performed.

Missions to objects not of concern for understanding the origin and evolution of life are assigned Planetary Protection Category I, with no further documentation or other requirements. Missions to objects that do not provide natural habitats for Earth life but that could retain organic and prebiotic compounds of scientific interest are assigned Planetary

Protection Category II, and limited documentation of mission operations is required—this includes the vast majority solar system objects. Missions to solar system objects that could provide habitats for Earth life—as noted previously and currently include Mars, Europa, and Enceladus—are assigned Planetary Protection Category III if hardware is not intended to contact the target object (flyby and orbiter missions) and assigned Planetary Protection Category IV if hardware is planned to contact the target (probe and lander missions). Because of the considerable interest in Mars as a target of human exploration beyond purely scientific investigations, and the more extensive information available about the planet, Planetary Protection Category IV landed missions to Mars are further divided on the basis of landing site and mission objectives, as described in the “future missions” section later.

In addition, a fifth category of “Earth Return” missions was established, recognizing explicitly the much higher priority placed on protecting the biosphere of the Earth than elsewhere, as noted in [Table 12.5.1](#). This Earth Return category, Planetary Protection Category V, is divided into “Restricted” and “Unrestricted” Earth Return, determined by evaluating scientific data supporting the hypothesis that samples to be brought to Earth contain no extraterrestrial life, which is by definition considered biohazardous. For most solar system objects, this is accomplished by responding to the six questions listed in [Table 12.5.2](#), about conditions on those objects and the natural influx of material to Earth.

When data are inconclusive or support the presence of possible habitats, as is true for Mars, Europa, and Enceladus, then a designation of Planetary Protection Category V “Restricted Earth Return” is given. Planetary Protection Category V “Restricted Earth Return” applies to all missions involved in a sample return effort—this is to ensure that information needed to support the pre-return Earth safety analysis and post-return biohazard test protocol is captured and retained by early outbound missions as well as the final return leg. Each mission carrying hardware intended for possible future return to Earth, including missions that emplace hardware possibly to be retrieved by future mission activities, also receives requirements appropriate to that particular orbiter or lander mission.

TABLE 12.5.1
Planetary Protection Mission Categories

	Planet Priority	Mission Type	Mission Category
A	Not of direct interest for understanding the process of chemical evolution. No protection of such planets is warranted.	Any	I
B	Of significant interest relative to the process of chemical evolution, but only a remote chance that contamination by spacecraft could jeopardize future exploration. Documentation is required.	Any	II
C	Of significant interest relative to the process of chemical evolution and/or the origin of life or for which scientific opinion provides a significant chance of contamination that could jeopardize a future biological experiment. Substantial documentation and mitigation are required.	Flyby, Orbiter Lander, Probe	III IV
All	Any solar system body	Earth Return <i>Restricted or Unrestricted</i>	V

TABLE 12.5.2
Six Questions for Restricted Earth Return

1. Does the preponderance of scientific evidence indicate that there was never liquid water in or on the target body?
2. Does the preponderance of scientific evidence indicate that metabolically useful energy sources were never present?
3. Does the preponderance of scientific evidence indicate that there was never sufficient organic matter (or CO₂ or carbonates and an appropriate source of reducing equivalents) in or on the target body to support life?
4. Does the preponderance of scientific evidence indicate that subsequent to the disappearance of liquid water, the target body has been subjected to extreme temperatures (i.e., >160°C)?
5. Does the preponderance of scientific evidence indicate that there is or was sufficient radiation for biological sterilization of terrestrial life-forms?
6. Does the preponderance of scientific evidence indicate that there has been a natural influx to Earth, for example, via meteorites, of material equivalent to a sample returned from the target body?

12.5.3.3 PLANETARY PROTECTION POLICY APPLIED TO EARLY PROGRAMS

12.5.3.3.1 Soviet Decontamination Efforts

Soviet scientists were involved, from the earliest international discussions, in raising concerns relevant to planetary protection, and it was reported to the international community that early Soviet lunar missions did comply with the nascent guidelines being developed by COSPAR. These announcements had significant influence on decisions made within the US to ensure that early NASA missions would be decontaminated, as documented in a memo dated September 14, 1959, from the executive director of the SSB, Hugh Odishaw, to the first NASA Administrator T. Keith Glennan (Space Science Board [SSB], 1959, pg. 84), and also in the final report of WESTEX, which states:

We applaud the respect for these considerations on the part of the USSR in the light of Academician Topchiev's announcement that Lunik-II has been decontaminated. (Space Science Board [SSB], 1959, pg. 13)

Throughout the 1960s, it was reported in public that Soviet spacecraft sent to Mars and Venus had been “sterilized,” but there was significant uncertainty in the West as to what this actually meant, as reviewed in Meltzer (2011). Questions were raised, in the international community, about the benefit of implementing stringent sterilization protocols on some spacecraft, if other spacecraft had already delivered Earth organisms to the same target—as if a single contamination event would render completely useless all subsequent efforts to limit additional contamination. This is a little like someone asking “Why should we keep brushing our teeth, after we’ve eaten our first candy-bar?”

12.5.3.3.2 Ranger

A number of NASA’s early missions were managed by the Jet Propulsion Lab (JPL) in Pasadena, California, which, along with

all other NASA facilities, was instructed to ensure appropriate sterilization of planetary spacecraft, in October 1959, following the recommendations from the SSB mentioned previously (see Hall, 1977 for details). Prior to this, JPL had established a program to develop methods for spacecraft sterilization, which presented a paper at the 10th International Astronautical Congress, containing the statement:

Sterilizing space probes is an engineering nuisance, however, the same ordeal has confronted surgical crews for quite some time. In both instances, anticipation of the task is necessary. (Davies and Comuntzis, 1960, included in Space Science Board [SSB], 1959).

Paradoxically, at the same time, JPL also began designing a multi-purpose planetary spacecraft bus, called “Vega,” that did not include any sterilization-tolerance requirements in the design constraints.

This design was adopted for use in the Ranger program in 1959, by which time it had already undergone considerable preliminary testing and refinement (Hall, 1977). In 1960, JPL staff proposed a sterilization protocol that involved subjecting components, subsystems, and the assembled spacecraft system to 125°C before shipment to the launch site, with a final ethylene oxide gas treatment applied at the launch site to eliminate organisms that might have recontaminated spacecraft surfaces during transport and launch preparations. Despite the plan to apply a system-level heat treatment, design constraints for the Ranger program, including those provided to subcontractors and instrument contributors, did not include heat tolerance among the requirements, and very little testing was done, during development of Ranger spacecraft hardware, to evaluate the tolerances of spacecraft components and subsystems to heat treatment.

Despite the October 1959 memo requiring spacecraft sterilization, and associated 1960 protocol, only a few of the components selected for the Ranger spacecraft, and none of the early engineering or flight models, were tested for compatibility with heat sterilization treatment. The first hardware to undergo a heat sterilization protocol was the flight model of the first lander spacecraft, Ranger 3. Multiple materials’ incompatibilities and failed components were identified during subsequent testing, which required extensive re-work. At the time, JPL reported:

Although no failures are directly traceable to heat damage, it is felt that heat sterilization does shorten the expected life of electronic components. (Hall, 1977, pg. 124)

Today, military specifications for high-reliability hardware require an operational high-temperature burn-in phase, to eliminate defective components at risk for early failure (MIL-STD-810G, 2008).

After the launch of Ranger 3, which included a pre-launch ethylene oxide gas treatment (tolerance to which was also not mentioned in design constraints), the spacecraft “performed flawlessly” (Hall, 1977, pg. 147), but incorrect

commands transmitted from ground control caused the spacecraft to lose contact, without accomplishing any mission objectives other than impact on the Moon. Despite this successful performance, the reaction from Ranger project managers was to attribute the failure to heat sterilization (Hall, 1977, pg. 125):

Although lacking firm evidence that this requirement caused the equipment failures, JPL now requested and received more waivers from NASA Headquarters on heat sterilizing certain crucial components.

Rangers 4 and 5 underwent only partial heat sterilization treatments, though they were subjected to pre-launch ethylene oxide gas because this was not considered a risk to spacecraft hardware—yet both missions were unsuccessful, with failures in spacecraft bus control systems despite electronic components having been exempted from heat treatment.

In 1962, after the failure of Ranger 5, the program was extensively reorganized, with new management and a much-strengthened quality-assurance program, and the program received approval to cease all sterilization treatments. In 1963, a few months prior to the planned launch of Ranger 6, it was discovered that a particular type of diode, used by the hundreds throughout each of the Ranger spacecraft, was often defective and susceptible to shorting in microgravity, *with potentially disastrous consequences* (Hall, 1977, pg 197). Potentially defective components were replaced extensively in Rangers 6 through 9, with much better quality control on the replacements—even so, the cameras on the Ranger 6 spacecraft did not function, though the rest of the mission was accomplished successfully. Rangers 7, 8, and 9 were considered to be fully successful and returned imagery that was of considerable interest to both the scientific community and the general public, as well as useful to the Apollo program for landing site selection.

The Ranger program was instrumental in establishing processes in space mission formulation that balance scientific and engineering concerns, as well as quality-control programs and interfaces for project management, that have subsequently become widely implemented on NASA's robotic missions. The influence of the Ranger program on the development (or lack thereof) of standard approaches for spacecraft sterilization is not so well recognized but is still considerable.

12.5.3.3 Apollo

The Apollo program remains the most complex effort in space exploration attempted prior to 2018, involving astronauts landing on another planetary body and returning to Earth with samples, as well as both samples and astronauts being subject to isolating containment and analytical and biohazard testing after return to Earth. Apollo was, applying current planetary protection policy, a Planetary Protection Category V Restricted Earth Return campaign, including all the additional health and safety concerns associated with human spaceflight. The history of the Apollo program has

been covered extensively elsewhere (e.g., Launius, 1994), so only two aspects of the Apollo program are mentioned here, as being of particular relevance to planetary protection.

In the words of US President Kennedy, the Apollo program was established for “landing a man on the moon and returning him safely to earth”—more for purposes of political and technological positioning than for scientific investigation (Launius, 1994). Even before the inception of the Apollo program, it was understood that the return of astronauts and extraterrestrial materials back to Earth had the potential to introduce extraterrestrial biohazards, as reviewed previously and by Meltzer (2011), and the US Government recognized that these risks needed to be controlled. In 1963, after questions were asked about backward contamination in Congress (Meltzer 2011), President Kennedy signed National Security Action Memo 235, on *Large-Scale Scientific or Technological Experiments with Possible Adverse Environmental Effects* (JFK Library, 1993), which established a process that required presidential approval prior to conducting any such experiments, in consultation with the NAS and other relevant federal agencies (e.g., the State Department). In particular:

Experiments which by their nature could result in domestic or foreign allegations that they might have such effects will be included in this category even though the sponsoring agency feels confident that such allegations would in fact prove to be unfounded.

and

international scientific bodies or intergovernmental organizations may be consulted in the case of those experiments that might have adverse environmental effects beyond the U.S.

This memo, declassified in 1993, was applicable both to US nuclear testing activities and to the Apollo program.

Following public expressions of concern about backward contamination, NASA consulted with the US Public Health Service, which assigned a liaison officer to support the development of a “quarantine” program. This resulted in the formation of an “Interagency Committee on Back Contamination” (ICBC), chartered to provide oversight of both astronaut quarantine and curation of lunar materials. The committee included the three US regulatory agencies covering public health, agriculture, and the environment, as well as two additional “interested agencies”: the NAS and NASA. A formal interagency agreement was established that required high-level interagency consultation prior to acting on any decision that was not *in accordance with the unanimous recommendation of the agencies represented on the Interagency Committee on Back Contamination*. NASA is not a regulatory agency, so this structure ensured that the regulatory agencies would exert effective oversight, even though over half the individual members of the ICBC were NASA staff (Radley and Rosen, 1969).

The interagency coordination framework that was established during the Apollo program, which was founded on

the best-available scientific advice and included the regulatory agencies responsible for ensuring the health and safety of humans, animals, and agricultural activities, and the wider environment, was sound. In practice, the ICBC did perform oversight of the Apollo program's sample return activities and issued determinations regarding astronaut quarantine and biohazard testing of lunar materials, including termination of the quarantine program after Apollo 14. However, it was very fortunate that lunar samples, in fact, are not biohazardous to astronauts or the Earth, because the implementation of quarantine measures during the Apollo program would not have been adequate to prevent release. Reluctance on the part of those responsible for implementing the program was motivated by disputes over jurisdiction and authority, cost concerns, and a rather widespread perception within the space exploration community that precautions were unnecessary, as reviewed in Meltzer (2011). Many very valuable lessons can be learned from the Apollo program, both on practices that were surprisingly foresighted, and should be replicated, and on aspects of sample return and post-return operations that would benefit from improvement.

One rather famous example, which would be good not to repeat, involves biological analyses performed on the Surveyor 3 camera, which were claimed to show survival of Earth organisms after traveling round trip to the Moon (Rummel et al., 2011). The Surveyor robotic mission landed on the Moon in 1967 and was not subject to decontamination procedures for planetary protection. The Apollo 12 mission landed near the Surveyor 3 site in 1969, and astronauts collected hardware from the Surveyor 3 lander spacecraft, including a camera, for return to Earth. The Apollo 12 astronauts and other lunar samples that had been collected were subject to quarantine and containment procedures; in contrast, the camera from Surveyor 3 was placed in a laminar flow hood and subjected to biological sampling. The organism *Streptococcus mitis*, commonly found in the human respiratory tract and rapidly killed by desiccation, was the only organism isolated from the camera and was found in only one sample collected very late in the sampling period. The sampling process was filmed, and these films document that the “sterile technique” practices used by the technicians collecting samples would not, today, be considered adequate to maintain sterile culture conditions. In addition, a photographer leaned into the hood and took close-up still images, just prior to biological sampling, of the location on the Surveyor 3 camera, from which the *S. mitis* organism was collected. The appearance of *S. mitis* in cultures from the Surveyor 3 camera prompted a review, during which the Surveyor 3 spacecraft engineering model was found possibly to have been contaminated by *S. mitis*. Following this observation, it was concluded that the organism collected after return must have survived the round-trip travel between the Earth and the Moon, including years of exposure on the lunar surface.

Several logical fallacies, of concern to planetary protection, can be identified in this procession of events, which would be better avoided in the future. First, given that lunar quarantine procedures were supposed to be in place, how is

it that the Surveyor 3 camera was sampled in what was effectively a shirt-sleeve environment, with a photographer present in street clothes rather than within containment? Second, the conclusion that a desiccation-sensitive organism must have survived several years of exposure to hard vacuum should have required some additional supporting data, beyond the merely circumstantial—the principle “Extraordinary claims require extraordinary evidence” does apply. Finally, the collection of unsterilized hardware by astronauts, who are subject to quarantine, adds the risk that they could be exposed to pathogenic Earth organisms from the collected hardware, possibly invalidating the purpose of a quarantine altogether. *Streptococcus mitis*, though mostly harmless, is a facultative human pathogen that can cause infective endocarditis—which was not, in the 1960s, an easy disease to diagnose. The trajectory of the Apollo program, and the future of human spaceflight, might have been quite different if, during quarantine, the Apollo 12 astronauts had come down with fever, bruising, exhaustion, stroke, and possibly heart or kidney failure.

12.5.3.3.4 Viking

If one early robotic exploration program stands out from all others for effective planetary protection compliance, that is the Viking program, which in the 1970s sent NASA's first lander missions to Mars (Daspit et al., 1988). The Viking program was managed by NASA Langley Spaceflight Center in Virginia, with prime contractor support from the Martin Marietta Corporation, and the lander spacecraft carried scientific instruments contributed by several academic institutions as well as other US government facilities. Each of the two Viking landers was transported to Mars by a Viking orbiter spacecraft, which carried replicate sets of scientific experiments. The two Viking landers returned the first meteorological, physical, and seismological measurements, as well as performed both metabolism- and chemistry-based life detection experiments, from two locations on the surface of Mars (Ezell and Ezell, 1984).

The Viking landers carried a suite of instruments designed to detect chemical constituents of possible Martian organisms, as well as metabolic indicators of possible Mars life. Both of these instrument payloads received cleanliness requirements that were more stringent than the rest of the Viking lander spacecraft (Daspit et al., 1988), to protect the integrity of the scientific results obtained from them. The chemistry-based experiment utilized a gas chromatograph-mass spectrometer (GC-MS) instrument to measure gases that evolved as Martian regolith was heated, results from which were interpreted at the time to indicate the presence of cleaning fluids used before launch from Earth. However, in 2017, it was reported that low-abundance peaks from the Viking GC-MS data indicate the presence of compounds, in the Viking samples, that were definitively identified by the Curiosity rover's Sample Analysis at Mars instrument as being Martian in origin (e.g., Glavin et al., 2013; Freissinet et al., 2015). The metabolic experiments included several culture cells that provided conditions predicted to support growth of Martian organisms, as well as the ability to heat samples of Mars regolith to temperatures expected to inactivate any organisms, as discussed in

DiGregorio et al. (1997). The results from this suite of experiments, known as the “Life Detection Package,” definitely detected heat-labile chemical reactivity but were inconclusive as to whether this was consistent with biological metabolism. At the time, because the GS-MS instrument data were interpreted to indicate the absence of organic material in the regolith samples, the Viking results were interpreted as a failure to detect Mars life, although this interpretation has subsequently been questioned (e.g., Navarro-Gonzalez et al., 2006).

The Viking program undertook the most stringent implementation of planetary protection requirements ever attempted, involving component or subsystem-level heat treatment to reduce microbial populations present inside the items or materials; careful cleaning of hardware surfaces to reduce the levels of heat-resistant microbes to fewer than 300 per square meter of spacecraft surface; packaging of the entire assembled lander and heatshield into a “bioshield” that was overpressured through launch, to prevent recontamination after heat microbial reduction; and finally, shortly prior to launch, a full-system heat microbial reduction treatment of the lander spacecraft inside the bioshield for over 40 hours at 112°C, which was demonstrated to reduce the levels of viable microbial contamination on lander surfaces by four orders of magnitude. The key to the successful implementation of this effort was the complete acceptance of planetary protection requirements on the part of project staff, including the Project Manager James Martin and the Project Scientist Gerald Soffen, both at NASA Langley, with strong support from program staff at NASA Headquarters (Daspit et al., 1988).

From the very beginning of the program, planetary protection requirements were fully captured in the design constraints for the landed hardware and integrated with controls on approved parts and materials, as well as testing, assembly, and operational procedures, that were followed by almost all hardware contributors. Viking Program staff at Langley were well-educated about planetary protection, having consulted with members of WESTEX, and studied heat-sterilization of hardware since 1964 (Ezell and Ezell, 1984) as well as attended meetings of the planetary protection advisory committee for several years prior to the start of the program in 1969 (Daspit et al., 1988). Although questions were raised about the need for heat microbial reduction prior to the start of the Viking program, once that was confirmed, on the basis of life-detection science contamination concerns as well as international policy considerations, planetary protection was managed as just another element required for project success.

From the start, it was recognized that electronic components and other spacecraft materials were not necessarily pre-qualified to tolerate temperatures planned for the final system-level heat microbial reduction, so the majority of parts and materials was acquired and tested in bulk. Issues related to heat treatments appeared on the project manager’s “Top 10 Concerns” lists early during the program (Ezell and Ezell, 1984), but all of these were retired, by appropriate qualification, substitution, or process modification, by mid-1972, prior to the assembly of spacecraft hardware. During hardware assembly, an extensive model testing program was carried out; it included evaluation of

heat tolerance, starting with smaller and then larger subsystems and continuing with full lander system qualification models. No significant issues were found after both of the flight systems underwent the full-system heat microbial reduction, validating the general assessment by Viking managers that the testing and qualification program significantly reduced risk and increased the reliability of the spacecraft (Daspit et al., 1988).

It is certainly true that the Viking requirement for heat tolerance required extensive component testing and replacement of susceptible parts and materials in heritage hardware, which might appear to increase program cost. However, multiple Viking managers observe that the bulk purchases and extensive testing program also had cost benefits, in reducing the need to evaluate components case by case and then re-work subsystems after they failed. For new hardware subsystems, requirements for heat tolerance could be addressed during the design phases and if done well should not have increased cost significantly, beyond the difference in component prices (Daspit et al., 1988). When these design constraints were not addressed adequately, both cost and schedule slips were the result, as demonstrated for the camera system originally contracted to the company TRW (Ezell and Ezell, 1984).

In the case of the GC-MS instrument, that was contributed by JPL, heat-tolerance requirements were not addressed effectively during the design phases, and a number of problems with this instrument were reported. The GC-MS instrument on the Viking 2 lander, which was located at higher latitude and therefore experienced greater thermal cycling, failed during the extended mission phase, with one engineer on that team attributing the problem to weaknesses induced by the pre-launch full-system heat microbial reduction. However, other Viking managers noted that the GC-MS team was reluctant to accept the heat-tolerance requirements, to a greater extent than other hardware providers (see Daspit et al., 1988). It is possible that this reluctance on the part of some JPL engineers to embrace heat sterilization is influenced by corporate memory of the Ranger program discussed previously.

It is sometimes claimed that planetary protection required 10% of the total Viking program budget, with an implication that this is an unreasonable cost for a mission that both protects the target of exploration and performs experiments searching for extraterrestrial life (e.g., Fairén et al. 2018). However, as described previously, it is not actually possible to pull out a subset of the Viking expenditures and label it as “planetary protection,” because implementation was so completely integrated into overall project management. It is more relevant, for students of astrobiology, to understand that the total Viking program budget was about \$1 billion, in 1975 dollars, with the Life Detection Package costing \$59 million and the GC-MS costing \$41 million (Ezell and Ezell, 1984). These actual costs demonstrate that the two instruments on Viking, addressing research of the greatest interest to astrobiology, together cost 20% of the total program budget—including all the effort to establish how to accomplish full-system heat microbial reduction and other associated cleaning processes. More recent estimates of the cost to retrofit a modern Mars rover for full-system heat microbial reduction, done independently by ESA and NASA, suggest that this cost

has remained at the equivalent of one major science instrument (e.g., Rummel and Conley, 2018). Whether the equivalent of one science instrument is a reasonable cost to answer key research questions in astrobiology is an important advocacy question for the astrobiology community to address.

It is a consistent conclusion among people involved in the Viking program that the requirements for full-system heat microbial reduction provided significant benefits to the reliability and success of the missions and was not as difficult to implement as initially anticipated. The most important lesson to learn from historical missions, for planetary protection in the future, was summarized very well by the Viking Project Manager, James Martin (quoted in Daspit et al., 1988):

There are many young people at JPL and elsewhere working on these problems, and they are so enthused by the technologies they're working on that they don't realize the extent of the impact PP and Contamination control requirements can have or how that impact can enlarge as a problem the longer it is neglected. The PP requirements should be expressed in a more forthright and regulatory sense, so that people aren't allowed to forget about it until five or ten years from now when they suddenly discover that 'you really can't make a widget that you can heat.'

12.5.4 APPLICATION TO MISSIONS IN PREPARATION

12.5.4.1 OUTER PLANETS MISSIONS

12.5.4.1.1 Probability of Contamination

It has been suggested that the greatest volume of environments providing conditions suitable for the growth of microbial life from Earth could be in the outer solar system, in the form of subsurface liquid water within the moons of the giant planets, and also any water that might remain liquid in the interiors of Kuiper Belt objects. Such habitable environments are of concern for planetary protection, to the extent that the probability of introducing a single viable Earth organism into a liquid water environment must be held lower than 1×10^{-4} per mission, which applies to both lander and orbiter/flyby missions and must take into account spacecraft and operational reliability. Fortunately for mission planners, it is thought to be extremely difficult to access potential liquid water volumes within the vast majority of objects in the outer solar system: a recent analysis of Ganymede, which is the object currently considered to have the most-accessible water after Europa and Enceladus, suggested that viable Earth organisms deposited on the surface would have a probability much lower than 1×10^{-4} of reaching subsurface liquid water (Grasset et al., 2013).

For this reason, missions that would not encounter Europa or Enceladus receive no *a priori* restrictions on hardware cleanliness, for planetary protection; rather, these missions are required to ensure, by careful operation of the spacecraft, that any liquid water bodies discovered during the mission are not contacted by spacecraft hardware, even after the mission ends. This requirement was applied, in the past, to the missions that discovered potential habitats within Europa and Enceladus: the Galileo spacecraft was de-orbited into Jupiter,

and the Cassini spacecraft was de-orbited into Saturn, in order to protect the newly discovered watery moons of those planets. The Juno mission to Jupiter, which will not encounter Europa during the prime mission, plans to dispose the spacecraft into Jupiter—but they also performed calculations to show that, should the deorbit maneuver fail and the inactive Juno spacecraft impact Europa at some point in the future, the impact energy would be so high as to incinerate all remaining viable organisms, in a sufficiently high fraction of the total impact cases in Monte Carlo simulations that the $<1 \times 10^{-4}$ probability requirement was met (Bernard et al., 2013).

12.5.4.1.2 Cleanliness and Life Detection

The detection of extraterrestrial life is of relevance to planetary protection because extraterrestrial organisms are by definition considered biohazards: this is based on long experience from Earth that introduced species can become invasive or pathogenic. For this reason, outbound-only missions to outer solar system objects that carry life detection investigations do not receive additional cleanliness requirements from planetary protection on the basis of instrument capabilities, beyond the 1×10^{-4} probability of contaminating liquid water and potential habitats.

In contrast, additional organic and biological cleanliness requirements will be imposed on sample return missions from potentially habitable environments in the outer solar system (currently Enceladus or Europa), to ensure adequate levels of confidence in the results of the post-return biohazard test protocol. During the Apollo program, sample collection hardware was carefully cleaned and samples were (in principle) quarantined until a biohazard test protocol had been completed. Subsequent to Apollo, a notional “Draft Test Protocol for Detecting Biohazards” has been established (Rummel et al., 2002), during the course of multiple rounds of studies preparing for missions that would collect samples and return from Mars. This draft test protocol requires additional refinement (e.g., Kmirek et al., 2014), to establish requirements on the level of statistical confidence needed to make a determination that extraterrestrial samples are “safe for release”—which is a risk assessment that needs to be made at a global societal level, not solely by space scientists or space agency staff (e.g., Haltigin et al., 2018). Confidence that the test protocol is not generating false-negative results would, of course, be reduced in proportion to the amount of Earth contamination present in collected samples, and it depends on the capabilities of instruments used to make measurements.

The development of biohazard test protocols and associated contamination requirements is ongoing.

12.5.4.2 MARS MISSIONS

12.5.4.2.1 Planetary Protection Requirements for Mars: It's Complicated

The planet Mars has been explored more extensively than any planet in the solar system other than Earth; likewise, Mars is also the focus of a wider diversity of human interests. From the earliest discussions of Mars exploration, the potential for future human colonization/settlement and the possibility of

terraforming Mars were taken seriously, and the potential for biological contamination from Earth to interfere with these long-term goals was recognized (e.g., Space Science Board [SSB], 1959). In response to the rapidly increasing scientific information about Mars and recognizing the diversity of short-term and long-term goals in Mars exploration, planetary protection requirements for Mars have undergone more discussion and refinement than those for any other target of exploration.

Spacecraft and hardware not intended to impact Mars are allowed to meet planetary protection requirements by avoiding impact onto Mars. Launched hardware items that were not maintained in a controlled clean environment—e.g., the upper stages of launch vehicles—are required to avoid impact onto Mars, for a period of 50 years after launch, at a probability of 1×10^{-4} . It is preferred that spacecraft intended to orbit or flyby Mars should also avoid Mars impact for a period of 50 years, though with a relaxed probabilistic constraint—this involves no greater cleanliness than assembly in controlled environments typical for spaceflight hardware assembly. If, however, impact avoidance is not feasible for orbiter spacecraft, due, for example, to aerobraking, then orbiter missions may demonstrate that they deliver no more organisms to Mars than are permitted on landed hardware that is expected to break open on impact.

Current planetary protection requirements for the cleanliness of hardware landing on Mars depend both on where the hardware is intended to land and on the purpose of the hardware. The Viking program imposed additional cleanliness requirements on some hardware, to ensure the integrity of the life detection experiments by removing contamination from Earth that could interfere with the detection of signals from Mars. No indications were observed of Earth organisms being present, so the terminal heat microbial reduction and additional cleaning of the Life Detection Package did accomplish the goal of eliminating Earth life. However, despite the program's best efforts, signals interpreted as Earth contaminants were the most abundant compounds measured by the Viking GC-MS instruments. At the time, it was assumed that these Earth contaminants were the only compounds present and that no organics from Mars had been detected (e.g., Space Science Board [SSB], 1977). Because the Viking landers were not collecting Mars samples for return to Earth, this interpretation did not put in jeopardy the safety of the Earth, which is of paramount importance to planetary protection.

12.5.4.2.2 “Average” Mars

After the Viking program demonstrated that most of the Martian surface is cold and dry, providing very limited resources that could support Earth life, cleanliness requirements for Mars landers were relaxed, to eliminate the four-order-of-magnitude heat-reduction step and protection from recontamination implemented on Viking (DeVincenzi et al., 1996). This basic level of cleanliness is required for all Mars missions, and missions receive a designation of Planetary Protection Category IVa if they do not carry life detection instruments or plan operations to access more-habitable locations on Mars.

Before the terminal full-system heat reduction, the Viking landers had been cleaned to 300 heat-resistant organisms per square meter of spacecraft surface over about 1000 square meters of area and also carried approximately 200,000 heat-resistant organisms in the interior of the spacecraft. The number of heat-susceptible organisms was not measured as part of the requirement, because any heat treatment that killed resistant organisms would eliminate susceptible organisms at a much higher rate. These relaxed requirements of less than 300 heat-resistant organisms per square meter, less than 300,000 heat-resistant organisms over all surfaces exposed to the environment of Mars, and less than 500,000 heat-resistant organisms in total (this includes organisms inside hardware that could break open on impact, such as heat shields, backshells, and parachutes), are necessary to meet Planetary Protection Category IVa.

12.5.4.2.3 Special Regions on Mars

Following orbital observations in the 2000s that confirmed the presence of active gully systems and water ice in the near-subsurface of Mars, the Viking requirement for four-log microbial reduction with recontamination prevention was reinstated for missions targeting locations on Mars where environmental conditions have the potential to provide, at least transiently, temperatures and available water that could support growth of Earth life. So-called Mars Special Regions are, as of 2017, defined as locations where temperatures reach above -28°C and “water activity” ($1/\text{relative humidity}$) reaches above 0.5 (equivalent to 50% relative humidity). These regions include features on Mars where the presence of such conditions is in question (Kminek et al., 2017). Each project planning a landed mission to Mars is required to do an analysis of their proposed landing sites, to establish whether Special Regions might be present: only if Special Regions are not within a landing ellipse that includes 3 standard deviations of targeting error after parachute opening (3-sigma) would a project be designated Planetary Protection Category IVa. Missions that do target areas with potential Special Regions inside the 3-sigma landing ellipse are designated Planetary Protection Category IVc and are required to use microbial reduction processes and recontamination prevention to achieve Viking-equivalent cleanliness of <0.03 viable Earth organisms per square meter of exposed spacecraft surface. Missions intended to access Special Regions outside the landing ellipse are required to clean at least the subsystems used for such access to Viking-equivalent levels and protect them from recontamination by other spacecraft hardware.

It is relevant to note that the definition of Special Regions, originally adopted in the mid-2000s, does not follow historical precedent in setting conservative limits on parameters of concern to planetary protection, with room for subsequent relaxation: in the 2010s, the temperature limit for Special Regions had to be reduced from -25°C to -28°C , after additional data on the capabilities of Earth organisms were obtained.

12.5.4.2.4 Mars Life Detection

The highest concern for planetary protection is to avoid “harmful contamination” of the environment of the Earth, which

includes imposing appropriate constraints on future round-trip missions, robotic and human. In this context, false-negative results from *in situ* experiments to detect Mars life are of considerable concern, because future requirements would be set based on an incorrect assessment of potential risk. One example of the consequences of false-negative results is that Mars exploration was put on hold for 20 years because “Viking had shown there were no organics” (Space Science Board [SSB], 1977)—yet recent data from the Sample Analysis at Mars (SAM) instrument informed a re-evaluation of Viking data, which identified Martian organic compounds not recognized previously (e.g., Glavin et al., 2013; Freissinet et al., 2015).

Missions to Mars that carry instruments capable of detecting Mars *life forms, precursors, and remnants*, in the language of the COSPAR policy (Kminek et al., 2017) automatically also are capable of detecting biological and organic contamination from Earth and receive a separate designation of Planetary Protection Category IVb. To address the greater policy-level concern about Mars life (by definition considered biohazardous) being brought to Earth, life detection missions are required, in addition to landing site constraints, to ensure that hardware subsystems with a potential to contaminate the life detection experiments meet the equivalent of the Viking lander overall requirements: cleaned to 300 resistant organisms per square meter of surface area, protected from recontamination, and reduced by four orders of magnitude. As noted previously and in histories of the Viking Program, this level of cleanliness is less than what was required for the Viking GC-MS and Life Detection Package, which was set based on the scientific objectives of those instrument (Daspit et al., 1988). Currently, rather than setting specific numerical limits on non-viable Earth contamination, planetary protection policy specifies that such requirements be set *driven by the nature and sensitivity of the particular life detection experiments* (Kminek et al., 2017), with the expectation that appropriate limits would be established by the instrument teams and project management during payload selection and accommodation, and subsequently monitored for compliance, along with all other planetary protection requirements. This is an effective approach for *in situ* experiments, but when samples are returned to Earth, additional considerations pertain.

12.5.4.2.5 Mars Sample Return

Mars is of astrobiological interest as a potential habitat for extraterrestrial life and therefore has the potential to host life that is, by definition, considered potentially biohazardous to the Earth. For this reason, missions planned to collect samples from Mars and bring them to Earth receive the designation “Planetary Protection Category V Restricted Earth Return,” which means that spacecraft hardware must be cleaned to levels that will ensure that Earth contamination is not introduced into Mars samples in quantities that could invalidate the biohazard test protocol that will be performed after return to Earth (e.g., Haltigin et al., 2018). This is in addition to meeting all requirements appropriate for mission operations at Mars, as well as ensuring that documentation of potential contamination is collected and provided for pre-return Earth Safety analyses

and reviews. During the return phase of the mission, samples are required to be contained, so as to ensure a probability of less than 1×10^{-6} that a particle greater than 10 nanometers in size is released into the environment of the Earth, including particles adhering to spacecraft surfaces, as discussed in Haltigin et al. (2018). In the special case of sample return from one of the moons of Mars, additional calculations would be needed to assess the amount of material from Mars present in the collected samples, due to recent impact ejection events, such as the 60-km Mojave impact crater (Chappaz et al., 2013).

After Mars samples have landed on Earth, it is required to contain them at levels equivalent to the strictest biosafety level (BSL-4/P-4, used for, e.g., ebola virus) and also protect them from Earth contamination while early analyses and the biohazard test protocol are performed (Rummel et al., 2002). This is required to ensure that the risk to the Earth from retaining Mars samples is acceptably low. For Restricted Earth Return missions, “acceptably low” is a regulatory determination that has not yet been fully developed—currently, there is a containment requirement but not a biohazard test confidence requirement. Containment procedures are required to ensure that the risk of releasing extraterrestrial material into the Earth’s environment is kept under one in a million, which was recommended based on comparison with other risks that human societies accept (European Science Foundation [ESF], 2012).

12.5.4.3 HUMAN MISSIONS

Human missions to other planetary targets almost invariably involve a return trip to Earth—as such, they would receive requirements equivalent to Planetary Protection Category V. Current planetary protection policy includes guidelines for human missions that focus predominantly on forward contamination. Protection of the Earth must be ensured, but specific practices to accomplish this have not been established—the Apollo program provides useful precedent in some areas and cautionary experience in others.

As with robotic missions, planetary protection concerns for human missions are divided conceptually by “habitable” vs. “non-habitable” targets: when humans explore non-habitable targets, neither contamination of the astronauts or the Earth nor contamination of the target by Earth life is relevant. Mars is the only feasible target for human exploration that is considered as potentially hosting native extraterrestrial life and is potentially “habitable” for Earth microbes; thus, human missions to Mars have received the most policy-level consideration (e.g., Space Studies Board [SSB], 2002; Conley and Rummel, 2010; Kminek et al., 2017; Haltigin et al., 2018).

It is recognized that human missions are unlikely to be fully contained; thus, provisions must be made to address contamination of astronauts by Mars material, as well as contamination of Mars by Earth microbes. By analogy, with the requirements for Special Regions, approaches have been proposed for early human missions that involve allowing a greater level of contamination in areas where humans travel, while protecting Special Regions to currently required levels. The degree of separation needed would be based on the

technical capabilities of the hardware and human support systems, which currently are not well-established. As is routine for planetary protection, the collection of additional scientific information may lead to relaxation of requirements, once it is demonstrated that the initial level of stringency is not needed.

Two additional factors pertain to the human exploration of Mars, which are not currently covered in planetary protection policy—yet these issues will need to be addressed at a policy level, before such events occur that require a response from the global society. The first question is the extent to which the environment of Mars might be toxic to astronauts or Earth microbes, in the absence of a Mars biota—this needs to be understood in order to assess the potential for false-positive indications of biohazards in samples from Mars. Measurements made on Mars suggest that the dust contains ~1 weight-percent of oxy-chlorine compounds, which are known to be toxic to humans and some Earth microbes. An understanding of the potential toxicity of Mars dust may be important to assess overall risk of human missions to Mars and to provide information both to the astronauts performing missions and to the societies that pay for them.

The second question, which is explicitly excluded from planetary protection policy but still needs to be addressed, is the extent to which Earth microbes could change during spaceflight, resulting in increased biohazard after they return to Earth. This issue was raised by the NASA Advisory Council but has not yet received significant attention, despite experiments from the International Space Station that seem to indicate increased virulence in *Salmonella* grown in microgravity (Sarker et al. 2010).

Societal perception and acceptance of these risks will be greatly facilitated by providing accurate and complete information, starting as early as possible in the process of mission development.

12.5.5 OPEN ISSUES IN INTERNATIONAL POLICY

12.5.5.1 RELATIONSHIP OF INTERNATIONAL POLICY TO NATIONAL OBLIGATIONS

The 1967 Outer Space Treaty, by its title, provides for COSPAR, also apply more broadly than just scientific exploration. Whether the COSPAR guidelines represent legally binding “customary law” has not yet been tested in court, although their recognition in 2017 by UN-COPUOS as a *long-standing... reference standard... in guiding compliance with article IX of the Outer Space Treaty* could strengthen that case. All the major international agreements on space exploration have elements that support planetary protection practices (Achilleas and Crapart, 2003), with the state responsible for space objects also being responsible for mitigating *harmful contamination* caused by them. In addition, the international framework of environmental law, although focused on terrestrial activities, includes language that could reasonably be extended to backward contamination brought to Earth by sample return missions (Achilleas and Crapart, 2003).

In addition, the 1992 Convention on Biological Diversity, Article 3, states the principle that states have:

the responsibility to ensure that activities within their jurisdiction or control do not cause damage to the environment of other States or of areas beyond the limits of national jurisdiction.

Whether such areas extend beyond the environment of the Earth has again not yet been tested in court, but it has been suggested that a plausible case could be made (Achilleas and Crapart, 2003).

Supporting these international obligations, some countries also have national laws that address environmental protection aspects of space activities. For example, the Russian Federation, in Decree No. 5663-1, states the principle of *provision of safety in space activity, including protection of the environment; and prohibits actions to create harmful contamination of outer space which leads to unfavourable changes of the environment*, (UNOOSA, retrieved 2018). Although the US has not yet passed legislation addressing planetary protection, several sections of the Code of Federal Regulations describe the applicability of the National Environmental Protection Act to Earth Return missions. In addition, the 1975 Presidential Directive that superseded the Apollo-era NSAM-235, PD/NSC-25 on *Scientific or Technological Experiments with Possible Large-scale Adverse Environmental Effects and Launch of Nuclear Systems into Space* specifies a consultation process that would need to be followed prior to implementing a Category V Restricted Earth Return Mission.

12.5.5.2 APPLICATION OF PLANETARY PROTECTION GUIDELINES TO COMMERCIAL MISSIONS

It is only recently that non-governmental entities have developed capabilities to engage in activities of concern for planetary protection, and the mechanisms for ensuring *authorization and continuing supervision* (UN, 1966) of private space exploration are still under development. Within the US, the commercial launch approval process overseen by the Federal Aviation Administration requires consultation with the State Department and NASA, and planetary protection compliance for commercial launches has been addressed. Other countries may have more straightforward internal structures for establishing legal and/or regulatory frameworks for commercial space exploration.

With the increasing interest and activity in private space exploration, and considering the potential for global negative consequences due to the release of a hazardous extraterrestrial entity, formal processes, both nationally and internationally, will undoubtedly be needed. Although planetary protection is the aspect of commercial space exploration with the broadest potential consequences, the establishment of an appropriate regulatory framework for commercial space activities is an issue that extends far beyond planetary protection. For example: if one commercial entity identifies a valuable target and another entity succeeds in reaching the same target more rapidly, how will rights and responsibilities for use of that target be determined?

12.5.5.3 INTERNATIONAL CONCERNS AROUND RESTRICTED EARTH RETURN

Over the past decade, the iMARS Working Group, chartered by the International Mars Exploration Working Group, has explored requirements for Mars Sample Return and made considerable progress on developing an architecture for handling Mars samples brought to Earth (Haltigin et al., 2018). The major concern for backward contamination is to prevent release of extraterrestrial organisms over the entire time for which extraterrestrial material is stored on Earth, thus the precautions taken involve two steps (e.g., Rummel et al., 2002; Kminek et al., 2014). First, the hardware returning to Earth must be carefully designed to reduce the risk of accidental breach to an acceptably low level, until the hardware is placed in a properly designed containment facility. In addition, the samples brought to Earth must undergo careful testing for possible extraterrestrial life, which is, by definition, considered biohazardous. This “Biohazard Test Protocol” must be performed early during the post-return sample analysis period, to minimize the risk of accidental release due to failures in containment. To ensure that the test protocol can detect extraterrestrial biology with high sensitivity, hardware used to collect extraterrestrial samples must be carefully cleaned of Earth contamination, and information retained, starting with the earliest mission phases, about the potential for and types of contamination that could be introduced. This set of requirements was recommended during the US Apollo program, to minimize the potential for “false negative” results due to the masking low levels of extraterrestrial biosignatures by higher levels of Earth contamination (e.g., Space Science Board [SSB] 1964).

The most significant long-lasting consequence of space exploration for human society and the environment of the Earth would be backward contamination, the release of a novel extraterrestrial entity that has adverse effects—this was recognized as a potential problem in the 1950s and is explicitly prohibited by Article IX of the Outer Space Treaty (UN, 1966). It has been recommended that COSPAR guidelines specify a probability of no more than “one in a million” that potentially viable extraterrestrial material be released into the Earth’s environment, a limit that was proposed after a survey of risk/benefit evaluations that are considered acceptable for other human activities (European Science Foundation (ESF), 2012; Haltigin et al., 2018). As mentioned previously, many spacefaring nations have national laws on environmental protection, as well as the existing international agreements—but the specific applicability of national and/or international regulatory frameworks to Restricted Earth Return efforts remains to be elaborated.

12.5.6 SOCIETAL CONSIDERATIONS

12.5.6.1 AMBIGUITY IN A “DETECTION” OF EXTRATERRESTRIAL LIFE

Planetary exploration is currently done almost entirely by using taxpayer funding—even companies that have planetary missions in preparation, such as Moon Express, receive

considerable government funding. Responsible use of these funds requires that the benefits of investment in planetary exploration outweigh the risk of loss, including loss due to lack of investment elsewhere. This is a societal decision, not a scientific or engineering one, so societal perception of exploration activities and scientific conclusions is critical. After the Viking missions reported a non-detection of Mars life, no missions were sent to Mars for several decades, despite continued interest on the part of spaceflight engineers and Mars scientists (Space Science Board [SSB], 1977), because funds were allocated elsewhere. If it had been recognized at the time that the Viking mass spectrometers did, in fact, detect Mars organic compounds, albeit at low levels (Glavin et al., 2013; Freissinet et al., 2015), the trajectory of Mars exploration would likely have been quite different.

The need to ensure accuracy in the conclusions of a life/biohazard detection protocol is of much greater importance when the samples being analyzed have been brought back to Earth. There has recently been some confusion regarding contamination control requirements supporting a Biohazard Test Protocol, resulting from conflation of concerns associated with “false positive” and “false negative” results (e.g., Space Studies Board [SSB] 2018). From the standpoint of interpreting scientific data, this results from ambiguity about which “null hypothesis” is being tested (Kminek et al., 2014). Astrobiologists and scientists interested in detecting extraterrestrial life will err on the side of not announcing a finding of “life” until they have high confidence in the detection: they are testing the null hypothesis “there is **no** life in these samples.” If Earth contamination is detected but there are not signals clearly indicative of extraterrestrial biosignatures, this would be interpreted as a “non-detection” of extraterrestrial life. This approach is consistent with careful scientific discovery, and it also ensures that no harm is done to scientists’ or space agencies’ reputations, from holding over-enthusiastic press conferences.

12.5.6.2 THE POTENTIAL FOR UNIDENTIFIED BIOHAZARDS

In contrast, concerns for Earth Safety require avoiding the release of potential biohazards into the environment of the Earth, and therefore, they need to test the contrary null hypothesis: to ensure safety of the Earth if samples are released, it is necessary to disprove the hypothesis “there is **extraterrestrial** life in these samples” (e.g., Kminek et al., 2014; Haltigin et al., 2018). When testing this null hypothesis, the detection of any Earth contamination would indicate the presence of biosignatures that could also be associated with extraterrestrial biohazards, and very careful further testing would be required to evaluate this possibility at acceptable levels of statistical significance. Samples can certainly be analyzed in containment, while biohazard testing is ongoing—in fact, many of the measurements made will inform both scientific and regulatory communities—but the risk that a breach in containment could release a potential biohazard increases the longer the question remains unanswered. This is a societal question, as much as a scientific one: the public will be

affected, if a breach occurs, so they will also want to know how safe the samples are. The space agencies bringing extraterrestrial samples to Earth have an obligation and responsibility to provide accurate answers.

12.5.6.3 QUARANTINE AND SETTLEMENT

The concern about detection of potential biohazards does not stop after the first Mars sample return mission, but the challenge of differentiating Mars life from Earth contamination will become progressively more difficult. Robotic exploration can be accomplished while maintaining stringent levels of cleanliness; however, once human missions to Mars are initiated, the concerns increase in ways that are outside the purview of planetary protection. All organisms known to be hazardous to humans are from Earth: this includes overt pathogens (e.g., *Clostridium tetani*) and environmental hazards (e.g., *Stachybotrys* fungi). Despite cleaning protocols, pathogenic organisms have been identified on the International Space Station (e.g., Lang et al., 2017), though fortunately, they have not yet caused illness in astronauts. Societal concerns could change rapidly, if an astronaut were to become ill from a spaceborne pathogen—as human spaceflight becomes more common, policies to control transport of Earth organisms will need to be developed.

Once humans attempt to settle elsewhere, those environments will facilitate independent evolution, and the possibility of exchanging biohazardous organisms that are originally from Earth will need to be addressed. Current and historical quarantine procedures may not be adequate, when people, with their microbes, want to go back and forth. If an infectious disease or hazardous organism has never been present in an environment, what rules should be imposed to control introduction? How should they be different for independently replicating (e.g., most bacteria and archaea) vs. obligate-parasite (e.g., viruses and some eukaryotic parasites) entities? What about quiescent or zoonotic infections that have no vector, for example, a human with trichinosis or malaria? Should the rules be different for infections that could spread, given an appropriate environment, such as *Giardia* and *Clostridium difficile*? All of these issues should be considered, at least at a policy level, before the actual circumstances develop.

12.5.7 SUMMARY AND CONCLUSIONS

This chapter provides a brief summary of planetary protection policy and implementation, including the current context and historical aspects of its development as well as outlining applicability to select future missions. The issues that planetary protection addresses range from the highly technical, including astrobiological and other scientific questions, as well as engineering implementation, to the purely societal and legal, including concerns over invasive species and negotiation of international regulations. As with most technical and academic endeavors, the wider context in which researchers carry out their studies may have an enormous impact on the research that can be performed. It is important for all

educated citizens but particularly for researchers involved in esoteric and expensive taxpayer-funded work, to participate in the social and cultural conversations that surround them.
